Foreword

Until the 1970s, there were no books, journals, or university courses on health psychology. Although the field's intellectual roots stretch back to the beginnings of psychology more than a century ago, its formal emergence depended on a convergence of influences (Friedman & Silver, 2007), including psychosomatic medicine, social-psychological and socio-anthropological perspectives on medicine, epidemiology, and medical and clinical psychology. Today, health psychology is a principal area of significant social science research and practice, with vital implications for the health and well-being of individuals and societies. Understanding the explosive trajectory of health psychology is useful to appreciating the strengths of the field and to approaching this new encyclopedia, the *Wiley Encyclopedia of Health Psychology*.

What is the nature of health? That is, what does it mean to be healthy? The way that this question is answered affects the behaviors, treatments, and resource allocations of individuals, families, health practitioners, governments, and societies. For example, if it is thought that you are healthy unless and until you contract a disease or suffer an injury, then attention and resources are primarily allocated toward "fixing" the problem through medications or surgical repairs. This is the traditional biomedical model of disease (sometimes called the "disease model"). Indeed, in the United States, the overwhelming allocation of attention and resources is to physicians (doing treatments) and to pharmaceuticals (prescription drugs and their development). In contrast, health psychology developed around a much broader and more interdisciplinary approach to health, one that is often termed the biopsychosocial model.

The biopsychosocial model (a term first formally proposed by George Engel in 1968) brings together core elements of staying healthy and recovering well from injury or disease (Stone et al., 1987). Each individual—due to a combination of biological influences and psychosocial experiences—is more or less likely to thrive. Some of this variation is due to genetics and early life development; some depends on the availability and appropriate applications of medical treatments; some involves nutrition and physical activity; some depends on preparations for, perceptions of, and reactions to life's challenges; and some involves exposure to or seeking out of healthier or unhealthier environments, both physically and socially. When presented in this way, it might seem obvious that health should certainly be viewed in this broader interdisciplinary way. However, by misdirecting its vast expenditures on health care, the United States gives its residents mediocre health at high cost (Kaplan, 2019). To approach these matters in a thorough manner, this encyclopedia includes four volumes, with Volume 1 focusing on the biological bases of health and health behavior, Volume 2 concentrating on the social bases, Volume 3 centering around the psychological and clinical aspects, and Volume 4 focused more broadly on crosscutting and applied matters.

Key parts of health depend on biological characteristics and how they interact with our experiences and environments. So, for example, in Volume 1, there are articles on injury to the brain, alcohol effects on the brain, nutrition, drug abuse, psychophysiology, and the tools and key findings of neuroscience. Note that even individuals with the same genes (identical twins) can and do have different health and recovery outcomes, and the articles delve into such complexities of health. Of course humans are also social creatures, and people's growth, development, and health behaviors take place in social contexts. So, in Volume 2, there are articles on such fundamental matters as social support, coping, spirituality, emotion, discrimination, communication, psychosocial stress, and bereavement.

Because our approaches to and conceptions of health are heavily influenced by society's institutions and structures revolving around medical care, much of health psychology derives from or intersects with clinical psychology and applied behavioral medicine. Volume 3 covers such clinical topics as psycho-oncology, depression, drug abuse, chronic disease, eating disorders, and the psychosocial aspects of coronary heart disease. Finally and importantly, there are a number of special and cross-cutting matters that are considered in Volume 4, ranging from relevant laws and regulations to telehealth and health disparities. Taken together, the articles triangulate on what it truly means to be healthy.

What are the most promising directions for the future that emerge from a broad and deep approach to health? That is, to where do these encyclopedia articles point? One key clue arises from a unique opportunity to enhance, extend, and analyze the classic Terman study of children who were followed and studied throughout their lives (Friedman & Martin, 2012). These studies revealed that there are lifelong trajectories to health, thriving, and longevity. Although anyone can encounter bad luck, a number of basic patterns emerged that are more likely to lead to good health. That is, for some individuals, certain earlier life characteristics and circumstances help propel them on *pathways* of healthier and healthier behaviors, reactions, relationships, and experiences, while others instead face a series of contingent stumbling blocks. There are multipart but nonrandom pathways across time linking personalities, health behaviors, social groups, education, work environments, and health and longevity. The present encyclopedia necessarily is a compendium of summaries of the relevant elements of health and thriving, but one that would and can profitably be used as a base to synthesize the long-term interdependent aspects of health.

In sum, this encyclopedia is distinctive in its explicit embrace of the biopsychosocial approach to health, not through lip service or hand-waving but rather through highly detailed and extensive consideration of the many dozens of topics crucial to this core interdisciplinary understanding.

Preface

The field of health psychology is a specialty area that draws on how biology, psychology, behavior, and social factors influence health and illness. Despite the fact that the formal recognition of the field is only about a half of a century old, it has established itself as a major scientific and clinical discipline. The primary reason for this is that there have been a number of significant advances in psychological, medical, and physiological research that have changed the way we think about health, wellness, and illness. However, this is only the tip of the iceberg.

We have the field of health psychology to thank for much of the progress seen across our current healthcare system. Let me provide some examples that illustrate the diversity of these important contributions. Starting with a broad public health perspective, health psychologists have been involved in how our communities are planned and how urban development has a significant and direct impact on our health behaviors. That is, if we live close to where we work, play, and shop, we are more likely to walk or bike to our destination rather than drive or take public transportation. Focusing on a smaller, but no less important, source of data, health psychologists are involved in using information obtained from our genes to help counsel individuals to make good, well-informed health decisions that could have an impact on the individual immediately or in the future. Being well-informed can direct a person toward the best possible path toward wellness, whether it be measures aimed at prevention, further monitoring, or intervention.

Of course, there are many other contributions. For instance, data indicates that several of the leading causes of death in our society can be prevented or delayed (e.g., heart disease, respiratory disease, cerebrovascular disease, and diabetes) via active participation in psychological interventions. Knowing that we can improve health status by changing our behaviors seems like an easy “fix,” but we know that behavior change is tough. As such, it is not surprising that health psychologists have been involved in trying to improve upon treatment success by examining patient compliance. When we better understand what motivates and discourages people from engaging in treatment or pro-health behaviors, we can improve upon compliance and help individuals adopt more healthy lifestyles. Health psychologists have also played a role in shaping healthcare policy via identifying evidence-based treatments. This work has direct effects on how individuals receive healthcare as well as what treatments are available/reimbursable by insurance companies. Finally, there are also factors beyond medical care to consider (e.g., economic, educational) that can lead to differential health outcomes. Thus, health psychologists likewise examine ways to reduce health disparities, ensuring that the public and government officials are made aware of the impact of the social determinants of health.

I could go on and on, however, examples like this illustrate the significant impact this broad and exciting field has had (and will continue to have) on our understanding of health and wellness. Given the constantly changing nature of the field, it is not possible to be all inclusive; however, the aim of these four volumes is to provide readers an up-to-date overview of the field. Each entry is written to stand alone for those who wish to learn about a specific topic, and if the reader is left wanting more, suggested readings are provided to expand one's knowledge. Volume I, *Biological Bases of Health Behavior,* includes entries that cover topics in the broad areas of neuroscience and biopsychology relevant to health behavior. General topics include degenerative and developmental conditions, emerging methodologies available in clinical research, functional anatomy and imaging, and gene × environment interactions. Volume II, *Social Bases of Health Behavior,* addresses topics related to theories and concepts derived from social psychology. Specifically, topics related to the self, social cognition, social perception, attitudes and attitude change, perception, framing, and pro-health behaviors are included. Volume III, *Clinical Health Psychology and Behavioral Medicine,* covers the applied aspects of the field of health psychology including practical topics that clinical health psychologists face in the workplace, behavioral aspects of medical conditions, the impact of unhealthy behaviors, and issues related to the comorbidity of psychiatric disorders and chronic health concerns. Finally, Volume IV, *Special Issues in Health Psychology,* contains a wide array of topics that are worthy of special consideration in the field. Philosophical and conceptual issues are discussed, along with new approaches in delivering treatment and matters to consider when working with diverse and protected populations.

It is my sincere hope that the *Wiley Encyclopedia of Health Psychology* will serve as a comprehensive resource for academic and applied psychologists, other health care professionals interested in the relationship of psychological and physical well-being, and students across the health professions. I would very much like to thank and acknowledge all those who have made this work possible including Michelle McFadden, the Wiley editorial and production teams, the volume editors, and of course all of the authors who contributed their outstanding work.

Lee M. Cohen, PhD

Preface Volume 3: Clinical Health Psychology and Behavioral Medicine

The theory developments, research outcomes, and practice guidelines for the fields of clinical health psychology and behavioral medicine have expanded dramatically during the last 30 years. Thousands of interesting journal articles and hundreds of relevant books have been published during that time interval. Numerous well-regarded journals focus entirely or in part on these clinical health psychology topics, such as the journals *Health Psychology*, *Annals of Behavioral Medicine*, *Journal of Consulting and Clinical Psychology*, *Journal of the American Medical Association*, *New England Journal of Medicine,* and over 100 specialty journals on focused topics such as specific diseases, psychological disorders comorbid with chronic health problems, translational issues in health care, psychosocial interventions in health psychology and behavioral medicine, and so forth. The topics covered in this third volume of the *Wiley Encyclopedia of Health Psychology* is focused on some of the recent theory, research, and practice issues relevant to the field of clinical health psychology.

This volume covers some exciting and important issues in the area. Specifically, entries touch on both broad and specific topics covering (a) methodological sophistication, (b) chronic diseases, (c) diversity and inclusiveness, (d) biological issues, (e) translation of health psychology knowledge, (f) chronic psychopathology that is comorbid with health problems and diseases, and (g) social justice. In sum, we have attempted to include a wide array of entries on what we consider to be the most relevant topics and trends, although we could not include all possible relevant topics and trends. Nevertheless, we believe that readers will find a wide range of interesting and important entries in this volume.

We should say something about our recruitment and editing guidelines for Volume 3. We tried to recruit well-regarded experts—in some cases with national and international reputations—in each of the entry topic areas. Many of the entries are multiauthored, so most of these experts collaborated with other experts in their specific areas. We also tried to recruit a broad sampling across the numerous trends and topic areas in the field, rather than having most or all of the entries focused on just a few topics. Further, we worked diligently to provide the authors feedback that we believed would make the entries stronger in terms of standard scholarship goals such as accuracy, clarity, thoroughness, and adherence to standard professional writing styles in clinical health psychology. It should be noted, however, that virtually all of the entries were already in excellent shape, when we first received them, which dovetails with the outstanding reputations of our authors.

We believe that Volume 3, *Clinical Health Psychology and Behavioral Medicine*, will be a helpful resource book on an important topic. We also believe that readers will find this volume an excellent addition to their professional library, along with the other volumes in the Wiley *Encyclopedia of Health Psychology*. In closing, we would like to acknowledge the excellent work of our authors, the helpful expertise of the staff at Wiley, the ongoing help of our home universities, and the wonderful support from our families.

C. Steven Richards, PhD
Lee M. Cohen, PhD

Acknowledgments

We would like to acknowledge the excellent work of our authors, the helpful expertise of Michelle McFadden and the staff at Wiley, the ongoing support of our home institutions, Texas Tech University and the University of Mississippi, and the wonderful support from our families—Carol, Dawn, Dave, and Jill (Steve) and Michelle, Ross, Rachel, and Becca (Lee).

C. Steven Richards and Lee M. Cohen
Editors

Editor-in-Chief Acknowledgments

I would like to publicly recognize and thank my family, Michelle, Ross, Rachel, and Becca for being supportive of my work life while also providing me with a family life beyond my wildest dreams. I love you all very much. I would also like to note my great appreciation and thanks to the faculty and staff of the Doctoral Training Program in Clinical Psychology at Oklahoma State University for providing me with an opportunity to expand my education and for providing extraordinary training. In particular, I would like to thank my late mentor Dr. Frank L. Collins Jr., Dr. Larry Mullins, Dr. John Chaney, and Patricia Diaz Alexander. Further, I am grateful to the University of Mississippi and Texas Tech University (and the colleagues and students I have had the privilege to work alongside) for affording me excellent working environments and the support to do the work I am honored to be a part of. Finally, I would like to recognize and thank the volume editors for their vision and perseverance to this project as well as to each of the contributors for their excellent entries and their dedication to this very important field.

Lee M. Cohen, Ph.D.
Editor-in-Chief

Body Image

[4]*Department of Psychiatry, University of California, San Diego, CA, USA*

Body image involves a person's subjective appraisal of his or her own physical characteristics and qualities (e.g., Pruzinsky, 2004; Sarwer & Steffen, 2015). Body image concerns are highly prevalent in Western societies and are more prominent among women (Fiske, Fallon, Blissmer, & Redding, 2014), although they occur among both men and women. Additionally, body image concerns appear to be common across the lifespan (Fiske et al., 2014). Evidence suggests that poor body image can negatively affect psychosocial functioning (Patalay, Sharpe, & Wolpert, 2015), health behaviors (Neumark-Sztainer, Paxton, Hannan, Haines, & Story, 2006), and overall quality of life (Mond et al., 2013). Conversely, positive body image is protective against numerous mental health problems and serves to increase overall psychological well-being (Gillen, 2015). Further, several mental disorders associated with mortality and reduced quality of life are marked by disturbances in body image (e.g., body dysmorphic disorder, eating disorders). Of particular relevance to the field of clinical health psychology, poor body image occurs in a variety of medical conditions and clinical populations (e.g., individuals with obesity, patients with cancer). Understanding and routinely assessing body image concerns may have utility in alleviating health problems and reducing further physical and mental health complications. In this entry, we describe body image in the field of clinical health psychology including risk factors and correlates of body image concerns.

The Wiley Encyclopedia of Health Psychology: Volume 3: Clinical Health Psychology and Behavioral Medicine,
First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

Body Image and Clinical Health Psychology

Body image concerns are important health symptoms to consider in clinical health psychology and occur in a myriad of medical conditions and diseases. The most prominent medical condition associated with poor body image is obesity. This relationship is in part propagated by a pervasive cultural emphasis on thinness and the associated stigmatization of individuals who are overweight or obese (Puhl & Latner, 2007). Thus, body image concerns may be a problem among any medical and psychiatric patients who present with co-occurring obesity. Further, while weight loss usually improves overall body image, body image concerns, specifically related to excess skin, may be present among individuals who lose a great deal of weight, notably those who receive bariatric surgery (Song et al., 2006). However, body contouring after large weight loss has been shown to be related to improvements in body image (Song et al., 2006).

Body image concerns are also relatively common in patients with various types of cancer and other medical conditions. For example, disturbances in body image have been observed in patients with breast cancer (Lasry et al., 1987), cervical cancer (Hawighorst-Knapstein et al., 2004), and head and neck cancers (Fingeret et al., 2013). Further, side effects of cancer treatment such as alopecia have also been associated with increases in body image concerns (Münstedt, Manthey, Sachsse, & Vahrson, 1997). Other medical conditions and diseases that may involve body image concerns are inflammatory bowel disease and Crohn's disease (Saha et al., 2015), endometriosis (Melis et al., 2015), lupus (Jolly et al., 2012), and systemic sclerosis (Ennis, Herrick, Cassidy, Griffiths, & Richards, 2012). Children and adolescents with various medical conditions may experience a similar pattern of concerns. For instance, in a meta-analysis examining relationships between body image and chronic illness among children and adolescents, Pinquart (2013) found that children and adolescents with obesity, cystic fibrosis, scoliosis, asthma, growth hormone deficits, spina bifida, cancer, and diabetes rated their bodies less positively than healthy comparison groups.

While body image concerns may be associated with particular diseases, certain characteristics of diseases and associated treatments may also be related to the manifestation of body image concerns. For example, disease activity and chronicity, treatment type, treatment complications, and presenting symptoms in various medical conditions may affect individuals' body image in various patient populations (e.g., Bullen et al., 2012; Ennis et al., 2012; Fingeret et al., 2013; Rhondali et al., 2013). Of note, treatment and improvement in disease activity are not always associated with improvements in body image (Saha et al., 2015). In addition, treatment for medical conditions may worsen body image—for example, increased body dissatisfaction has been reported after mastectomy in breast cancer patients (Lasry et al., 1987). On the other hand, some medical treatments have been shown to reduce body image concerns more so than others (e.g., ileal pouch–anal anastomosis in ulcerative colitis patients; Larson et al., 2008; and robotic thyroidectomy among patients with papillary thyroid carcinoma; Lee et al., 2014).

Risk Factors for Body Image Concerns

A host of risk factors for body image concerns has been identified. Demographic, sociocultural, and psychosocial variables are among the most widely studied and will be the focus of this section of the chapter. First, demographic characteristics including gender, race/ethnicity, and sexual orientation are associated with body image concerns. Women, Caucasian individuals, and men who identify as gay or bisexual are generally are more at risk for body image concerns; however, differences in these groups appear to be narrowing in some respects (Field et al., 2014; Morrison, Morrison, & Sager, 2004; Roberts, Cash, Feingold, & Johnson, 2006). Second, numerous sociocultural variables (i.e., characteristics of society that includes cultural norms for beauty and attractiveness) have been linked to body image concerns. For instance, greater media consumption and exposure (e.g., magazines, television, social media, Internet-based media) has been found to be associated with increased body image concerns (Grabe, Ward, & Hyde, 2008). Relatedly, internalization of societal norms regarding thinness and perceived sociocultural pressure for thinness are strongly related to increased body image concerns (Stice & Whitenton, 2002). Further, social comparisons, which involve tendencies to compare oneself with other people, are also highly predictive of body image concerns, especially in response to comparisons in which the other person is perceived as more attractive (Myers & Crowther, 2009).

Various psychosocial aspects also have been found to be related to elevated body image concerns. For example, certain personality characteristics are related to poor body image, including neuroticism and other forms of trait negative affectivity as well as perfectionism (Pennesi & Wade, 2016). Lifetime and recent stressful events including weight teasing and discrimination are also related to body image concerns (Eisenberg, Neumark-Sztainer, Haines, & Wall, 2006). Furthermore, greater internalizing problems, notably anxiety, depression, and low self-esteem, are related to increased body image concerns (Patalay et al., 2015; van den Berg, Mond, Eisenberg, Ackard, & Neumark-Sztainer, 2010). Finally, interpersonal and social deficits including attachment insecurity (Abbate-Daga, Gramaglia, Amianto, Marzola, & Fassino, 2010), poor peer relationships (Schutz & Paxton, 2007), and decreased social support (Stice & Whitenton, 2002) are also associated with increased body image concerns.

Correlates and Consequences of Body Image Concerns

Studies of clinical populations have primarily shown body image concerns to be related to reduced disease-specific and overall quality of life, as well overall psychological well-being (Rhondali et al., 2013; Yagil et al., 2015). Furthermore, Bullen et al. (2012) reported that preexisting disturbances in body image predicted later psychopathology in patients with colorectal disease. Thus, body image concerns related to disease and medical problems, as well as preexisting body image concerns, may impact mental and physical health outcomes. Additionally, in the broader body image literature, poor body image has been found to be related to numerous domains of mental and physical health, maladaptive behavior, and overall functioning. Below, we briefly review relationships between body image and each of these domains.

Psychological Functioning and Mental Health

Poor body image is broadly associated with poorer overall mental health (Mond et al., 2013), as well as lower self-esteem and increased internalizing symptoms among men and women (Field et al., 2014; Patalay et al., 2015). In addition, body image concerns are related to interpersonal and social problems and difficulties (Gupta & Gupta, 2013; Mond et al., 2013). Other research has also found increased body image concerns to be associated with suicidal ideation (Gupta & Gupta, 2013) and sleep problems (Gupta, Gupta, & Knapp, 2015).

Eating- and Weight-Related Behaviors

Body image concerns are related to a number of eating- and weight-related behaviors, including dietary restriction, use of diet pills, diuretics, and laxatives, and self-induced vomiting (Andrew, Tiggemann, & Clark, 2016; Neumark-Sztainer et al., 2006). Additionally, among men in particular, body image concerns in the form of a desire for greater muscularity are associated with use of steroids and other appearance- and performance-enhancing drugs (Murray, Griffiths, Mond, Kean, & Blashill, 2016). In turn, maladaptive eating patterns, such as binge eating and overeating, have been shown to be related to increased body image concerns (Neumark-Sztainer et al., 2006).

Psychiatric Conditions

In addition to being broadly associated with eating- and weight-control behaviors, body image concerns are a central feature in certain psychiatric disorders and commonly occur in others. For example, the experience of persistent, intrusive thoughts about one or more perceived flaws in one's appearance is the hallmark feature of body dysmorphic disorder. In addition, body image concerns are most notably associated with eating disorders and are included in nearly all models of disordered eating (Pennesi & Wade, 2016). Specifically, the overvaluation of body shape and weight is a defining characteristic of anorexia nervosa (AN) and bulimia nervosa (BN) and is also commonly observed in subclinical eating disorders and binge eating disorder (BED), the latter of which is characterized by a high prevalence of overweight and obesity.

Other Health Behaviors

While research has typically assessed relationships between body image concerns and eating- and weight-related behaviors, there is evidence that body image concerns are associated with other health-related behaviors as well. For example, studies have found associations between lower body satisfaction and lower physical activity, increased screen-based media use, and increased smoking among males and females (Farhat, Iannotti, & Caccavale, 2014; Neumark-Sztainer et al., 2006). In addition, in an online sample of women, body dissatisfaction was related to less skin screening behaviors and more alcohol consumption, whereas body appreciation was related to more sun protection behaviors (Andrew et al., 2016). Among males, elevated concerns over muscularity among males have been associated with a number of problematic behaviors, including binge drinking and drug use (Field et al., 2014; Jampel, Safren, & Blashill, 2015). Finally, one study of body image concerns and physical health found that chronic weight dissatisfaction predicted elevated risk for type 2 diabetes, over and above weight status (Wirth, Blake, Hébert, Sui, & Blair, 2014).

Sexual Health

Body image concerns have also been shown to be related to multiple domains of sexual functioning (Woertman & van den Brink, 2012). For example, women with body image concerns report more appearance concerns during sexual interactions, lower levels of desire and arousal, and decreased pleasure and sexual satisfaction (Woertman & van den Brink, 2012). In addition, a recent meta-analysis showed that increased body dissatisfaction was related to less condom use self-efficacy (Blashill & Safren, 2015). Further, body image concerns were associated with risky sexual behavior among women (Merianos, King, & Vidourek, 2013). Conversely, body appreciation was related to better sexual functioning among women (Satinsky, Reece, Dennis, Sanders, & Bardzell, 2012).

Conclusions

Body image concerns are prominent in numerous clinical populations, both medical and psychiatric. Body image concerns are generally associated with reduced quality of life in patients and may lead to the development of additional mental and physical health problems. In addition, poor body image may be associated with engaging in numerous maladaptive behaviors including unhealthy eating- and weight-related behaviors, alcohol and drug use, and risky sexual behaviors. Poor body image may also be associated with less positive health behaviors, notably cancer screening behaviors (Andrew et al., 2016) and reduced physical activity. Due to the wide range of negative outcomes related to body image concerns, screening for body image concerns in clinical health settings is imperative in order to provide optimal medical care and reduce disease burden.

Author Biographies

Tyler B. Mason, PhD, is an assistant professor in the Department of Preventative Medicine at the University of Southern California. He received his PhD in applied psychological science in 2015 and BS in psychology in 2010 from Old Dominion University. His primary research interests include etiology and treatment of binge eating and obesity.

Kathryn E. Smith, PhD, is a T32 postdoctoral research fellow at the Neuropsychiatric Research Institute. She received her BA in psychology from Macalester College and her PhD in clinical psychology in from Kent State University. Her primary interests include emotion regulation and co-occurring psychopathology in eating disorders and obesity.

Jason M. Lavender, PhD, is an assistant research scientist in the Department of Psychiatry at the University of California, San Diego. He completed his undergraduate education at Duke University and his PhD in clinical psychology at the University at Albany, SUNY. His research addresses emotion, neurocognition, and personality in eating disorders.

Stephen A. Wonderlich, PhD, is the Chester Fritz distinguished professor and associate chairperson in the Department of Psychiatry and Behavioral Science at the University of North Dakota, chair of eating disorders and co-director of the Eating Disorder and Weight Management Center at Sanford, and president and scientific director of the Neuropsychiatric Research Institute.

Caregivers and Clinical Health Psychology

Allison Marziliano and Anne Moyer

Department of Psychology, Stony Brook University, Stony Brook, NY, USA

An informal caregiver is defined as "any relative, partner, friend, or neighbor who has a significant personal relationship with, and provides a broad range of assistance for an older person or an adult with a chronic or disabling condition" (Family Caregiver Alliance, 2016). The American Association of Retired Persons (AARP) and the National Alliance for Caregiving (NAC), a nonprofit coalition of national organizations, collaborate every 5 years to produce a research report on unpaid family caregivers in the United States, the most recent of which was published in June of 2015 (National Alliance for Caregiving, 2016a, 2016b). According to this publication, Caregiving in the U.S. 2015, it is estimated that 34.2 million adults in the United States have provided care to another adult or adults over the age of 50 years old within the last 12 months, representing approximately 14.3% of the American adult population. The majority of caregivers are relatives of the care recipient (85%) and female (60%), and most (82%) care for one other individual rather than multiple individuals. The average age of caregivers in general is 49.2 years, compared with the average age when limiting the sample to spousal caregivers, 62.3 years old.

In addition to providing useful information about caregivers, the research report, Caregiving in the U.S. 2015, also provides descriptions of the individuals for whom they provide care, or care recipients (National Alliance for Caregiving, 2016a, 2016b). Care recipients are often older individuals with functional disabilities who had a prior relationship with the person who has come to assume the role as their unpaid caregiver. Nearly half (47%) of care recipients live in their own homes, about 1/3 (35%) live with their caregivers, and 18% reside in long-term care or senior housing. The average age of those individuals receiving care is 69.4 years old, with nearly half (47%) of care recipients above the age of 74 years old.

Caregiver Burden

Caregiver burden is multifaceted. In a systematic review of the literature on assessment tools to measure the impact of family caregiving, caregiver burden is described as a negative response to the impact of providing care on the caregiver's physical, psychological, emotional, social, and financial condition. Burden is often the result of the caregivers' belief that demands placed upon them surpass their own physical or mental capacity.

Some research has addressed the financial burden associated with caregiving. Providing care to a loved one is costly in and of itself; however, caregiving may interfere with time previously devoted to employment for both the patient and caregiver, which may lead to reductions in the flow of income, further compounding financial strain. Caregivers often report less time for themselves and competing financial demands as a result of their role. In one study, schedule burden was cited as the most prevalent form of burden experienced by caregivers, reported by 58% of end-of-life caregivers and 32% of caregivers of patients with chronic illness (Sautter et al., 2014). In one study, 60–80% of caregivers of patients with Parkinson's disease reported disruptions in their financial status (Sanyal et al., 2015). In a sample of caregivers of patients with head and neck cancer, financial stress was significantly related to high levels of unmet needs (Balfe et al., 2016). In caregivers of individuals suffering from schizophrenia, only approximately 1/3 (31.9%) endorsed "agree" or "strongly agree" when responding to whether they believed they have the financial capacity to provide adequate care to their loved one (Gupta, Isherwood, Jones, & Van Impe, 2015).

Particular attention has been devoted to financial burden in the context of female caregivers. Research using data from 2,093 women over the age of 52 with at least one living parent or parent-in-law participating in the Health and Retirement Surveys in 2006, 2008, and 2010 supported a reciprocal relationship between parental caregiving and lower household income (Lee, Tang, Kim, & Albert, 2014). In a study of female caregivers of patients with Alzheimer's disease, the authors suggested that the greatest financial challenge was the high cost of the care they deliver, with females bearing six times the cost of care than men do (Yang & Levey, 2015).

In addition to financial burden, physical and health-related burden has been reported by caregivers. In a cross-sectional study of family caregivers of individuals with schizophrenia, approximately 2/3 of the sample (65.5%) believed themselves to be in poor physical health (Thunyadee, Sitthimongkol, Sangon, Chai-Aroon, & Hegadoren, 2015). Not only do caregivers often perceive themselves as being in ill-health, but also there is some research to suggest that their health is indeed affected by their caregiving role. Spousal caregivers are at a 600% increased risk of developing dementia (Wennberg, Dye, Streetman-Loy, & Pham, 2015), and caregivers more generally are at risk of experiencing sleep trouble, fatigue, insomnia, weight gain, pain, headaches, and heartburn (Gupta et al., 2015; Skalla, Lavoie Smith, Li, & Gates, 2013).

Research has identified correlates and predictors of burden in caregivers. A large body of literature suggests that caregiver burden is related to certain patient-related factors such as higher levels of patient cognitive impairment (Corallo et al., 2016; Vaingankar et al., 2016) and patient motor disability (Sanyal et al., 2015). Other correlates and predictors of caregiver burden include less use of hospice care, female gender, student status, spousal relationship to care recipient, the use of emotion-focused coping strategies, duration of caregiving, hours spent caregiving, social isolation, and lack of choice in assuming the caregiving role (Adelman, Tmanova, Delgado, Dion, & Lachs, 2014; Duggleby et al., 2016; Gupta et al., 2015; Sanyal et al., 2015; Thunyadee et al., 2015).

Negative Psychosocial Sequelae

Although caregiver burden is not a classifiable syndrome, such burdens can result in clinical diagnoses such as depression and anxiety and even lead to suicide (Adelman et al., 2014). The prevalence of depressive disorders has been found to be as high as 22% among caregivers of dementia patients (Cuipers, 2005). The prevalence of depressive symptoms for caregivers of critically ill patients is similar but is reported to be even higher during the critical care period (Haines, Denehy, Skinner, Warrillow, & Berney, 2015). Although the evidence regarding this is more sparse, clinically significant anxiety is estimated to occur in about a quarter of caregivers for people with dementia (Cooper, Balamurali, & Livingston, 2007). In the context of life-threatening diseases such as cancer, one of the most common physical conditions for which patients receive informal caregiving (Girgis, Lambert, Johnson, Waller, & Currow, 2013), a reciprocal relationship has been found between caregiver and patient distress (Northouse, Katapodi, Schafenacker, & Weiss, 2012). In addition, cancer diagnosis and treatment follow a dynamic course; as a cancer patient's condition declines or nears death, caregivers' depression, anxiety, and distress worsen, and a caregiver's depression and anxiety may also have consequences for the patient (Williams & McCorkle, 2011). Estimates of the prevalence of anxiety in partners and caregivers of people with cancer have been found to range from 16 to 56%, and even PTSD has been documented in 4% (Girgis et al., 2013).

Positive Psychosocial Sequelae

The picture is not all bleak, however. Evidence suggests that the capacity exists for caregivers to experience, as a result of their role, positive psychosocial sequelae (Moore et al., 2011), such as posttraumatic growth (PTG), the cognitive process through which those who are faced with a traumatic event positively reinterpret and find meaning in the event (Tedeschi & Calhoun, 1996), and benefit finding (BF), one's perception that positive changes have occurred as a result of experiencing difficult life events. Furthermore, in some studies, caregivers score higher in certain facets of PTG, such as personal strength, than the patients for whom they provide care (Cormio et al., 2014). Research has identified common correlates of increased caregiver PTG and benefit finding as increased social support, self-affirmation, having a positive outlook on life, positive affect, and the use of positive religious coping strategies (Balfe et al., 2016; Thombre, Sherman, & Simonton, 2010). Some research has focused on the relationship between caregiver PTG and patient-related factors, indicating a positive relationship between cancer caregivers' report of patients' quality of life at end of life and caregiver PTG (Hatano, Fujimoto, Hosokawa, & Fukui, 2015). While BF is an important construct in and of itself, its importance also lays in that some research has found caregiver BF to positively predict caregiver quality of life (Navarta-Sanchez et al., 2016).

Albeit less of a focus than PTG and BF, other research has examined the positive constructs of resilience and accomplishment in relation to caregiving. In a study of caregivers of children with cancer, correlates of parent resilience include coping strategies, social support, positive provider interactions, and lack of psychosocial distress (Rosenberg, Baker, Syrjala, Back, & Wolfe, 2013). In another study of caregivers of individual with multiple sclerosis (MS), positive perception of accomplishment was related to older age of the patient and greater number of hours per week the caregiver provided care, while negative perception of accomplishment was related to caregiver perception that caregiving is an emotionally draining role, higher levels of caregiver education, and a spousal relationship between patient and caregiver (Buchanan & Huang, 2012). Although a great deal of literature has demonstrated the negative effects of caregiving, fortunately, recent research has focused on routes to amplifying the positive psychosocial sequelae associated with caring for a loved one.

Support for Caregivers

The challenges associated with caregiving mean that assistance, including finding ways to take care of themselves, is important for caregivers. These types of assistance include support in the legal, financial, emotional, social, educational, physical, and mental health areas of functioning. National organizations provide supportive resources in the form of information and education for both caregivers and healthcare and policy professionals, online and in-person support groups, first-person stories, connections to clinical trials and research studies, and advocacy. For instance, the Family Caregiver Alliance provides a national registry to assist caregivers of people who are living at home or in a residential facility to locate local public, nonprofit, and private programs, such as government health and disability programs, legal resources, and disease-specific organizations (Family Caregiver Alliance, 2016). Examples of local resources include information, assistance, individual counseling, support groups, caregiver training, respite care, and supplemental services, such as transportation and home modifications (New York State Office of the Aging, 2016). The NAC conducts authoritative research on trends in the needs of caregivers with a focus on reaching a broad, racially and ethnically diverse population sample and works to increase public awareness of family caregiving issues (National Alliance for Caregiving, 2016a, 2016b).

Practical and tangible forms of support such as respite, or time away from the duties of caregiving, are considered particularly valuable by caregivers, although the influence of social norms (e.g., related to a sense of familial duty) may make caregivers reluctant to let go of their caregiving responsibilities. Making use of respite services can allow caregivers to continue their employment or education, social activities, or hobbies integral to their identity; engage in self-care activities like recreation, exercise, and good nutrition; and seek legal and financial counsel. To be effective, however, respite needs to be regular or substantial (i.e., at a frequency of at least twice a week) and involves large blocks of time. In response to evidence that caregivers often feel their respite time goes to waste or is unfulfilling, frustrating, or even increased their stress, some research has begun to investigate how to improve the ways that respite time can best meet individual needs, through goal setting that reflects personal priorities and forming strategies to optimize goal attainment (Lund et al., 2014). Practical ways that healthcare providers can support the caregivers of the patients they treat are to assess what types of difficulty they might be having, encourage them to engage in self-care, provide information about their care recipients' illness, and provide referrals to assistance available to them (Adelman et al., 2014).

Technological forms of assistance can also be useful. These include emergency response systems, webcams or mobility trackers for monitoring, lifts, medication reminder systems, and socialization via Skype (Adelman et al., 2014). Education and counseling can be readily provided by web- and video-based platforms, and decision-making support can be facilitated via telephone and videoconferencing.

Psychosocial Interventions for Caregivers

A number of interventions have been developed for caregivers of individuals with dementia. A large (*N* = 1,222) multisite study (the Resources for Enhancing Alzheimer's Caregiver Health [REACH] initiative) tested a group of site-specific, theory-driven interventions that were tailored for the ethnic groups served (Wisniewski et al., 2003). The interventions were diverse and based on different theoretical frameworks, but they were similar in being based on a basic stress–health model that addressed stressors themselves, their appraisal, and/or caregivers' response to them. These included *care-recipient-focused behavior management skill training and caregiver-focused, problem-solving training* (involving didactic instruction, role-playing, modeling, feedback, manuals, and videotapes, home visits, and therapeutic telephone calls), a 24-hr/day *telephone-linked computer intervention* (involving a voicemail support network, information on specific care recipients' behavioral problems, access to a geriatric nurse specialist, and providing distracting conversation), *information and referral* delivered within primary care clinics (involving commercially available pamphlets regarding dementia), *behavioral care* (involving targeted one-on-one information and counseling sessions related to care recipients' behavioral problems supplemented by telephone calls), *enhanced care* (involving specific cognitive and behavioral strategies to reduce caregiver distress taught in person and supported by telephone calls), a *family-based structural multisystem in-home intervention* (involving in-home family therapy sessions to enhance family functioning and reduce caregiver distress) with and without a computerized telephone integration system, a *coping with caregiving class* (involving mood-management skills to reduce stress and distress), an *enhanced support group* (involving professional leadership and a commitment to meet regularly for 1 year), and an *environmental skill building program* (involving in-home individualized environmental strategies delivered by an occupational therapist). Across all interventions, burden and depression scores were lower for active conditions compared with control conditions at 6 months, but this was only statistically significant for burden and the effect was small (Gitlin et al., 2003). Nonetheless, the interventions were rated as beneficial, helpful, and valuable by participants, and there were significant subgroup effects for those who were female and had lower education for burden and for those who were Hispanic, non-spouses, and had lower education for depression (Gitlin et al., 2003).

As alluded to by the design of some of the interventions in the REACH study, because there is a potentially synergistic relationship between the behavior of the person with dementia and their informal caregiver's level of burden and the strategies they use to manage the behavior of the person with dementia, interventions are often directed at both individuals in the dyad. For instance, for the person with dementia, such things as behavioral problems, cognitive functioning, mood, independence in daily activities, sleep, and quality of life may be the focus, and for the caregiver, mood, burden, competence, and quality of life may be the focus. These dyadic interventions include components such as information, training in daily life activities, walking or exercise, and adaptations to the physical environment for the person with dementia and information, psychoeducation, skills training, and coping strategies for the caregiver. A systematic review of 20 of these programs showed them to be promising in terms of effectiveness for one or both members of the dyad (Van't Leven et al., 2013).

An approach that differs from psychosocial interventions is meditative-based interventions that involve mindfulness or concentration-based techniques, some of which are designed to be undertaken at home. A systematic review of eight studies suggests that they hold some promise in alleviating burden and depression in dementia caregivers (Hurley, Patterson, & Cooley, 2014). Interventions involving relaxation and yoga have been found to be most likely to be effective specifically for anxiety in caregivers, an often untargeted outcome (Cooper, Balamurali, Selwood, & Livingston, 2007).

Barriers to Utilizing Psychosocial Interventions

There is evidence to suggest that family caregivers underutilize the mental health services and interventions that may be available to them. In one study (Mosher et al., 2013) of caregivers reporting anxiety and depressive symptoms, only a quarter of participants reported using mental health services, and 39% reported using complementary and alternative medicine in the 3-month period in which the research took place. These findings are in contrast to those who expressed an interest in support services; 29% of caregivers who did not receive mental health services desired them. Thus, these findings suggest that it may not be a lack of empirically validated interventions for caregivers, but rather the presence of barriers that inhibits caregivers from seeking the psychosocial support they need.

A commonly reported barrier to seeking mental health services for both caregivers and patients alike is the fear of stigmatization (Gulliver, Griffiths, & Christensen, 2010). In one study, caregivers of individuals with mental health illnesses indicated their concerns for their loved one seeking treatment as hindering their employment opportunities, being viewed as weak or crazy, being embarrassed or ashamed, or being unable to afford services (Dockery et al., 2015). Correlates of reporting stigma related to patients' seeking of mental health services included being a female caregiver and being an African American caregiver. Caregivers also cite stigma as a concern preventing them from seeking their own mental health support services (Boots, Wolfs, Verhey, Kempen, & de Vugt, 2015), which may negatively affect their capability to care for not only themselves but also the care recipient.

In addition to stigma, research on caregivers has identified other barriers preventing them from utilizing mental health services and interventions. Commonly cited barriers reported by caregivers of patients with various diagnoses also include struggling with acknowledging their own needs, low acceptance of their new role, negative view of mental health professionals, desire for independent management of their issues, perceived conflict between their role as a caregiver and obtaining treatment for themselves, anticipated negative self-perception, feeling unequipped to manage their situation, and reluctance to allow help (Boots et al., 2015; Mosher et al., 2013). It is critical to consider these barriers during intervention design in order to maximize the efficacy of mental health treatment for caregivers.

Post-caregiving

Some research refers to the period following the cessation of care, post-caregiving, as a stage well within the caregiving life course that requires, but often lacks, unique attention (Hash, 2006). Research demonstrates the potential for cognitive and psychological changes that may begin during caregiving but last into the post-caregiving stage. For example, in a study of caregivers of palliative care patients who completed neuropsychological assessments as caregivers and at least 6 months from the death of the care recipient, results showed an improvement in self-monitoring and regulating attentional resources and a decline in spatial working memory and delayed episodic memory (Mackenzie, Smith, Hasher, Leach, & Behl, 2007). In another study, individuals who care or cared for chronically ill same-sex partners commonly reported loneliness and depression in the post-caregiving period (Hash, 2006). During this stage, then, caregivers continuously encounter difficult transitions such as coping with grief and mourning, rebuilding, or returning to their pre-caregiving life.

Conclusion

In sum, informal caregivers report financial, schedule, and health-related burden, as well as experience depressive disorders, anxiety, and distress. Fortunately, research on growth and finding benefit in the caregiving experience is increasing and demonstrates the potential for positive psychosocial sequelae associated with this role. Although support for caregivers comes in various forms, from promotion of respite to psychosocial and meditative interventions, research suggests that mental health services and interventions are underutilized due to specific barriers such as fear of stigmatization. Future research would be wise to focus on overcoming the barriers to accessing mental health services that caregivers often face and providing such support into the post-caregiving period.

Author Biographies

Allison Marziliano is a doctoral candidate in social and health psychology at Stony Brook University and a predoctoral fellow in the Department of Psychiatry and Behavioral Sciences at Memorial Sloan Kettering Cancer Center. Her research interests include the study of psychosocial issues surrounding cancer patients, their families, and their caregivers, as well as grief and bereavement.

Anne Moyer is an associate professor of social and health psychology at Stony Brook University. Her research focuses on psychosocial factors surrounding cancer and cancer risk, medical decision making, research methodology and research synthesis, and the psychological aspects of human research participation.

Close Relationships

Kieran T. Sullivan

Department of Psychology, Santa Clara University, Santa Clara, CA, USA

Close relationships are strongly related to physical health. People who are married live longer and are less likely to experience a host of serious health problems, including heart attacks and chronic illnesses (Johnson, Backlund, Sorlie, & Loveless, 2000). This health advantage holds true when comparing married people with all unmarried groups: divorced, widowed, and never married people (though with recent increases in cohabitation, the gap is narrowing between married and never married people). People in dissatisfying, difficult marriages, however, do not enjoy these health benefits; in fact, they actually fare worse than unmarried people; high conflict and having a critical or demanding spouse undermines health as surely as supportive interactions protect it (Umberson, Williams, Powers, Liu, & Needham, 2006).

How Relationships Affect Health

There are several mechanisms by which intimate relationships influence health. The role and responsibilities of being a long-term intimate partner entail an internal sense of obligation to remain healthy for partners and any children. Indeed, there is ample evidence that simply being married is a significant deterrent of health-compromising behaviors. Beyond the mere presence of a partner and related role obligations, spouses, partners, and close others provide social support, which may entail emotional support or practical (instrumental support) or both. In fact, spouses and intimate partners are by far the most likely person to provide social support when needed. Social support positively affects biological processes (e.g., leads to a stronger immune system), affect, psychological functioning, health behavior, and the ability to cope with illness. Conversely, a lack of social support in close relationships is associated with anxiety and depression, which, in addition to affecting physiological processes, are associated with behavioral patterns that increase risk for disease and mortality.

The Wiley Encyclopedia of Health Psychology: Volume 3: Clinical Health Psychology and Behavioral Medicine,
First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

Social Support

The health benefits of social support are due in part to the mitigation of stress reactions and assistance in coping with stress. The stress-buffering hypothesis suggests that social support provided by intimate partners in the face of stress provides a buffer from the negative effects of stress by positively shaping the stress appraisal response. Individuals who know they have close others who will help them cope with stressors (e.g., provide resources, provide emotional support) appraise that stressor differently than those without such close others. Support may also buffer the effects of stress on physiological processing by attenuating or eliminating the stress reaction or by directly influencing physiological processes (Cohen & Wills, 1985). Indeed, people with high levels of social support, such as those in intimate relationships, who experience stress are less likely to succumb to bacterial and viral infections, are less likely to develop mental health problems as a consequence of stress (such as depression), and are less likely to incur damage caused by neuroendocrine, immune, and cardiovascular responses to stress. Matching the type of support with the type of stressor (i.e., a solution for a practical problem or emotional support for an emotional issue) is key for the buffering effect to occur.

Many studies investigating social support and health have focused on couples dealing with serious or chronic illnesses, a useful context for capturing the practical and emotional support provided by close others. Social support increases patient adherence to medical regimens prescribed by physicians following an illness; the odds of adherence are more than twice as high among patients with greater levels of social support. When distinguishing practical and emotional support, studies indicate that the odds of adherence are more than three and a half times greater for patients receiving practical support (e.g., assistance, reminders, and support for a specific behavior) and almost twice as high for patients receiving emotional support (e.g., nurturance) compared with patients without these types of support (DiMatteo, 2004). Psychosocial interventions with patients and their families designed to increase social support suggest a modestly positive though mixed effect of family involvement; overall evidence indicates that family involvement leads to decreases in depression and mortality (Martire, Lustig, Schulz, Miller, & Helgeson, 2004). Mixed findings regarding social support and illness may be due to variation in the match between desired and received support and the extent to which received or enacted support is perceived as support by the receiver.

Intimate partners also strive to prevent future health problems by deliberating attempting to promote health-enhancing behaviors and inhibit health-compromising behaviors. Such attempts may take the form of social support (helping close others achieve or maintain health through emotional and practical support) and/or social control (deliberate attempts to influence close others' health behaviors).

Social Control

Like social support, social control can have a positive effect on partner health, but it can also impede health behavior change and have negative effects on partners and relationships. According to the dual-effects hypothesis of social control, deliberate attempts by close others to influence health behavior do sometimes improve health behavior but may also lead to psychological distress, including feelings of irritation, hostility, sadness, and guilt (Lewis &

Rook, 1999). Early research guided by this hypothesis, based on general measures of social control, reported mixed results and contributed, in part, to leading researchers to make a distinction between positive and negative social control. Subsequent studies clarified that negative social control (involving tactics such as disapproval, guilt induction, and pressuring) is much less likely to lead to health behavior change and more likely to lead to psychological distress. Negative social control is also much more likely to backfire—resulting in partners hiding behaviors and negatively affecting the relationship. Positive social control (involving tactics such as reinforcing behavior change, modeling, and persuasion) is more likely to positively influence behavior and less likely to lead to psychological or relationship distress. Further, positive social control may even lead to increases in well-being (Craddock, vanDellen, Novak, & Ranby, 2015).

Types of attempts have been delineated beyond positive and negative categories. Researchers have examined the effects of bilateral attempts, such a discussing the issue with the spouse, versus unilateral attempts, such as throwing out unhealthy food, and the effects of direct attempts, such as trying to persuade a partner to make a change, versus indirect attempts, such as inducing guilt. Bilateral and direct attempts are more likely to be associated with health-enhancing behavior compared with unilateral and indirect attempts, though the findings have been mixed (Lewis & Butterfield, 2007). Some evidence suggests that direct attempts do not affect partner behavior immediately, but do affect behavior over time. Conversely, indirect attempts help in the short run, but do not last over time.

The differential effect of types of attempts can be accounted for, at least in part, by the emotions partners experience in response to social control attempts. Early findings that positive and negative aspects of social control are independent gave rise to the domain-specific model, which posits that positive social control is related to positive affect but not related to negative affect, whereas negative social control is related to negative affect but not positive affect; evidence for this model is mixed and a recent meta-analysis suggests that positive social control is positively related to positive affect and negatively related to negative affect. The same holds for negative social control, that is, that negative social control is positively related to negative affect and negatively related to positive affect (Craddock et al., 2015).

According to the meditational model of social control, proposed by Tucker and colleagues, variance in behavioral response to social control strategies is significantly reduced when the affective response to attempts is accounted for, indicating that the way a partner feels about a social control attempt is at least partly responsible for how the partner responds behaviorally (Tucker & Anders, 2001). This model, which has been well supported across many studies, explains why the same attempt (e.g., "Honey, let's go for a walk") can have a positive or a negative effect—it all depends on how the partner feels about the suggestion. Positive emotional responses to social control attempts are more likely to lead to behavior change, whereas negative emotional responses are more likely to backfire—engendering resistance and/or hiding of health-compromising behavior.

The expanded meditational model proposes that the effect of social control on health behavior can be better explained if motivation to change the health behavior and reactance (resistance to partner's attempts to influence health behavior) are taken into account, along with emotional response. Preliminary evidence suggests that health behavior change is more likely when positive social control attempts elicit positive affect *and* predispose the partner to make the change. Further, reactance has a direct negative effect on the likelihood of making a health behavior change. This effect may be in the form of ignoring the attempts and/or hiding the unhealthy behavior (Logic, Okun, & Pugliese, 2009).

Cognitions and Readiness to Change

Social support and social control are distinct concepts, but they are related to one another. Distinguishing between the two—and when an attempt might be construed as positive and negative—can be challenging, as the same type of attempt to influence health behavior may be considered supportive by one person and controlling by another. Researchers have proposed that the attributions that individuals make about their partners' change tactics (e.g., concern about health vs. concern about appearance) may account for variance in how change tactics are received (Lewis & Butterfield, 2005). Cognition is also a feature of the readiness model, which proposes that an individual's readiness to make a change determines whether an attempt is perceived as supportive or controlling and, subsequently, how the individual responds emotionally (Sullivan, Pasch, Bejanyan, & Hanson, 2010). Initial evidence suggests that readiness to make a change causes changes in how an attempt is perceived and the emotional reaction to the attempt and that those perceptions and emotions affect how likely the individual will be to make a change. Perceptions of attempts as supportive and subsequent positive emotional responses lead to greater intentions to make a behavior change, and perceptions as controlling and subsequent negative emotional reactions lead to lower intentions to make a health behavior change.

Predictors and Consequences of Using of Social Control

Much of the research in the area of social control and health focuses on the recipients of control attempts, how they feel, and whether they respond behaviorally. Less is known about the antecedents of social control attempts and the personal and relationship consequences of attempting to influence a partner's health behavior. In a seminal study, Butterfield and Lewis (2002) examined characteristics of the partner trying to influence the other (agent) and characteristics of the partner being influenced (target), as well as characteristics of the relationship and the situation to clarify predictors of social tactic use. In this and a subsequent study, they found that social control approaches vary based on agents' cognitions and emotions. That is, agents used all types (i.e., bilateral, direct, etc.) of tactics more frequently when they were more ready for the partner to make a change. Further, agents' perceptions of how difficult it is for their partners to make the change led to more frequent use of negative and indirect tactics. Finally, agents' learned helplessness regarding their ability to influence partners' health behavior was positively associated with less frequent use of bilateral tactics and more frequent use of negative tactics. Targets' characteristics affected agents' tactic use as well; the more ready a target was to make a change, the more the agent used positive, direct, and bilateral tactics. In terms of consequences of attempts to influence partner behavior, agents experience more stress and more tense interactions when they use social control tactics, but less stress and more enjoyable marital interactions when they employ support tactics.

Context

The contextual model emphasizes the importance of including situational variables in models of social support and social control and understanding the process by which contextual variables affect partner influence on health behavior. The contextual variables that have received attention to date include relationship satisfaction, gender, ethnicity, personality, history of control attempts, and type of behavior (i.e., health enhancing vs. health compromising).

All but the first two variables have received attention only very recently, and the information provided is based on only one or two studies.

Relationship Satisfaction

Relationship satisfaction may moderate the effect of social control on health behavior such that partners experiencing social control attempts are much more likely to benefit from those attempts when their relationship satisfaction is high. Partners who are less satisfied with their relationships are less likely to change their behavior in response to social control attempts, have lower levels of positive affect and higher levels of negative affect in response to partner control attempts, and are more likely to hide unhealthy behavior in response to positive and negative social control attempts. In contrast, couples high in satisfaction are much less likely to experience psychological distress and hide unhealthy behaviors only in response to negative social control. Finally, relationship length is positively associated with behavior change in dating relationships. It is important to note, however, that findings regarding relationship satisfaction are mixed, with some studies reporting no effect of relationship satisfaction.

Gender

Gender appears to be related to the receipt and provision of social control; men are more likely to be the recipients of social control, and women are more likely to attempt to control the health of their partners. There is also evidence of gender differences in affective reactions to and effectiveness of social control attempts. Attempts to influence health are more likely to lead to positive and negative affective responses for women compared with men. Regarding the effectiveness of social control attempts, there is evidence that female partners' change attempts are more effective than male partners' change attempts. Further, male partners' change attempts are more likely to backfire and have the opposite effect of what was intended than women's change attempts. As with relationship satisfaction, it is important to note that findings regarding gender effects are mixed, with some studies reporting no gender differences in receipt/provision of social control or the affective reactions to and effectiveness of social control attempts. Gender may also interact with equity in affecting social control attempts, for example, husbands have been shown to use unilateral and positive tactics more frequently when their wives view the relationship as unequal.

Ethnicity

Few studies have examined ethnic differences in social support or social control of partner health behaviors. One study of dietary behavior in people with diabetes found that partner social support and social control were associated with good dietary behavior in Mexican Americans, but only social support was associated with good dietary behavior in non-Hispanic whites.

Personality

Again, studies here are sparse, but there is evidence that partners who are high in neuroticism experience more social control attempts than partners lower in neuroticism. Further, those high in neuroticism have more negative affective responses to change attempts and are less likely to change their health behavior.

History of Control Attempts

Based on initial evidence, it appears that a history of control attempts by an intimate partner on an individual is associated with an individual's increased use of indirect tactics when attempting to influence the intimate partner's health.

Type of Behavior

Partners use negative tactics less frequently when trying to initiate a health-enhancing behavior compared with when they are trying to terminate a health-compromising behavior. Further, health-compromising behaviors and behaviors with more severe consequences elicit more social control attempts by intimate partners compared with health-enhancing behaviors and behaviors with less serious consequences.

Future Directions

There are a number of avenues by which the understanding of the relationship between intimate relationships and health behavior can be further illuminated: The first is research on the buffering effect of social support and how it may vary based on type of stressors and characteristics of the situation, the support provider, and the recipient. The second is the continued examination of contextual variables and the role they play in the frameworks provided by major models in the field. Because there is so little work on contextual variables, replication is needed for variables presented here, and additional variables need to be examined (e.g., age, previous history of health behavior, whether the health behavior is a shared problem, and health barriers). The third is further research on the characteristics of the partners, including readiness and motivation to change, as well as the attributions regarding control attempts and the affect they have on psychological well-being and health behavior change.

Author Biography

Kieran T. Sullivan is a professor of psychology at Santa Clara University. She has published widely in the area of intimate relationships. She is a consulting editor for the *Journal of Family Psychology*. Her current research focuses on support, control, and health behavior in intimate relationships.

Infertility, Miscarriage, and Neonatal Loss

Amy Wenzel

Department of Psychiatry, University of Pennsylvania School of Medicine,
Philadelphia, PA, USA
Private Practice, Rosemont, Pennsylvania, PA, USA

For many people, becoming a parent is a life task that carries great significance and meaning. Although the prospect of becoming pregnant and having a child is associated with joy and eager anticipation for many couples, it can be associated with sorrow and despair for couples who experience difficulties. Some couples experience *infertility*, or the inability to conceive after 12 months of regular sexual activity free of birth control. Other couples conceive but lose the baby in various stages of pregnancy. *Miscarriage* and *neonatal loss* occur when the embryo or fetus dies before it can live on its own. The term, miscarriage, is typically used when the loss occurs before the 20th week of gestation (sometimes 24th week of gestation in select studies). In contrast, the term neonatal loss (or *stillbirth*) is typically used when the loss occurs at or after the 20th week of gestation, including instances in which a fetus is carried to term but dies during childbirth. Together, miscarriage and neonatal loss are understood as *perinatal loss.* This article describes the phenomenology of, emotional consequences of, and interventions for infertility and perinatal loss.

Infertility

Infertility is typically designated in two ways. *Primary infertility* occurs when a woman has never conceived, and *secondary infertility* occurs when a woman had been previously pregnant, even if the pregnancy resulted in a loss. Although the definition of infertility presented earlier indicates that it is diagnosed after 12 months of trying unsuccessfully to conceive without using birth control, it is often diagnosed after 6 months of trying unsuccessfully to conceive in women over the age of 35. The rationale underlying the use of a different criterion for women

The Wiley Encyclopedia of Health Psychology: Volume 3: Clinical Health Psychology and Behavioral Medicine,
First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

over the age of 35 is that the likelihood of conceiving declines rapidly after the age of 30, so implementing fertility treatment sooner rather than later in women of advanced maternal age increases the likelihood of a successful pregnancy. Research shows that among women who have attempted to achieve pregnancy, the rate of infertility varies between 16 and 28%. In women over age 40, between 3 and 6% are involuntarily childless due to infertility, and an additional 4–6% have fewer children than desired (Schmidt, 2006).

The causes of infertility are multifaceted. Approximately 80% of infertility cases can be explained by female factors, male factors, or both, leaving the remaining 20% of cases unexplained by medical causes. Causes of female infertility include factors related to ovulation, the cervix or uterus, and/or the fallopian tubes. Women who infrequently ovulate or do not ovulate are at high risk for infertility; these difficulties can be caused by hormonal factors such as polycystic ovary syndrome (PCOS), altered levels of follicle-stimulating hormone (FSH), or luteinizing hormone (LH) due to stress or sudden weight gain or loss, or excess prolactin. Uterine and cervical causes of infertility include fibroids, an abnormally shaped uterus, and cervical stenosis (i.e., narrowing of the cervix). Women who have endometriosis, a condition in which the uterine lining extends outside the uterus, can have difficulty conceiving because resultant scarring can block the fallopian tubes. Moreover, the fallopian tubes can also be blocked by pelvic inflammatory disease, which is an infection of the uterus and fallopian tubes caused by sexually transmitted infections. Male infertility is typically caused either by a low sperm count or poor-quality sperm that are not mobile enough to reach the partner's egg. Some research demonstrates that anxiety and stress are associated with poorer outcomes in infertility treatment (e.g., Boivin & Schmidt, 2005); however, emotional distress is rarely viewed as the sole cause of infertility.

The emotional consequences of infertility can be devastating for those who experience it, as becoming a parent is often central to people's expectations for the course they believe their lives will follow. It is common for people struggling with infertility to report a sense of failure, defectiveness, and incompetence, as well as jealousy of and isolation from others who seem to achieve parenthood easily. Female infertility is commonly associated with a sense of betrayal by one's body. Male infertility is commonly associated with a threat to virility. Although the prevalence of mental health diagnoses is not elevated in people who struggle with infertility, they often report elevated levels of emotional distress on self-report inventories of depression, anxiety, and life satisfaction (Greil, Schmidt, & Peterson, 2016). Women tend to report higher levels of infertility-related depression, anxiety, and stress than do men. In contrast, people who are characterized by resilience, or the capacity to respond adaptively to negative life events, report comparatively lower levels of infertility-related stress, higher quality of life, and more adaptive coping strategies (Sexton, Byrd, & von Kluge, 2010).

Over the past 30 years, technology has allowed for the development of sophisticated approaches to medically assisted reproduction. Assisted reproductive technology (ART) is a category of medical procedures used to achieve pregnancy. Perhaps the most well-known ART is in vitro fertilization (IVF), a procedure in which (a) a woman takes hormones to increase the number of eggs; (b) her eggs are removed and placed in a petri dish along with sperm; (c) fertilization occurs in the petri dish; and (d) one or more embryos are placed in her uterus. Some women choose to freeze embryos and later thaw one or more embryos and have them transferred to the uterus, a procedure called frozen/thawed embryo transfer cycle (FET). Fertilization can also occur using donor eggs, such that after the eggs are fertilized, they are transferred into a woman's uterus. Non-ART medically assisted reproduction interventions include ovulation induction using pharmacotherapy and intrauterine insemination (IUI) using the husband/partner's or a donor's sperm. In developed countries, approximately 56% of people who struggle with infertility seek some form of medically assisted reproduction (Boivin, Bunting, Collins, & Nygren, 2007). The live birth rate in women under age 40 after undergoing ART is between 15 and 25%, depending in the specific intervention (Schieve, Devine, Boyle, Petrini, & Warner, 2009).

Many people experience a great deal of stress when they undergo medically assisted reproduction interventions, as these interventions can be unpredictable, ambiguous, and time consuming. In many cases, treatment assumes a central focus in their lives, and it can be difficult to know when to discontinue treatment. Some research suggests that infertility treatment confers stress above and beyond that conferred by infertility itself (Greil, Lowry, McQuillan, & Shreffler, 2011). As might be expected, infertility-related emotional distress decreases with successful treatment, and it often persists when treatment is unsuccessful. In addition, infertility and infertility treatment can put great strain on the partner or marital relationship. However, a subset of couples who remain involuntarily childless report that their relationship strengthened because of the shared experience (Peterson, Pirritano, Block, & Schmidt, 2011).

When women become pregnant through medically assisted reproduction technology, they view pregnancy as more stressful and report more anxiety than women who did not experience infertility. Moreover, women who became pregnant through infertility treatment report more emotional distress following a pregnancy loss than women who did not become pregnant through infertility treatment. However, there is no evidence that women whose children were born through infertility treatment parent any differently or report differing levels of parenting stress than women whose children were conceived naturally, although parents who had children using medically assisted reproduction technologies endorse stronger feelings toward their children and a high level of gratitude (Sundby, Schmidt, Heldaas, Bugge, & Tanbo, 2007). There are few long-term consequences of infertility-related emotional distress in couples who eventually have a successful pregnancy or who adopt children; however, emotional distress persists in a subset of people who remain involuntarily childless.

Although the need for infertility-specific mental health services for people experiencing infertility has been recognized, there is a paucity of research that has examined the efficacy of specific interventions for infertility-related emotional distress. Interventions based on cognitive behavioral therapy (CBT) typically include components such as relaxation, cognitive restructuring (i.e., a process by which people evaluate the accuracy and helpfulness of negative thoughts associated with emotional distress), stress management, and psychoeducation about infertility and its emotional consequences. Research shows that such CBT approaches are more efficacious than routine care (Domar et al., 2000) and pharmacotherapy (Faramarzi et al., 2008) in reducing depression, anxiety, and stress in people who struggle with infertility. In contrast, evidence is mixed regarding the degree to which mental health intervention targeting people struggling with infertility actually improves pregnancy rates.

Miscarriage and Neonatal Loss

Because the achievement of parenthood is an important developmental task for many adults, a loss can be devastating on many levels. According to perinatal loss experts David and Martha Diamond,

> In addition to the loss of the fetus or baby, which can be a devastating event in and of itself, there are lost opportunities for progress in adult development, for the repair of old wounds, and for the redefinition of relationships with others. The grief, loss, and trauma may re-evoke unresolved grief from the past. Preexisting psychopathology can be exacerbated, and new disorders can be precipitated (Diamond & Diamond, 2016, p. 488).

The often-abrupt shift from the expectation that there will be a new addition to the family to the stark realization that this will not occur prompts a profound sense of disappointment and despair in many people who experience it. Perinatal loss is a particularly difficult event for women to endure, given that they are already in a vulnerable state due to fluctuating hormones, shifting their identity to that of being a parent, and perhaps grappling with hurts from their own parentings of which they were reminded during their pregnancy. However, it is important not to underestimate the toll that perinatal loss takes on men as well.

The overall incidence of miscarriage is between 15 and 20%, and it increases substantially with age, with as many as 75% of women experiencing a miscarriage after age 45 (Hemminki & Forssas, 1999). Most miscarriages occur in the first 12 weeks of gestation, which is why many people refrain from sharing news of the pregnancy until they have completed the first trimester. Symptoms of miscarriage are cramping and vaginal bleeding. An ultrasound verifies that the pregnancy is no longer viable. Many women are advised to simply allow the miscarriage to proceed naturally; however, in instances in which this does not occur, medical intervention may be necessary. Some women undergo *dilation and curettage* (often referred to as a D&C), in which a medical team dilates a woman's cervix and uses surgical intervention to remove the contents of the uterus. Other women are given medicine to induce contractions. The incidence of neonatal loss—loss that occurs at or after 20 weeks of gestation—is approximately 0.6% (MacDorman & Gregory, 2015). Women whose fetus died in utero typically go through the process of labor and delivery. Other women deliver live infants that die soon after birth.

There are many factors that account for perinatal loss. Between 50 and 70% of first trimester miscarriages can be attributed to genetic problems, such as chromosomal abnormalities. Additional causes of miscarriage include infections, maternal medical conditions like diabetes or thyroid disease, hormone problems, immune system responses, uterine abnormalities, and instances in which the egg did not implant properly. Risk factors for miscarriage include advanced maternal age (i.e., age 35 or older), maternal medical conditions like diabetes or thyroid disease, a history of three or more miscarriages, smoking, drinking alcohol, use of illicit drugs, toxins, and obesity. Causes of neonatal loss include placental abruption, premature rupture of membranes (i.e., water breaks prematurely), preeclampsia (i.e., a condition that typically occurs after 20 weeks of gestation, characterized by high blood pressure and potential damage to an organ system like the kidneys), birth defects like structural abnormalities, growth restriction, infection, and umbilical cord abnormalities.

Many people experience a pronounced grief reaction in the time following a perinatal loss. However, the grief is focused on what their child would have been like and what life would have been like with the child, rather than on memories. Grieving a perinatal loss is particularly challenging because there are few culturally sanctioned grieving practices. Many women report significant feelings of guilt and shame, a sense of failure, and self-blame. Women who miscarried in the first trimester often grieve in silence, as they had not yet disclosed the pregnancy to others. Women who were visibly pregnant and suffer a neonatal loss must contend with announcing the news to others and fielding questions from acquaintances and co-workers who ask pregnancy. Men also report elevated grief after perinatal loss, although it is typically less pronounced than in women and more profound in response to a neonatal loss, rather than to a miscarriage. One explanation for this is that men have not experienced quickening (i.e., the perception of fetal movements) and the bodily changes that women typically experience. It is likely that results from studies finding gender differences in grieving perinatal loss can be explained by gender differences in the general expression of grief and emotional distress, with men being more likely to remain stoic and use problem-solving strategies to cope with loss and women being more likely to express their emotions openly.

Complicated grief occurs when the grief reaction becomes chronic and is associated with life interference and significant personal distress. Approximately 10–20% of women who experience perinatal loss struggle with complicated grief, although this range is not appreciably different from the percentage of complicated grief reactions in response to other losses (Brier, 2008). Factors that put women at risk for complicated grief reactions to perinatal loss include poor psychological functioning prior to the loss, poor social support, and a history of other perinatal losses.

A body of research has examined specific symptoms associated with mental health disorders reported by people who have experienced perinatal loss. Research indicates that elevated symptoms of depression in women persist 6 months to 1 year following a perinatal loss and that the women at greatest risk for depression are those who are childless, are highly invested in the pregnancy, and/or have concerns about infertility (Robinson, 2014). Men also report elevated depressive symptoms in the first few months following a perinatal loss, but in contrast to symptoms reported by women, their symptoms drop significantly after 3 months. Moreover, women who have experienced perinatal loss typically report high levels of anxiety during subsequent pregnancies, with the understandable worry that they will experience another loss. In fact, there is evidence that women who have experienced multiple perinatal losses have more emergency department visits and hospitalizations than women without such a history (Kinsey, Baptiste-Roberts, Zhu, & Kjerulff, 2015). Women also endorse rumination and intrusive thoughts up through at least 6 months' post-loss.

Experts have been increasingly recognizing the traumatic nature of perinatal loss. The definition of trauma in the *Diagnostic and Statistical Manual, Fifth Edition* (DSM-5) indicates that a person must have exposure to actual or threatened death, which indeed is the case with a perinatal loss. Many women who experience perinatal loss contend with a great deal of blood and pain. There is a profound sense that something is going horribly wrong, coupled with a sense of uncontrollability. The woman has literally lost an extension of herself in her child, as well as an integral part of a dream for parenthood. For these reasons, Diamond and Diamond (2016) have described perinatal loss as being one type of *reproductive trauma*. Rates of posttraumatic stress symptoms in women who have experienced perinatal loss range from 10 to 25% at 1-month post-loss (Diamond & Diamond, 2016).

In addition, other family members often experience emotional distress associated with the perinatal loss. Children who knew about their mother's pregnancy can experience grief, along with confusion over what happened to the baby. Even when children do not know about the pregnancy, they can often sense when their parents are upset. Grandparents are also affected tremendously by perinatal loss, both in terms of the loss of a grandchild and concern for what their own child is enduring (Robinson, 2014).

Although there is little consensus on the best interventions to deliver to parents who experience perinatal loss, most experts agree that it is important for healthcare providers to acknowledge the meaning associated with the loss, as well as to provide parents with some latitude to choose the best way to proceed with logistical issues (such as how to dispose of the remains, whether to have a memorial service). There is insufficient evidence to support the provision of counseling in the immediate aftermath of a perinatal loss. However, psychotherapy and counseling should be offered as an option when people experience a perinatal loss, with the understanding that it is their choice as to whether they take advantage of it. Psychotherapy or counseling should be recommended at follow-up visits when it becomes clear that their emotional distress is at a level that causes life interference. A topic of debate is whether women who experience advanced neonatal loss should hold their babies. Some parents find that doing so provides a sense of closure. However, some research shows that there is an increase in depressive, anxiety, and posttraumatic stress symptoms in parents who held their baby, relative to parents who did not (Hughes, Turton, Hopper, & Evans, 2002).

Mental health professionals who work with people who have experienced perinatal loss are encouraged to provide the utmost empathy and compassion. They should create an atmosphere in which the client experiences, rather than avoids, the painful affect associated with the loss. Psychoeducation can be helpful in normalizing grief reactions, and previous unresolved losses that have been activated by the current loss should be addressed (Diamond & Diamond, 2016). CBT interventions have demonstrated efficacy in reducing prolonged grief, depression, anxiety, and posttraumatic stress in an open trial (Nakano, Akechi, Furukawa, & Sugiura-Ogasawara, 2013) and a randomized controlled trial (Kersting et al., 2013).

Prevention and Health Across the Lifespan

John L. Romano

Department of Educational Psychology, University of Minnesota Twin Cities, Minneapolis, MN, USA

Throughout history and across different disciplines, there has been a strong consensus that it is better to prevent a problem than to correct it after it is manifested. This axiom has especially been applied in matters of health, as we are regularly reminded about a host of behaviors and actions that we should take to ward off health problems. These include, among many, eating a healthy diet, being physically active, reducing stress, and getting flu shots. These actions are designed to reduce premature illness and disability and promote the quality of life into older age. However, although there is strong agreement among professionals and the lay public alike about the importance of prevention, there is reluctance and difficulty following preventive actions that science tells us will reduce disease and extend life. In addition to exploring the reluctance and lack of motivation to follow preventive recommendations, this chapter will summarize other areas of prevention as they pertain to matters of health across the lifespan. These areas of prevention include recent definitions of prevention, American Psychological Association (APA) Guidelines for Prevention in Psychology, protective factors to promote health and well-being, prevention in the US Affordable Care Act (ACA), psychological interventions for prevention, and prevention and health in the twenty-first century.

Definitions of Prevention

While the word prevention has an intuitive meaning to most people, the word has generated discussion and nuances among scholars. Primary, secondary, and tertiary prevention were described by Caplan (1964) as activities and interventions designed as appropriate for an entire population (primary), for those at risk for developing a problem (secondary), and to reduce the impact of an existing problem (tertiary). These terms have been in use for many years.

The Wiley Encyclopedia of Health Psychology: Volume 3: Clinical Health Psychology and Behavioral Medicine, First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

However, Gordon (1987) conceptualized prevention interventions differently, describing prevention interventions as universal, selective, and indicated. Gordon argued that once a problem was manifested (tertiary), interventions for them are not prevention. Gordon's universal prevention is similar to primary prevention, while selective and indicated refer to interventions for groups who are at less (selective) and greater (indicated) risk for developing a disorder. The US Institute of Medicine's Committee on Prevention of Mental Disorders adopted Gordon's definitional terms for prevention in their seminal volume "Reducing Risks for Mental Disorders" (Mrazek & Haggerty, 1994). Romano and Hage (2000) expanded this definition by incorporating the strengthening of individual protective factors and institutional change strategies as importantcomponents of a comprehensive definition of prevention. In a later volume, the National Research Council and Institute of Medicine (2009) also incorporated reduction of risk and promotion of protective factors in its conceptualization of prevention. In a recent volume, Conyne (2015) described everyday wellness and prevention as actions taken to improve "personal wellness and to avert significant problems, while contributing to the health and well-being of others" (p. 19). This definition incorporates individual empowerment and systemic change as important prevention strategies. As the professional specialty of prevention has expanded, definitions of prevention have become more focused and inclusive, not only attending to individuals and groups but also recognizing that systemic and institutional preventive interventions are needed to address major societal problems. As will be discussed in this chapter, the US ACA: Affordable Care Act (Federal Law, also called "Obama Care," 2010), while controversial, is one example of legislation that incorporates prevention services as important to overall healthcare, and as described in the following section, APA's Guidelines for Prevention in Psychology reinforce the importance of prevention in psychology.

Guidelines for Prevention in Psychology

It has been well documented that historically prevention has not held a very visible or prominent position in the field of psychology (Romano & Hage, 2000). Prevention is generally not a core course within psychology graduate programs, and prevention has not been considered as a specific competency or domain in accreditation of graduate training programs, or as an educational requirement for license as a psychologist. While community psychology, with a strong prevention and social justice focus, was organized as a specialty in the mid-1960s and other organizations such as the Society for Prevention Research and the Prevention Section of APA's Society of Counseling Psychology (Division 17) were created over the last 25 years, the impact of these organizations on the broader profession of psychology has been modest.

To advance the cause of prevention, science and its visibility in psychology, a group of APA-member psychologists, began the arduous task (over multi-years) of developing an APA set of guidelines for prevention in psychology. The guidelines, based on an earlier "*Best Practices in Psychology*" manuscript (Hage et al., 2007), were vetted by all major psychology stakeholders (e.g., professionals and consumers), revised accordingly, and eventually approved by APA Council and published in the *American Psychologist* (APA, 2014).

The *Guidelines for Prevention in Psychology* are very relevant to all of psychology, including health psychology. The Guidelines, which are aspirational, consist of nine guidelines of best practices for prevention psychology. The Guidelines recommend the following: (a) prevention interventions that are theory driven and supported by evidence, (b) prevention science that attends to socially and culturally appropriate practices, (c) prevention that addresses risk as well as protective factors to enhance well-being, (d) prevention activities include research and evaluation as integral to assess prevention practices, (e) prevention research and practices that include consideration of ethical issues as they pertain to prevention, (e) prevention specialists who attend to social disparities that may inform science and practice, (f) psychologists encouraged to seek out prevention training through various avenues throughout their career, (g) psychologists engaged in systemic change interventions to strengthen organizations and units of society to reduce distress and disability, and (h) psychologists encouraged to contribute to public policy discourses to inform decision makers about topics relevant to prevention science.

The APA Prevention Guidelines are important to health psychology as they offer a set of aspirational recommendations to psychologists and other mental health workers to advance the cause of prevention in their clinical and research work. The Guidelines also reinforce the importance of not only stopping and reducing problematic behaviors but also strengthening factors that can be protective to individual persons as well as groups and communities. For example, health psychologists can work with schools and workplaces to promote healthy lifestyles, which serve as protections against future disease. The Guidelines also address the relevance of focusing on institutional and public policies to reinforce prevention of health problems and health promotion at the macro levels of society. In the United States, these macrolevel initiatives have reduced tobacco addiction (although it took many years and needs to be regularly reinforced), have produced dietary guidelines to promote good health, and passed laws to reduce traffic fatalities (e.g., use of seat belts, alcohol use, distracted driver penalties), to name a few examples. Community policies and laws to promote health are often contentious and controversial, and thus, at systemic levels, prevention and health promotion initiatives usually become very much a question about individual and community values, beliefs, and attitudes, as exemplified by efforts to enact legislation prohibiting cigarette smoking in bars and restaurants and laws to control access to guns to reduce crime.

Protective Factors to Promote Health and Well-Being

The promotion of protective factors is important to an overall framework of prevention initiatives. Protective factors are characteristics of an individual, small group, institution, or a larger community that can serve as protections against problematic behaviors now or in the future. Scholars have conceptualized protective factors in different ways. For example, Lösel and Farrington (2012) identified six types of protective factors that can serve as buffers to violent behaviors, that is, biological, personality, family, school, peers, and community. While Lösel and Farrington directly applied these factors to the prevention of youth violence, they offer a comprehensive framework for prevention of other problems and health promotion across the lifespan. For example, in healthcare settings, providers can assess protective factors related to health problems of an elder patient, such as support from family to follow prescribed care to reduce the risks of an emerging health problem; in younger adults, providers can assess genetic influences that may be related to a potential health problem. In addition, providers can assess personality characteristics (e.g., conscientiousness) and motivations to make health-enhancing changes to reduce risk. Too often, patients hear what not to do (e.g., stop smoking, eat better, exercise, etc.), but for many these represent long-term habits (e.g., addictions) and are very difficult to change without specific direction and guidance from professionals. Therefore, it is important that health providers discuss with patients how they might go about making lifestyle changes to improve health and provide referrals and other recommendations that offer specific guidance for making positive changes in lifestyle behaviors. The change process will be strengthened if protective factors are enhanced as part of the strategy to reduce problem behaviors.

Others have also address protective factors through specific frameworks. For example, Romano (1997) articulated the importance of promoting student well-being in schools by focusing on strengthening students' knowledge, skills, attitudes, and behaviors that promote well-being in school, at home, and in the community. Building resiliency in youth and young adults has also enriched research and practice to strengthen protective factors (e.g., APA Task Force on Resilience and Strength in Black Children and Adolescents, 2008; Luthar, Cicchetti, & Becker, 2000). Promoting protective factors in older adults has also been examined. These interventions can take the form of providing psycho-educational programs related to healthy lifestyles, developing social support networks to reduce social isolation, and following medical regiments (Reynolds et al., 2012). In addition, positive psychology (Seligman & Csikszentmihalyi, 2000), with its emphasis on the study of strengths and well-being, has received much attention in clinical and research practices, and thus, positive psychology offers another perspective through which to focus on protective factors in prevention science.

Finally, at the macro level, it is important to also promote community and societal protections and buffers to problem behaviors to reduce risks. Vera and Shin (2006) refer to the importance of reducing toxic environments, communities, and institutions that allow discrimination and disenfranchisement to exist among particular groups within a locale or larger society. Advocating for protections that provide adequate healthcare, housing, employment, and education for all members of a community is extremely important to support an overall health and wellness agenda across all population groups. However, suggestions on how best to achieve such community-wide initiatives are usually burdened with political controversies. One notable example is the US ACA, which became the law in 2010, but the ACA merits have been hotly debated ever since passage. However, as discussed in the next section, ACA includes many benefits to support preventive interventions across the lifespan.

Prevention and the Affordable Care Act

The US ACA has generated much controversy since it was passed in 2010 as policy for delivering and providing healthcare across the United States. Despite the political controversies surrounding the law, ACA provides for many benefits that support prevention, and psychologists are well positioned to provide leadership and services. Specifically, ACA provides for the Prevention and Public Health Fund that supports grants and state funding for a range of prevention programming, including school-based health services, maternal health and early childhood home visit programs, and cultural competence training. In addition, ACA supports preventive patient healthcare across the lifespan, including adolescent alcohol and drug screening and assessment, developmental screening for children under age three with continued surveillance throughout childhood, and adolescent screening and counseling for obesity. In addition, ACA provides for screenings and counseling for adults coping with alcohol misuse, diet counseling for those at risk for chronic disease, and tobacco use screening and interventions. The law also provides for annual wellness visits for seniors through Medicare and preventive services for those on Medicaid. Psychologists are encouraged to review the benefits of the ACA law and educate their clients about services that can be received under the law.

In addition, psychologists can be an excellent resource for primary care physicians and other health professionals as they are often the first ones who learn that their patients are at risk for mental or physical health problems. (See special issue of the *American Psychologist* on primary care and psychology [McDaniel & deGruy, 2014] for several papers on this topic.) Working in collaboration, psychologists and primary care providers can form a powerful partnership to prevent health problems and reduce patient risk. Integrated models of care between psychologists and physicians have been advanced to strengthen these collaborations (Vogel, Kirkpatrick, Collings, Cederna-Meko, & Grey, 2012). Psychologists not only can assist in direct patient care but also can serve as partners and consultants in developing public health media campaigns and prevention materials that are usually available in healthcare settings. One adolescent survey conducted by Taveras et al. (2007) found that while adolescents reported to health providers during physical exams about their lifestyle behaviors that placed them at risk for different problems, they were not offered counseling to change risk behaviors. With benefits available through ACA, perhaps more patients across the lifespan will receive prevention counseling to change problematic lifestyle behaviors and habits that place them at risk for future disease and disability. The ACA offers opportunities for prevention-oriented psychologists to engage with healthcare professionals to offer benefits and services to improve health across the lifespan.

Psychological-Based Theoretical Interventions for Prevention

Patients are often told to change a habit of lifestyle to improve health and well-being by healthcare professionals. These directives may include, for example, improve diet, lose weight, stop smoking, consume less alcohol, control anger, etc. However, much less often are patients in primary care settings given the tools to make these behavioral changes, and, in addition, most primary care physicians and other health professionals do not have the time and expertise to engage in counseling and coaching with their patients on how best to make these changes. Therefore, behavioral specialists, for example, counselors, psychologists, or other mental health and behavioral specialists, are the most appropriate professionals to engage patients in the process to make necessary behavioral changes, thus, another important reason to advance integrated models of care (Kelly & Coons, 2012). Mental health and behavioral professionals are most often educated and trained in theories of counseling and psychotherapy that have been popularized through research and practice in settings that focus on crisis intervention and remediation. Common theories taught in applied psychology and counseling graduate programs include psychodynamic theories, cognitive behavioral theory, person-centered theory (PCT), and behavioral theories. While these theories may also be applied in preventive counseling and coaching situations, there are other psychological theories and perspectives that are neglected in many graduate training programs. However, less commonly taught theories can provide additional theoretical frameworks for the preventive counseling practitioner and researcher. These theories will be briefly summarized in this section.

Romano (2015) presented a summary of several theories that have been applied in prevention research and practice. They will briefly be reviewed here, and readers who are unfamiliar with these theories are encouraged to learn more about them.

Transtheoretical Model of Behavior Change (TTM)

TTM is a stage model of behavioral change introduced by Prochaska and colleagues (Prochaska, DiClemente, & Norcross, 1992; Prochaska, Johnson, & Lee, 2009). TTM asserts that behavioral changes occur in stages, although the stages are not necessarily linear. The six stages of change are precontemplation, contemplation, preparation, action, maintenance, and termination. This model is useful because it acknowledges that before change can occur, clients must be motivated to make a change, prepare a plan of action and carry out the plan, and provide a system for maintaining the change. For many behavioral changes of lifestyle, for example, smoking cessation, improvements in diet, maintenance continues, and termination is not relevant. TTM is useful in behavioral change counseling because it acknowledges that clients may not be ready or motivated for change (action stage), and if the counselor begins with preparation and action stages, without considering the client's readiness for change (precontemplation and contemplation), the counseling effort may go for naught and result in early termination of counseling. Prochaska and colleagues have developed a well-thought-out and evidence-based theory that is useful when assisting clients to make behavioral changes.

Theory of Reasoned Action and Planned Behavior (TRA/PB)

The TRA was first proposed by Fishbein (1967) and subsequently extended by Ajzen (1991) into the TRA and PB. TRA offers a framework to understand the relationship between beliefs, attitudes, and behaviors, and Ajzen's component (theory of PB) addressed the extent that a person believes that a behavior is under his/her control. TRA/PB is a cognitive model of behavior change in which change is influenced by a person's beliefs and attitudes about the behavior change, and these variables are further influenced by the opinions of others (social norms) about the behavior change and the person's belief that he/she can make the change. Thus, within a prevention framework and applying this theory, it is important to assess the client's attitudes and beliefs about making a change and the extent that the person believes that change is possible for him/her. Applying TRA/PB to alcohol use prevention with adolescents, for example, a provider would assess the adolescent's beliefs and attitudes about not using alcohol and how nonuse would be viewed by others important to him/her (e.g., peers, parents, coaches, etc.). In addition, the provider would discuss the youth's self-perception of being able to avoid alcohol use. In this example, the adolescent may believe that avoiding alcohol will make him/her less popular with peers, but abstinence from alcohol would receive strong approval from parents and other adults important to the adolescent.

Thus, in the TRA/PB framework, assessing beliefs and attitudes is necessary to bring about behavior change. One contribution of TRA/PB is elicitation research, which is a process to assess perceived beliefs among a group targeted for behavior change prior to initiating prevention activities associated with the desired change. For example, a medical clinic with a large Hmong client population may use elicitation research to initially assess with a pilot group of similar Hmong patients the most important beliefs about a desired behavior change (e.g., regular health screenings) prior to initiating a larger-scale program to encourage change among the Hmong population. Elicitation research data can be collected in different ways, for example, focused groups, questionnaires. Elicitation research recognizes that beliefs about a behavior change are not universal and that the most effective interventions will be population specific.

Health Belief Model (HBM)

HBM was developed by US social psychologists in the 1950s to better understand why some people do not participate in health screenings to prevent illness (Rosenstock, 1974). HBM is a cognitive theory based on a person's beliefs about the importance of health screenings. HBM is based on four perceived personal beliefs about his/her risk for contracting an illness or disease, and these beliefs influence whether or not a person participates in preventive health screenings and actions. The four perceived beliefs are susceptibility, severity, benefits, and barriers. Personal beliefs about susceptibility and severity of an illness as well as perceived benefits and barriers, according to HBM, are determinants and motivations for participating in health screenings. For example, a woman with a family history of breast cancer is likely to be more diligent scheduling regular mammograms, and her motivation to receive the screenings will be increased if the procedure is paid for by health insurance. While HBM was originally developed to better understand the lack of participation in some preventive health screenings, the model can also be considered as a preventive theory to address nonmedical problems, for example, assessment of risk associated with drinking and driving. The model may be especially useful with children and adolescents who underestimate their susceptibility and risk associated with problem behaviors, for example, experimenting with cigarette smoking will not lead to addiction ("I can quit anytime"). It can also be helpful to practitioners to assess perceived personal beliefs among clientele from different ethnic groups to better understand differences between a provider's beliefs about engaging in a preventive behavior and beliefs of clients from different ethnic groups.

Motivational Interviewing (MI)

MI has received considerable attention in the literature, especially in recent years (Miller & Rollnick, 2002). MI has its foundation in the work of Carl Rogers and his PCT. Although MI is more directive than PCT, MI recognizes the value and importance of the therapeutic relationship in behavior change. Four principles guide MI: (a) *express empathy*, as the counselor communicates empathetic understanding toward the client; (b) *develop discrepancy*, in which the counselor confronts the client about motivations to maintain or change behavior; (c) *roll with resistance,* as the counselor nonjudgmentally accepts client resistance to change; and (d) *support self-efficacy,* as the counselor assists the client to gain awareness about skills that he/she possesses to make behavioral changes. While MI was initially developed to help people stop addictive behaviors, it has been applied across a wide range of behaviors. MI would be most useful to assist individuals who are at risk for problematic behaviors (selective and indicated prevention). For example, MI might be used in a college setting to assist students who have low academic achievement or students who have been cited for problematic behavior related to alcohol use. In a medical setting, MI can be a framework to assist individuals whose lifestyle behaviors place them at risk for developing a future medical disease, such as obesity as a risk for diabetes. MI has been applied in brief counseling interventions with supplemental activities to change behaviors (e.g., Murphy et al., 2012), and thus, MI offers an advantage in medical settings where time may be limited for longer interventions.

The theoretical frameworks summarized in this section are examples of models that can form a foundation for health providers to assist people make behavioral changes. There are other theories that can also be helpful to clinicians, and it is also understood that theoretical approaches do not necessarily function in isolation from each other. A practitioner may use more than one theory to facilitate client change during the counseling/coaching process, depending on the nature of the desired behavioral change, client demographics and readiness for change, and the provider's comfort applying the theoretical framework.

Prevention and Health in the Twenty-First Century

This manuscript has presented background on prevention science and the specialty's contribution to strengthening the overall health of a population. Prevention science can be applied across the lifespan, and as psychologists and other mental health professionals gain increased opportunities to collaborate with medical personnel, the collaboration offers tremendous opportunities to assist people make necessary behavioral changes to improve health. Prevention offers much promise to reduce noncommunicable diseases (contributed to by behaviors of lifestyle) and extend the quality of life, especially with an aging US population. The role of psychologists as members of integrated healthcare teams is increasing, and applying prevention in these settings is critically important (see McDaniel & deGruy, 2014 and recently released APA video [www.apa.org/health/psychologists-integrated-care.aspx]).

Psychologists are encouraged to become familiar with the US government's major initiative in setting and monitoring health goals for the nation, *Healthy People 2020* (www.healthypeople.gov). *Healthy People* was first published in 1979 and at subsequent 10-year intervals, to measure progress, set goals, and make recommendations to improve the overall health and well-being of the population. The mission of *Healthy People 2020* is to identify national health improvement priorities; increase public awareness and understanding about the determinants of health, disease, and disability; apply measurable objectives and goals to monitor progress; engage multiple sectors of the society to improve health; and identify critical research, evaluation, and data collection needs to assess progress. The goals of *Healthy People 2020* are to promote longer life that is free of preventable disease, promote health equity and eliminate health disparities, create social and physical environments that support health, and promote quality of life and healthy development and healthy behaviors across the lifespan.

Healthy People 2020 is the single best resource to review and collect information about the health status of the US population and become knowledgeable about health promotion and disease prevention in the United States. Researchers and practitioners can search for research literature, evidence-based interventions, and professional tools that support health improvements/promotions and disease prevention across many health conditions and within different sectors of the society.

In addition, to provide direct health promotion and disease prevention programs and activities with at-risk patients, psychologists are encouraged to consider prevention interventions that offer assistance to those who are in relationship with people with illnesses. For example, psychologists can provide assistance and support to caregivers of the elderly who have developed cognitive disorders. Attending to caregivers of the elderly will become increasingly important with an aging US population. As the population ages, chronic disease and disability will also increase. Therefore, offering programs and support for those who care for this population, either in institutions or at home, is critically important in the twenty-first century. For example, personnel in nursing homes and assisted living settings will need support to help them understand the needs of disabled elders and also to prevent burnout and emotional stress that can accompany caring for disabled elderly. In addition, relatives who care for family members also need assistance to help them understand the disease and disability of their loved one and also to help them manage their own stress levels related to caregiving. Psychologists and other mental health professionals can also assist with end-of-life processes and issues that arise with terminally ill patients and their loved ones. Hospice programs are increasingly utilized across the United States to support quality of life at the end of life for the terminally ill. Hospice programs funded through Medicare/Medicaid and most private insurance policies offer psychological support and medical assistance during this difficult time to patients and their caregivers to manage patient pain and to educate and provide support during the dying process. As written in the Medicare legislation, direct mental health and social services in hospice programs are usually provided by social workers. However, psychologists may serve as bereavement counselors and can support the programs by applying their expertise through training and education of hospice personnel as well as family members of the dying patient to prevent excessive stress and burnout of professional personnel and family members.

Summary

This paper has highlighted some of the ways that health and prevention science intersect. In a previous volume, Romano (2015) summarized research and literature germane to the work of psychologists that has been conducted in the medical sector such as prevention of depression in geriatric patients and public health campaigns to improve health and prevent disease. There are many opportunities for psychology to apply the theories and practices of the profession to advance the health and well-being of the population through prevention science research and applications. The time is ripe to apply scientific advances in prevention science to reduce illness and disability and enhance the quality of life across the life cycle.

Author Biographies

Dr. John L. Romano is an emeritus professor of educational psychology at the University of Minnesota. Romano received his bachelor, masters, and doctoral degrees from Le Moyne College (Syracuse, NY), Pennsylvania State University, and Arizona State University, respectively. He has authored prevention-focused journal articles and books including the books *Prevention Psychology: Enhancing Personal and Social Well-Being* (APA, 2015) and coedited *The Cambridge Handbook of International Prevention Science* (Cambridge, 2017). He served as cochair and chair of the work group that produced the *APA Guidelines for Prevention in Psychology*, and he has been the recipient of several US Department of Education grants to promote safe and drug-free schools. Romano is a fellow of the American Psychological Association (APA). He has received several awards including the Prevention Section (APA's Society of Counseling Psychology) Inaugural Lifetime Achievement Award, Distinguished Contributions to Counseling Psychology (APA Society of Counseling Psychology), APA's International Psychology Division International Mentoring Award, and the American Counseling Association Research Award. He has been a visiting professor, consultant, and external examiner at universities in several countries.

Self-Affirmation and Responses to Health Messages: An Example of a Research Advance in Health Psychology

Allison M. Sweeney[1] and Anne Moyer[2]

[1]*Department of Psychology, University of South Carolina, Columbia, SC, USA*
[2]*Department of Psychology, Stony Brook University, Stony Brook, NY, USA*

People, especially those at risk, tend to resist persuasive appeals to change their behavior. When people are uninterested in changing a health behavior, they may try to discredit unwanted health information by forming counterarguments or alternative explanations (Ditto & Lopez, 1992). To the extent that people tend to prefer positive information that reflects well on the self, it is not surprising, then, that people scrutinize unfavorable information more than favorable information (Giner-Sorolila & Chaiken, 1997). To the extent that health information reminds people of their shortcomings, it can be a potent threat to their positive self-views. Ironically, the more personally relevant a health message is, the less likely an individual is to process it objectively (Liberman & Chaiken, 1992).

One promising approach to overcoming resistance to health information involves leading people to think about their most important values or actions, a process known as self-affirmation (Steele, 1988). Self-affirmation theory proposes that highlighting important sources of self-worth restores or reinforces an individual's overall sense of self-integrity. By making salient aspects of the self that are important to one's identity, but are unrelated to the threat at hand, self-affirmation helps to offset any potential self-threat elicited by health information (Sherman & Cohen, 2006). As a result, self-affirmation should reduce any motivation to respond defensively to health information. Supporting this prediction, a number of studies have found that when people are self-affirmed, they are more likely to process health information in an objective manner (Reed & Aspinwall, 1998; Sherman, Nelson, & Steele, 2000).

The Wiley Encyclopedia of Health Psychology: Volume 3: Clinical Health Psychology and Behavioral Medicine,
First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

Much of the early research on self-affirmation and health focused on the ability of self-affirmation to change people's responses to health information, including message acceptance (Sherman et al., 2000). Further efforts have been made to clarify whether increasing people's openness toward health information translates into a change in future health-related behaviors. Several studies indicate that self-affirmation facilitates behavior change across a diverse range of behaviors, including physical activity, fruit and vegetable consumption (Epton & Harris, 2008), alcohol consumption (Armitage, Harris, & Arden, 2011), and adherence to medication (Wileman et al., 2014). Such studies typically examine the influence of self-affirmation over the course of a week or longer, with some studies finding effects extending over several months (Harris et al., 2014; Wileman et al., 2014).

Self-affirmation has a small-sized effect on health behaviors (Epton, Harris, Kane, van Koningsbruggen, & Sheeran, 2015; Sweeney & Moyer, 2015). Although small, the effect size of self-affirmation is similar to those obtained in meta-analyses of other health behavior change interventions (e.g., Gallagher & Updegraff, 2012). Thus, self-affirmation holds considerable promise as a useful framework for explaining when people accept health information and, in turn, make changes in their behavior. In this chapter we will examine some of the recent developments and discoveries among studies of self-affirmation, including (a) the incorporation of diverse research methods, (b) the identification of moderating variables, and (c) efforts to combine self-affirmation with other intervention strategies. We will then highlight two major questions for future research: (a) how does self-affirmation influence health behaviors and (b) what is the trajectory of self-affirmation?

Applying Diverse Research Methods to Studies of Self-Affirmation

Many early studies on self-affirmation and health-related outcomes consisted of laboratory-based studies that measured immediate responses to health information. After completing a self-affirmation or a control task, people were presented with health information and reported on their responses to it, such as behavioral intentions and message processing (Reed & Aspinwall, 1998; Sherman et al., 2000). Within the last decade, however, researchers have begun to examine whether self-affirmation impacts outcomes beyond people's self-reported experiences. An emerging literature encompassing a diverse array of methods suggests that self-affirmation impacts the body's immediate and physiological response to threat. For example, relative to non-affirmed individuals, people who are self-affirmed have a lower cortisol response when exposed to a stressful situation (Creswell et al., 2005) and take less time for their mean arterial blood pressure to return to baseline after receiving threatening information (Schmeichel & Tang, 2015).

To date, two studies have examined the influence of self-affirmation on neural activity.

To examine the effect of self-affirmation on immediate sensitivity to threat, participants completed a speeded response time task while their neural activity was recorded with electroencephalography (EEG) (Legault, Al-Khindi, & Inzlicht, 2012). The response time task was a go/no-go task that involved making or withholding a response depending on the type of stimuli presented. Participants were instructed to respond as quickly as possible and, thus, were prone to errors. The researchers tested whether self-affirmation would impact people's sensitivity to making errors by examining their error-related negativity (ERN) response, an event-related potential found in past research to index motivational significance. Participants who self-affirmed prior to the go/no-go task displayed a greater ERN response, suggesting that they were more sensitive toward making mistakes during the response time task. To the extent that errors are experienced as aversive, the authors interpreted this finding as suggesting that self-affirmation increases people's openness to processing threat.

Adopting a different approach, one recent study used functional magnetic resonance imaging (fMRI) to examine neural activity during the processing of health information (Falk et al., 2015). The results indicated that people who were self-affirmed showed greater activation in the ventromedial prefrontal cortex (VMPFC), an area of the brain associated with self-related processing when reading the health message. Furthermore, increased activation in the VMPFC was associated with greater health behavior change, suggesting that self-affirmation may engender health behavior change by allowing people to process otherwise threatening health information as self-relevant. Taken together, research by Legault et al. (2012) and Falk et al. (2015) provide initial evidence that applying a neurophysiological approach to self-affirmation may be a useful framework for further understanding the cognitive and motivational processes that underlie self-affirmation.

Another notable change among studies of self-affirmation has been an increased emphasis on measuring behavioral changes arising from self-affirmation. Attempts to examine the impact of self-affirmation on health behaviors have relied primarily on self-reports (e.g., Armitage et al., 2011; Epton & Harris, 2008). Recently, however, a few studies have begun to incorporate more objective measures of health behavior change. For example, one study found that self-affirmation led to a reduction in sedentary behavior, as assessed with accelerometers worn by participants for 1 month (Falk et al., 2015). Another study examined whether self-affirmation would encourage hemodialysis patients to adhere to recommendations (Wileman et al., 2014). By measuring patients' serum phosphate levels across 1 year, the researchers were able to show a positive effect of self-affirmation on medication adherence.

Moderators of Self-Affirmation's Effects: The Content of the Message and Characteristics of the Individual

As research on self-affirmation has accumulated, researchers have identified several factors that moderate the effectiveness of self-affirmation. For example, it may be worthwhile to consider the content of health messages and the way that this interacts with self-affirmation. One study examined the strength of a message related to the risk of fibrocystic disease (FBD) in those who consumed caffeinated beverages (Klein, Harris, Ferrer, & Zajac, 2011). The rationale was that if those who are self-affirmed are more likely to attend to messages and become sensitive to their strength, then self-affirmation should result in stronger inclinations to change behavior in response to strong messages. Messages of high strength about the link between caffeine consumption and fibrocystic disease cited reputable organizations and sources that supported the link; messages of low strength cited less well-known organizations and mentioned sources that did not support the link. Significant interactions between message strength and self-affirmation were found for feelings of vulnerability (i.e., worry) and intentions to reduce caffeine intake, such that these were higher in those who were self-affirmed and were exposed to the strong message. Furthermore, feelings of vulnerability were found to mediate the effect on behavior change intentions, suggesting that attention to message strength may be facilitated by self-affirmation's effect on worry.

An additional consideration in the effectiveness of self-affirmation is the characteristics (i.e., disposition, life history, or affect) of those who are exposed to health messages. Importantly, if individual differences do interact with self-affirmation's effects, examining only main effects may result in some important effects being obscured, if moderating effects are not examined (Düring & Jessop, 2015). For instance, people are continually exposed to conflicting health information in their everyday lives, and this can result in confusion and feelings of fatalism about such things as the causes of cancer (Niederdeppe & Gurmankin Levy, 2007). For individuals who perceive high levels of ambiguity about a health topic, health messages may be especially threatening because, in addition to the disconcerting nature of the information, any additional information may only increase this sense of ambiguity (Klein, Hamilton, Harris, & Han, 2015). Self-affirmation may be particularly useful in reducing defensiveness and facilitating receptivity to health messages in people who feel confused by health recommendations. This idea was tested in a study that exposed women with varying levels of risk and perceptions of ambiguity about the causes of cancer to a clear, unambiguous, and authoritative article describing the connection between high alcohol consumption and increased breast cancer risk (Klein et al., 2015). Self-affirmation increased message acceptance in those who perceived high levels of ambiguity in extant cancer prevention recommendations.

Although self-affirmation can be experimentally induced, people are also thought to exhibit tendencies to spontaneously self-affirm (Pietersma & Dijkstra, 2012). These tendencies are assessed by items such as “When I feel threatened or anxious, I find myself thinking about my strengths” (Harris, Napper, Griffin, Schuz, & Stride, in press, cited in Ferrer et al., 2015). Such tendencies have been found to moderate the relationship between anticipated (but not current) negative affect and intentions to obtain genetic test results for diseases that did not have any medically actionable precautionary measures, such as Huntington disease (Ferrer et al., 2015). Similarly, spontaneous self-affirmation and optimism moderated the tendencies of those who tend to avoid information to have lowered intentions to learn results for such diseases (Taber et al., 2015).

In addition to individual differences in the tendency to spontaneously self-affirm, another potential moderating variable of self-affirmation’s effects is self-esteem. To the extent that those with low self-esteem have fewer resources to draw upon when presented with messages that threaten the sense of self, self-affirmation may prove especially beneficial. Accordingly, those with low self-esteem who were affirmed had more positive attitudes toward behavioral change (increasing exercise), stronger endorsement of intentions to exercise, and lower levels of message derogation, but were no different in terms of behavioral control or actual behavior change (Düring & Jessop, 2015).

So, considering moderating characteristics of individuals or health messages is promising, and looking beyond main effects of self-affirmation can prove illuminating. Some further considerations include whether self-affirmation’s effects for those who perceive high levels of ambiguity extend to receptivity to, for instance, more ambiguous messages (Klein et al., 2015). Weaker messages may also be more ambiguous; for example, in the study cited above, the strong message read: “The link between FBD and breast cancer is well-established and FBD has been recognized as a breast cancer risk factor by the Centers for Disease Control and Prevention,” whereas the weak message read: “At a recent meeting of the American Academy of Osteopathic Medicine, a small group of dieticians with links to the fast food industry issued a formal statement supporting the link between FBD and breast cancer as well as the link between caffeine and FBD” (p. 1239). Given the potential effects of perceptions of ambiguity, it could be important to disentangle the effects of message strength and level of ambiguity.

Combining Self-Affirmation With Other Intervention Strategies

Another approach to expanding research on self-affirmation has been to combine self-affirmation with other health behavior change techniques. For example, implementation intentions ("if-then" plans that concretely specify how to reach a particular goal; Gollwitzer, 1999) are thought to be useful in channeling the motivation generated via self-affirmation into volition and actual behavior change (Jessop, Sparks, Buckland, Harris, & Churchill, 2014; van Dijk & Dijkstra, 2014). Accordingly, some research has begun investigating the effectiveness of incorporating this technique to enhance the effectiveness of self-affirmation.

Armitage and colleagues (Armitage et al., 2011; Armitage, Rowe, Arden, & Harris, 2014) developed a self-affirmation implementation intention intervention to reduce alcohol consumption in adolescents. Forming implementation intentions for alcohol consumption may help individuals plan appropriate behavioral responses when critical situations are encountered, such as being offered a drink. A goal in the design of this intervention was to affirm the self without essay writing or questionnaire elaboration, which depends on good verbal fluency, in order to make it more broadly implementable. Accordingly, participants completed the stem, "If I feel threatened or anxious, then I will…" with one of four options that involved thinking about things they valued in themselves, remembering things they have succeeded in, or thinking about things they stood for, before viewing a diagram depicting the body parts and conditions affected by alcohol consumption. In a first study, this briefer intervention was as effective as a more traditional self-affirmation manipulation and more effective than a control condition in reducing alcohol consumption 1 month later (Armitage et al., 2011), and, in a second study, more effective than a control condition 2 months later (Armitage et al., 2014).

Harris et al. (2014) examined the independent and synergistic effects of self-affirmation and implementation intentions with a 2 × 2 study design. There was a significant interaction between the two techniques at the 7-day but not the 3-month follow-up, such that self-affirmed participants who formed implementation intentions prior to being exposed to a message emphasizing the benefits of eating fruits and vegetables consumed significantly more. Conversely, however, in a series of two studies with a similar 2 × 2 design, combining self-affirmation and implementation intentions resulted in a *negative* effect on exercise behavior at 1 week (Jessop et al., 2014). The authors suggested that the counterintuitive finding may have stemmed from the combined techniques producing conflicting construal levels of the behavior or counteracting types of information processing.

Other research has examined whether self-affirmation interacts with aspects of the health message, such as the framing of health information in terms of gains or losses. One study tested the combined effects of self-affirmation and message framing on intentions to engage in indoor tanning (Mays & Zhao, 2016). Because indoor tanning, despite being a significant risk factor for skin cancer and melanoma, is believed to be related to the sense of self and feelings of attractiveness, self-affirmation was thought to be a particularly appropriate technique to prevent defensiveness to loss-framed messages. Loss-framed messages (that emphasize the costs of tanning) may be more threatening than gain-framed messages (that emphasize the benefits of not tanning). After completing a self-affirmation or a control task, participants viewed an image with an accompanying message that emphasized either the risks of indoor tanning or the benefits of avoiding indoor tanning.

For both intentions to indoor tan and intentions to quit indoor tanning, contrary to expectations, there was no interaction between the framing of the message and self-affirmation. In addition, although there were main effects for message framing, with loss-framed messages being more effective, the main effect for self-affirmation was only significant for intentions to tan, with those in the self-affirmation conditions reporting *stronger* intentions to tan. An explanation for this puzzling finding was suggested by the fact that self-affirmation led to perceptions of lower argument strength. The authors speculated that because indoor tanning is so tied to the self-concept, the self-affirmation manipulation could have increased the salience of the importance of indoor tanning and, thus, exacerbated defensiveness to the messages. This finding also brings attention to the notion that the type of target behavior, and its relevance to sense of self, may be an important consideration in self-affirmation research.

In a rare example of using self-affirmation techniques in clinical samples, patients with cardiopulmonary disease (angioplasty, hypertension, and asthma) were exposed to a positive affect and self-affirmation intervention, in addition to a patient education workbook that the control groups also received, in three randomized trials (Mancuso et al., 2012; Ogedegbe et al., 2012; Peterson et al., 2012). The self-affirmation induction involved thinking of something participants had done that they were proud of and the suggestion that reflecting on these could help them overcome challenges in engaging in a new health behavior. In this instance, the self-affirmation intervention was intended, in combination with techniques aimed to increase positive affect, such as thinking about small things that made them feel good, to overcome barriers to behavioral change rather than to reduce defensiveness to a message. Related to the point made earlier, the trials with different populations had somewhat different target behaviors, which also yielded different effects: in the angioplasty patients the intervention resulted in increased physical activity relative to the control group; in the hypertensive patients the intervention resulted in increased medication adherence relative to the control group; and in the asthmatic patients the intervention and control groups were no different in terms of physical activity. It is also important to note that, where the interventions were effective, the extent to which the effects can be attributed to the self-affirmation manipulation versus the components intended to create positive affect is not clear.

In sum, the emerging evidence regarding the combination of self-affirmation with other intervention techniques is mixed, such that the research on even the most commonly studied added technique, implementation intentions, shows both increases and decreases in effectiveness. However, the literature is diverse, with different target behaviors, study populations, follow-up time points, and even types of self-affirmation inductions, which may contribute to this lack of uniformity. Considering aspects of the message itself (e.g., framing) may be especially worthwhile, as these vary in the literature also, and, as most messages are framed either positively or negatively, giving explicit attention to this is worthwhile. Finally, some authors have pointed out that self-affirmation may play only a small role in the larger behavior change process, among other techniques, such as self-monitoring and identifying barriers, so continuing to consider its role in combined interventions is useful, despite the mixed evidence that has emerged thus far (van Dijk & Dijkstra, 2014).

Having highlighted some of the recent developments among studies of self-affirmation and health-related outcomes, we will now turn to discussing some of the major research questions that remain for future research.

How Does Self-Affirmation Lead to Health Behavior Change?

Although numerous studies have indicated that self-affirmation increases acceptance of health information and facilitates behavior change, surprisingly little is known about *how* it impacts health outcomes. To date, researchers have focused primarily on people's self-reported responses to health information as a source of potential mediators. For example, one possibility is that self-affirmation changes people's attitudes toward health information (e.g., by increasing perceptions of risk), which, in turn, leads to changes in health behavior. Although there is some preliminary evidence that an increase in perceived vulnerability mediates the effect of self-affirmation on behavioral intentions (Klein et al., 2011), other studies have found that neither attitudes toward the health behavior nor perceived threat (Armitage et al., 2014) mediates the effect of self-affirmation on health behavior.

Another possibility is that self-affirmation engenders a change in intentions, which, in turn, leads to a change in behavior. Supporting this prediction, one study found that among people who are at a higher risk for developing type 2 diabetes, intentions to take an online diabetes risk test mediated the effect of self-affirmation on risk test participation (van Koningsbruggen & Das, 2009). Other studies of self-affirmation, however, have failed to find a mediating effect of intentions on behavior change (Armitage et al., 2014). Further casting doubt on the viability of behavioral intentions as a mediator, several studies have found that self-affirmation does not always elicit a positive change in behavioral intentions (Harris et al., 2014; Reed & Aspinwall, 1998). Among studies of self-affirmation measuring both health intentions and behavior, one meta-analytic review found that intention effect sizes did not predict behavior effect sizes (Sweeney & Moyer, 2015), suggesting that a change in behavioral intentions does not translate to a comparable change in behavior. Taken together, limited research supports a causal intention–behavior relation among self-affirmation studies.

Whereas much of the extant research has focused on the role of single potential mediating variables, future research may examine whether self-affirmation influences health outcomes through multiple variables. Few self-affirmation studies have adopted a path analysis approach to examine whether a set of variables helps to explain the impact of self-affirmation on health behavior. One exception is by Armitage, Harris, Hepton, and Napper (2008) who found that health message acceptance mediated the relation between self-affirmation and intentions and intentions mediated the relation between message acceptance and behavior. Self-affirmation has been applied to health behaviors that vary across a number of dimensions, including the type of behavior (i.e., health promoting vs. health damaging) and the temporal impact of the behavior (i.e., immediate vs. distant consequences). Given this variability, in addition to the inherent complexities associated with long-term health behavior change, future research may consider adopting an analytic approach that examines a set of variables and takes into account variables specific to the targeted health behavior.

Another avenue for future research may involve testing mediating variables that extend beyond people's immediate self-reported responses to health information. Several studies have suggested that self-affirmation facilitates a broader perspective from which to view information (Critcher & Dunning, 2015; Sherman et al., 2013). For example, when people are self-affirmed, they are more likely to think about actions in terms of their abstract, superordinate aspects (e.g., why to improve one's health), rather than in terms of their concrete, subordinate aspects (e.g., how to improve one's health; Sherman et al., 2013).

In the context of health behaviors, a broader perspective may be helpful for several reasons. For example, threatening information may be experienced as less aversive when viewed from a distance (Sherman, 2013). Offering preliminary support for this prediction, one study tested whether thinking in broad (vs. narrow) terms would influence tanners' receptivity toward health information on the risks of tanning (Belding, Naufel, & Fujita, 2015). Tanners led to think that broad, superordinate categories were more motivated to reduce their risk of skin cancer than tanners led to think in narrow, subordinate categories. These authors suggest that thinking in broad terms promotes long-term self-change motivation, rather than short-term self-protection motivation. Relatedly, when a threat or temptation does not loom quite so largely, a broadened perspective may make it easier for people to exert self-control. Several studies have indicated that people are better at practicing self-control when led to think in broad (vs. narrow) terms, as evidenced, for example, by differences in preferences for healthy versus unhealthy foods (Fujita & Han, 2009).

Another possibility is that a broadened perspective helps people to connect their current actions to their long-term aspirations. Supporting this prediction, past research has found that construing information in broad (vs. narrow) terms facilitates attention toward one's long-term goals when faced with reminders of goal-related temptations (Fujita & Sasota, 2011). Such research suggests, for example, that a dieter who adopts a broader perspective may find it easier to bring to mind his or her dieting goal when faced with tempting food. Furthermore, other research has found that a broad (vs. narrow) perspective helps people to recognize the commonalities across their various life goals (Clark & Freitas, 2013). As a result, a broadened perspective may make it easier to connect a targeted health behavior (e.g., eating more fruits and vegetables) with one's long-term goals (e.g., living a long and happy life).

Having established that self-affirmation has the potential to be a useful tool for promoting health behavior change, an important next step for researchers is to develop an empirically supported mechanistic account of self-affirmation. Given that people's immediate self-reported responses to health information do not appear to mediate the effect of self-affirmation, future research may consider other ways in which self-affirmation impacts the self and the consequences this has for evaluation, motivation, and goal-directed action. Identifying the mechanisms that underlie self-affirmation effects may help to further refine self-affirmation theory as a whole and also offers important practical benefits, such as increasing understanding of the specific conditions under which self-affirmation is most effective.

What Is the Trajectory of Self-Affirmation?

Much of the research on self-affirmation and health has focused on the immediate changes that occur after self-affirming, such as changes in message acceptance. However, measures of people's deliberate responses to health information after self-affirming have yielded some inconsistent findings. As noted previously, for example, self-affirmation does not always lead to a positive change in behavioral intentions (e.g., Harris et al., 2014; Jessop et al., 2014). Similarly, other studies have failed to find a significant effect of self-affirmation on outcomes such as perceived behavioral control, perceived threat, message derogation, or self-efficacy (Armitage et al., 2008, 2014; Jessop et al., 2014). Although most studies have assessed whether self-affirmation elicits immediate changes in health-related cognitions, one recent study measured intentions and attitudes immediately after participants read a health message and again during a 1-week follow-up. There were no immediate differences in intentions and attitudes between the self-affirmation and control group; however, the self-affirmation group did express greater intentions and attitudes 1 week later.

Such findings may lead one to wonder whether self-affirmation elicits an immediate change or is the effect gradual? In a meta-analytic review Epton et al. (2015) found that self-affirmation exerts a smaller effect on outcomes that are measured immediately after encountering health information (i.e., message acceptance) than measures that typically involve some delay (i.e., behavior). Importantly, however, the time of measurement of a health behavior (e.g., days vs. weeks) has not been found to moderate the effect of self-affirmation on behavior (Epton et al., 2015; Sweeney & Moyer, 2015). Furthermore, as reviewed previously, a recent study using fMRI found that when people were self-affirmed, they engaged in greater self-related processing, as reflected through activity in the VMPFC, while reading health information (Falk et al., 2015). Additionally, neural activity during message processing predicted changes in health behavior that were distinct from changes predicted from participants' self-reports of behavioral intentions and attitudes. These findings suggest that self-affirmation enacts immediate effects on the self (as reflected through participant's neural activity) that relate to subsequent behavior change.

Taken together, self-affirmation appears to exert some immediate influences, as evidenced, for example, by studies showing that self-affirmation produces an immediate change in physiological responses to threat (e.g., Creswell et al., 2005) and in neural activity (e.g., Falk et al., 2015). However, the observed heterogeneity in people's self-reported responses suggests that self-affirmation may not elicit a change in health-related cognitions that can be reliably captured at a conscious level. That is, some of the influence of self-affirmation may occur outside of people's conscious awareness.

Increased attention is being given to understanding how health-related decisions are shaped by both conscious and unconscious processes (Sheeran, Gollwitzer, & Bargh, 2013). To date, relatively few studies have examined the implicit effects of self-affirmation in relation to health outcomes. One exception is Klein and Harris (2009) who used a dot probe task to examine whether self-affirmation enhances people's tendency to direct their attention toward threatening health information. After completing a self-affirmation or control task and reading a message about the risks of alcohol consumption, female participants completed a task in which a neutral and a threatening word from the health message were presented simultaneously and followed by a dot. Participants were asked to quickly identify whether the dot appeared on the left or right side of the screen. Self-affirmed participants were faster to identify the location of the dot when it appeared after a threat-related word, suggesting that self-affirmed participants displayed a stronger attentional bias for threat-related words than non-affirmed participants. Whereas other studies have used self-report measures to assess differences in perceived threat, this methodology allowed for a novel test of the extent to which self-affirmation elicits differences in implicit processing of health information.

Another exception is van Koningsbruggen, Das, and Roskos-Ewoldsen (2009) who used a lexical decision-making task to examine whether self-affirmation increases responsiveness toward health information at an implicit level. After completing a self-affirmation or control task and reading a message about the risks of caffeine, coffee drinkers and non-coffee drinkers completed a response time task that required them to distinguish between non-words, neutral words, and threat-related words (e.g., "heart disease"). Among coffee drinkers, those who self-affirmed were faster at recognizing threat-related words than non-affirmed individuals, suggesting self-affirmation increased accessibility of threat-related cognitions among people for whom the health message was most relevant.

These two studies provide initial support for the potential usefulness of implicit measures in studies of self-affirmation and health. In light of recent research suggesting that people may not always be able to reliably report on conscious changes that arise after self-affirmation, future research may consider adopting a framework that encompasses both conscious and unconscious processes. Increasingly health behavior change models are adopting a dual-systems approach that incorporates both reflective and automatic health-related processes (Sheeran et al., 2013). Whereas much of the extant research has focused on conscious changes arising from self-affirmation, future research is needed to further elucidate the nonconscious influences of self-affirmation.

Conclusions

Research on self-affirmation and health outcomes has grown extensively in recent decades. Building upon studies that highlighted the potential of self-affirmation as a tool for reducing defensive processing, numerous studies have been devoted to understanding the different types of health-related cognitions that are influenced by self-affirmation and any implication this may have for health behavior change. In this chapter, we highlighted three recent developments in this area of research including the adoption of a wide array of methodological approaches, emphasis on identifying moderating variables, and efforts to combine self-affirmation with other behavior change techniques. By drawing attention to the need for developing a mechanistic account of self-affirmation and the need to further our understanding the trajectory of self-affirmation, we hope this chapter will encourage future investigations of self-affirmation as a tool for health behavior change.

Author Biographies

Allison M. Sweeney is a postdoctoral researcher at the University of South Carolina. Integrating theories and methods across health, social, and cognitive psychology, her research focuses on developing theory-based interventions for promoting health behavior change.

Anne Moyer is an associate professor of social and health psychology at Stony Brook University. Her research focuses on psychosocial factors surrounding cancer and cancer risk, medical decision making, research methodology and research synthesis, and the psychological aspects of human research participation.

Stigma of Disease and Its Impact on Health

Lindsay Sheehan and Patrick Corrigan

Department of Psychology, Illinois Institute of Technology College of Science, Chicago, IL, USA

For people who experience chronic diseases and health conditions, stigma threatens to compound the physical and mental manifestations of illness, leading to unfavorable health and life outcomes. Particularly stigmatizing conditions such as HIV/AIDS (Farber, Shahane, Brown, & Campos, 2014), lung cancer (Chambers et al., 2015), irritable bowel syndrome (IBS; Taft, Ballou, & Keefer, 2013), drug addiction (Barry, McGinty, Pescosolido, & Goldman, 2014), and mental illness (Parcesepe & Cabassa, 2013) have been targets of research on the stigma of disease. This paper defines stigma types, explains various mechanisms by which stigma can impact health, and explores strategies for changing stigma.

Erving Goffman (1963) first described stigma as a discrediting mark that leads the stigmatized person to feel shame and hide the condition from others. More recently, four necessary components of stigma are described by Link and Phelan (2001). First, a stigmatized group or individual is recognized and labeled as different from others. Next, society perceives these differences as negative. Third, an "us" versus "them" (the stigmatized) mentality is established. Finally, the stigmatized person or group is subject to discrimination and loss of social power. Stigma may include stereotypes (thoughts), prejudice (feelings), and discrimination (unfair behaviors) toward individuals or groups from the stigmatizing condition. For example, a person with HIV may be stereotyped as careless, irresponsible, or morally inferior; may experience prejudice in the form of being feared by others; and may be discriminated against when family members avoid social contact. Stereotypes that comprise stigma are culturally created and disease specific, such that health conditions are connected with unique stereotypes that elicit specific prejudice and discrimination. The stereotype of incompetence in schizophrenia leads to discriminatory behavior such as employers not hiring them. When people with lung cancer are viewed as culpable in causing the illness through smoking, others will be less likely to provide help and support.

First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

Types of Stigma

Several types of stigma have the potential to impact health and are illustrated in Table 1. Thus far, we have described public stigma, the stigma that is perpetrated by members of the public toward the stigmatized individual. This stigma can impact the individual through direct experience ("experienced stigma") in which the person is treated in unfair ways such as being denied housing (Thornicroft et al., 2009). Public stigma also impacts individuals through mere knowledge or fear of the stigma that could be perpetrated against them ("anticipated stigma") (Thornicroft et al., 2009). In anticipated stigma, a person who experiences addiction worries how others will treat him or her if they know about the addiction. Stigmatized individuals may also self-stigmatize, whereby they internalize the public perceptions and believe that they really *are* as incompetent as society believes them to be (Corrigan, Watson, & Barr, 2006). The stigmatized individual may cognitively and emotionally give in to the "why try" effect, thinking that efforts toward improving health outcomes are futile ("I'm so stupid, why should I even bother taking my medications"). Not surprisingly, internalized stigma is linked to depression, low self-esteem, and reduced self-efficacy (Corrigan, Larson, & Rüsch, 2009).

Two other types of stigma are important to examine in the context of health psychology: associative stigma and structural stigma. If Fred's partner has HIV, Fred's employer might assume he has HIV as well and limit his career advancement opportunities. Sarah's mother might be judged as incompetent when Sarah is diagnosed with ADHD. In associative stigma, family members, friends, or other acquaintances are tarnished by stigma through their connections to the stigmatized individual. In response to associative stigma, family or friends may distance themselves from their loved one to avoid actual or perceived negative societal reactions. Associative stigma can also apply to health workers who treat stigmatized conditions (Verhaeghe & Bracke, 2012). Mental health workers who provide services to "those crazy people" experience less respect and social status than those working in other helping professions.

Table 1 Stigma types, definitions, and examples.

Type of stigma	*Definition*	*Example*
Public stigma	Unfair beliefs, attitudes, or behaviors directed at individuals or groups	Jasper finds out his neighbor Bob has schizophrenia. He feels scared and starts avoiding Bob
Experienced stigma	Stigma experienced by the individual, usually through discrimination	An employer refuses to hire a person with HIV
Anticipated ("felt") stigma	Stigma felt when stigmatized person fears negative reactions from others	Renee is worried about what others will think if she reveals her addiction
Internalized stigma/ self-stigma	Stigma that occurs when the stigmatized person agrees with and applies the public stigma to themselves	George feels he is just a worthless overweight person who does not deserve a girlfriend
Associative stigma	Stigma experienced by associates of the stigmatized group/individual (family, friends, acquaintances, service providers, etc.)	Ariel's sister is shunned by neighbors
Structural stigma	Stigma perpetrated through social systems or institutions, either intentionally or unintentionally	Funding for substance abuse treatment is substantially less than for other diseases

In some cases, whole systems fail a stigmatized group. Institutional policies that restrict opportunities of the stigmatized group result in structural stigma (Angermeyer, Matschinger, Link, & Schomerus, 2014). Structural stigma may be intentional, such as laws that limit parental rights of people with mental illness, or unintentional, such as inequalities in research funding for stigmatized conditions (Corrigan et al., 2005). In both instances, stereotypes and prejudices about the group—beliefs that people with mental illness are, for example, dangerous or incompetent—lead to discriminatory policies resulting in exclusion, restriction, or denial of rightful opportunities.

The Impact of Stigma

Disease stigma works through numerous mechanisms and has serious consequences for health. First, stigma has direct effects on psychological health: the experience of stigma is stressful. In a meta-analysis examining the connection between perceptions of discrimination and psychological well-being, average effect sizes in the small to medium range (overall $r = -.23$) were found with self-esteem, depression, anxiety, psychological distress, and life satisfaction (Schmitt, Branscombe, Postmes, & Garcia, 2014). Although chronic health conditions elicit stress and depression on their own, stigma-related distress and depression have been uncovered in people with HIV (Earnshaw, Smith, Cunningham, & Copenhaver, 2015), lung cancer (Chambers et al., 2015), and IBS (Taft et al., 2013).

Second, stigma interferes with care seeking. Affected individuals may engage in a process of label avoidance, whereby they forgo, delay, or minimally engage in treatment in order to elude the label of the condition ("I do not want to be seen walking into an HIV clinic!") (Corrigan, Druss, & Perlick, 2014). Although there are many reasons that people might not seek treatment, stigma is certainly a factor in preventing 40% of people with serious mental illness from engaging in care (Substance Abuse and Mental Health Services Administration [SAMHSA], 2012) and the 12% of people living with undiagnosed HIV (Valdiserri, 2002). Individuals might avoid entering treatment because of the stigma of diagnosis and in later stages of treatment might avoid visiting healthcare providers or following treatment regimen to prevent being seen by others. Associative stigma experienced by family members or close friends can make social support network unsupportive of treatment efforts and lead to early treatment dropout (Corrigan, Druss, et al., 2014). In addition, health providers can themselves engage in label avoidance. Medical residents, for example, have stigma-related concerns about addictions, mental health diagnoses, and STDs, such that 18% of residents delayed or avoided treatment for themselves (Dunn, Hammond, & Roberts, 2009).

Once sick individuals decide to seek treatment, quality of that treatment is also impacted by stigma (Harangozo et al., 2014). Stigma perpetrated by health providers is especially harmful when it creates a non-nurturing, coercive, or paternalistic environment that drives patients from care or restricts choices for treatment. Structural stigma leads to clinics that fail to train providers in the respectful and culturally competent practices, poor availability of services, lack of access to health insurance, or other hurdles in obtaining care. Taken together, these factors greatly influence decisions of individuals to stay in treatment.

Fourth, stigma influences illness, self-management, and treatment adherence. The distress associated with stigma can make comprehension of medical instructions and follow-up with healthcare recommendations more challenging. People who are preoccupied with stigma stress will have less cognitive resources available for adhering to treatment regimens (Major, Hunger, Bunyan, & Miller, 2014). When exposed to stigma, individuals have more difficulty self-regulating, including reduced information processing, sustained attention, and persistence on task (Richman & Lattanner, 2014). Also, label avoidance restricts access to self-management resources, and a desire to hide illness status can interfere with treatment. Fearing reactions from supervisors or coworkers, a person with HIV might avoid bringing medications to work. A person with mental illness or addiction will not be comfortable requesting time off work for treatment appointments when such requests would necessitate disclosure. Internalized stigma is another barrier to treatment self-management (Livingston & Boyd, 2010). Depression and lack of self-efficacy occur when a person self-stigmatizes, leading to lack of recovery efforts ("Why even go see a counselor? I'm just a worthless addict who will never recover"). In fact, adults with chronic illness who self-stigmatize or who have experienced stigma in the past from health workers expect future stigma-laden interactions, avoid care, and have a lower quality of life (Earnshaw & Quinn, 2012).

Stigma also harms people through the breakdown of social relationships. Acts of discrimination typically involve social avoidance, exclusions, or microaggressions that serve to damage relationships. Landlords are hesitant to rent to people with schizophrenia, friends avoid inviting the person with IBS out to dinner, or acquaintances use underhanded remarks to people with addiction ("you still cannot kick the habit, huh?"). These interactions chip away at personal relationships and social networks. The absence of social support during an already difficult period of illness causes further stress and limits social resources needed to engage in treatment (e.g., help driving to doctor appointment). Internalized or perceived stigma results in the person withdrawing from others due to feelings of worthlessness ("Now that I have lung cancer, I have only myself to blame, and no one should have to help me").

Finally, structural stigma has a broad influence on health outcomes. Disparities in research funding, programmatic funding, and insurance coverage for stigmatizing diseases such as mental illness and addiction create fewer quality treatment options that are less accessible for those that would use the services (Angermeyer et al., 2014). People with chronic illness and disability are too often institutionalized despite their capacity for independent living. Given adequate community supports and financial assistance, some individuals in skilled care facilities could live in more independent settings; however, a dearth of supportive services and transition services have continued the segregation of people with disabilities in nursing homes. Legislation and court decisions such as the Americans with Disabilities Act (1990) and Olmstead v. L.C. (1999) challenge structural stigma by mandating civil rights for people with disabilities to live and work in the community. Likewise, the Mental Health Parity Act (2008) and the Affordable Care Act have expanded insurance coverage for mental illness. However, insurance coverage concerns continue to plague people with mental illness and especially those seeking addiction treatment (Jones, Campopiano, Baldwin, & McCance-Katz, 2015).

Moderators of Stigma

Several factors moderate disease stigma, including perceived responsibility for illness, fear, and familiarity. Stigma is greater when the person is viewed as having responsibility for the onset of illness ("onset responsibility") or as having control over improving or ending the illness ("offset responsibility") (Weiner, 1995). People with HIV, addiction, and lung cancer are viewed as highly responsible for the onset of the illness, whereas those with addiction are seen as responsible for both onset and offset (Corrigan et al., 2002). Obesity, while not a disease in itself, is a highly stigmatizing condition with high perceived responsibility both for onset and offset. Conditions such as heart disease and diabetes that have been connected with obesity and are seen as preventable also have high perceived responsibility on the part of the affected person.

Greater stigma results when the public views the particular groups as dangerous. For example, people with mental illness are seen as dangerous and unpredictable, resulting in public fears and discrimination (Janulis, Ferrari, & Fowler, 2013). Fear of contagion is also a factor in stigma related to illness such as in H1N1 influenza and SARS (Williams, Gonzalez-Medina, & Le, 2011), potentially leading to ostracism and reduced opportunities for treatment.

Familiarity may be inversely related to stigma (Broussard, Goulding, Talley, & Compton, 2012). Those who have personally experienced the disease, who have a family member with the disease, or who are otherwise familiar with the disease tend to perpetrate less stigma. When community members or family members have a personal connection, they can see the impacted individual as a person, rather than as a member of the stigmatized group. Stigma is especially harmful however when it is perpetrated by family and close friends, as it reduces the person's social and economic resources.

Combating Stigma

Research linking familiarity with stigma is the basis for anti-stigma interventions that use education about disease and contact with impacted individuals to change attitudes and behaviors toward the stigmatized group. Educational interventions provide information that counteracts stigmatizing attitudes (e.g., Power Point presentation outlining myths about mental illness), whereas a contact intervention involves an interaction between a person with the illness and those in the intervention condition (e.g., person with HIV gives presentation about personal experience with HIV stigma). In adults, anti-stigma programs that promote meaningful contact between people impacted by the disease and members of the public seem most powerful. A meta-analysis examining stigma change interventions for people with mental illness found change effect sizes for changes in attitudes and intended behavior ranging from .1 to .3 (Corrigan, Morris, Michaels, Rafacz, & Rüsch, 2012). However, it is important to note that few studies have been able to capture actual changes in behavior that result from anti-stigma interventions.

Not all approaches are effective. In the mental illness literature, biogenetic explanations for illness were introduced to reduce stigma reducing the perceived responsibility of the person ("it's not the person with schizophrenia's fault that he's ill, it's a brain disorder"). However, this approach risks highlighting the differences between the stigmatized individual and society while downplaying possibilities for recovery. A meta-analysis found that biogenetic explanations for mental illness were associated with less blame but that perceptions of dangerousness were greater and that the public desired more social distance from people with mental illness (Kvaale, Haslam, & Gottdiener, 2013).

Anti-stigma approaches that target health providers may improve health outcomes. These programs should ideally target all levels of health provider (physicians, nurses, dieticians, psychologists, case managers, etc.) and aim to reduce negative reactions as well as promote positive or affirming reactions toward people with a health condition (Sheehan, 2015). Whereas more traditional anti-stigma messages have attempted to reduce negative attitudes, advocates have called for more affirming messages focused on recovery and empowerment of the stigmatized person (Corrigan, Powell, & Michaels, 2014). Research on mental illness stigma interventions aimed at health providers find that those using both education and contact are effective (Stubbs, 2014).

Efforts to reduce internalized stigma (i.e., self-stigma) have focused on helping the stigmatized individual identifying the impact stigma has on his/her life and identifying ways to change personal reactions toward stigma. Interventions to enhance resistance to internalized stigma include peer support groups, peer education, and cognitive behavioral type interventions (Taft et al., 2013). Efforts to explicitly address internalized stigma have only recently begun to be tested, showing some potential for reducing the impact of stigma (Conner, McKinnon, Ward, Reynolds, & Brown, 2015).

In addition to stigma of the primary health condition, service providers must recognize and address multiple levels and types of stigma. Racial, ethnic, or sexual minority stigma can interact with and compound stigma related to the disease condition. Thus, health providers working in an HIV clinic should be sensitive to both stigma related to HIV and stigma related to sexual orientation. Health providers should understand cultural differences in disease-related stigma and the impact these have on minority patients. Latinos being treated for addiction have different cultural stigmas than do Blacks or Asians. An individualized approach that is sensitive to the complex needs of the person in treatment will help to better engage those of minority status.

Also of concern are co-occurring disease-related stigmas such as those of mental illness and obesity. Obesity stigma affects many individuals within the patient population, and stigma perpetrated by health providers can be a barrier to physical healthcare (Teixeira & Budd, 2010). The stress associated with obesity-related stigma is implicated in a cycle of increasing weight gain (Tomiyama, 2014), and internalized obesity stigma is recognized as an important concern (Ratcliffe & Ellison, 2015). Recognition of various types of stigma (public, internalized, associative, and structural) points healthcare providers to specific solutions for addressing each.

Conclusion

Primary prevention, early intervention, and prevention of physical deterioration and impact are primary concerns of health psychology (Boyer, 2008). Stigma affects the individuals on all of these levels by increasing vulnerability to psychological problems, creating barriers to care seeking, reducing quality of care, reducing self-management capabilities of the patient, and compromising social support systems. While interventions to combat stigma exist, these can be more thoroughly and systematically implemented and tested throughout the healthcare system.

Author Biographies

Lindsay Sheehan is a senior research associate at the Illinois Institute of Technology where she conducts research on mental illness stigma, suicide stigma, and health disparities for individuals with serious mental illness. She is a managing editor of the American Psychological Association journal, *Stigma and Health*. Dr. Sheehan is also a licensed counselor and has experience working in community mental health.

Patrick Corrigan is a distinguished professor of psychology at the Illinois Institute of Technology. Dr. Corrigan leads the National Consortium on Stigma and Empowerment

(NCSE), which focuses on increasing self-determination and empowerment for people with psychiatric disability. Dr. Corrigan has written more than 300 peer-reviewed articles and is an editor of *Stigma and Health*. Corrigan has authored or edited 15 books, most recently, *The Stigma of Disease and Disability*.

Alcohol Use Disorder: Overview

Brittany E. Blanchard, Angela K. Stevens, Molin Shi,
and Andrew K. Littlefield

Department of Psychological Sciences, Texas Tech University, Lubbock, TX, USA

Definitions of Alcohol Use Disorder

Initially, alcohol use disorder (AUD), labeled *alcoholism*, was classified under the personality and other nonpsychotic disorders sections in the first two editions of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*), and this personality-based conceptualization of AUDs remained prominent in mental health until 1980 (American Psychiatric Association [APA], 1980). Although the disease concept of alcoholism, which led to the medicalization of this disorder, appeared in 1956 (see Jellinek, 1960), it was not until the third edition of the *DSM* that "alcoholism" was replaced with alcohol abuse and dependence and was moved to the substance use disorder section (APA, 1980). These changes, in part, reflected the conceptualization of alcohol dependence syndrome (see Edwards & Gross, 1976).

Recently, the fifth edition of the *DSM* drastically changed the classification of alcohol-related diagnoses (and other substance use disorders). In addition to abolishing the biaxial system in favor of single *AUD,* which combines abuse and dependence criteria, critical changes to criteria were made based on research conducted since the publication of DSM-IV (e.g., removal of legal issues and addition of craving; APA, 2013; see Hasin et al., 2013). Under *DSM-5* criteria, an individual must exhibit at least 2 of the 11 criteria in the past year (i.e., briefly, hazardous use, difficulty quitting, social/occupational problems, tolerance, withdrawal, drinking for larger/longer than intended, great deal of time spent obtaining/using/recovering from alcohol, craving, failure to fulfill role obligations, continued drinking despite interpersonal/social problems, continued drinking despite psychological/physical problems; see APA, 2013), and these symptoms must yield significant distress and/or impairment for diagnosis (APA, 2013, p. 491). A severity specifier allows clinicians to rate severity of the AUD based on a symptom count (APA, 2013).

Because only one symptom was necessary to establish an alcohol abuse diagnosis in *DSM-IV* (APA, 2000), the latest criteria change (i.e., 2+ symptoms required) may improve diagnostic

First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

reliability and validity by reducing the number of diagnostic imposters (Lane & Sher, 2015). Although the newest edition of the *DSM* has made great improvements in classification of individuals with AUD for clinical and research purposes, several limitations remain (e.g., varying severity among symptoms, disregard for symptom constellations; see Lane & Sher, 2015). One proposal to rectify this issue is to require both harm (e.g., presence of alcohol-related problems) and dysfunction (e.g., presence of either compulsive use or withdrawal) to make an AUD diagnosis (Wakefield & Schmitz, 2015).

Prevalence of AUDs

Based on data from the 2012 to 2013 National Epidemiologic Survey on Alcohol and Related Conditions III, a representative US noninstitutionalized civilian sample of adults 18 years or older, the lifetime and 12-month prevalence of *DSM-5* AUD were 29.1 and 13.9%, respectively (Grant et al., 2015). Both lifetime and past-year rates of AUD were highest among males, White and Native American individuals, and younger, never married, or previously married adults (Grant et al., 2015). Normatively, the prevalence of AUD and levels of heavy, problematic alcohol use peak in the early 20s and decline thereafter into later adulthood, although heterogeneity exists in trajectories of alcohol outcomes (see Chassin, Sher, Hussong, & Curran, 2013).

Etiological Influences

A myriad of theoretical conceptualizations that attempt to explain the mechanisms responsible for the onset, maintenance, and relapse processes of AUD have been proffered (e.g., Cox & Klinger, 1988; Sher, Grekin, & Williams, 2005). Extant literature highlights multiple etiological pathways for problematic alcohol involvement. Importantly, different pathways are not mutually exclusive, and there is potential for both additive and superadditive effects (see Sher, Martinez, & Littlefield, 2011, for a detailed review). Most widely accepted models in research and clinical work utilize the biopsychosocial framework, which posits that biological (e.g., genetics, neuroadaptation, pharmacological vulnerability; see Kendler, Myers, & Prescott, 2007; Sher, Trull, Bartholow, & Vieth, 1999; Volkow, Koob, & McLellan, 2016), psychological (e.g., expectancies, motives, personality; see Jones, Corbin, & Fromme, 2001; Kuntsche, Knibbe, Gmel, & Engels, 2005; Littlefield & Sher, 2014), and social factors (e.g., parental and peer influences; Nash, McQueen, & Bray, 2005) contribute to the onset and maintenance of AUD (Marlatt, Baer, Donovan, & Kivlahan, 1988). For example, the motivational model of alcohol use postulates that historical factors (biochemical reactivity, personality, and sociocultural factors), current factors (current affective state and alcohol availability), and alcohol-related expectancies interact to affect decision-making processes regarding alcohol consumption (Cox & Klinger, 1988). Diathesis–stress models (including genetic diathesis; see Dick et al., 2008) propose that individuals have biological and/or psychological vulnerabilities, which trigger the onset of AUD in the face of stressful life events (Goldstein, Abela, Buchanan, & Seligman, 2000). Supporting this model are findings from gene–environment interaction research, which suggests that individuals with specific genetic variants develop AUD only under certain environmental conditions (Caspi & Moffitt, 2006).

Social cognitive theories of alcohol use integrate psychological factors (e.g., cognitive expectancies, drinking refusal self-efficacy, drinking motives) and social environmental influences (e.g., parental and peer alcohol use) to predict alcohol consumption and AUD development

(Cooper, Russell, & George, 1988; Giovazolias & Themeli, 2014). The deviance proneness model (Sher et al., 1999) suggests that substance use behavior is a facet of a general pattern of deviant behaviors (i.e., heterotypic continuity; Moffitt, 1993). In addition to the genetic vulnerability of externalizing behaviors in childhood, these behaviors are also thought to be a result of environmental factors such as inadequate socialization and/or associating with a deviant peer group. In sum, multiple integrative models exist within the literature, the most comprehensive of which include examination biological, psychological, and sociocultural/environmental factors in considering etiological pathways to AUD, as well as alcohol consumption, more broadly.

Definitions of Alcohol Consumption

Alcohol consumption is necessary to experience alcohol-related problems and receives a diagnosis of AUD, yet this is not assessed in the *DSM-5* or *the International Classification of Diseases* (*ICD-10;* World Health Organization, 1992). Despite exclusion from formal criteria for AUDs, alcohol quantity, frequency, and "binge drinking" are typically assessed. Although there are discrepancies in definitions of binge drinking (also called heavy episodic drinking), the current standard is the National Institute on Alcohol Abuse and Alcoholism (NIAAA) definition, which is five or more standard drinks for males and four or more standard drinks for females, over approximately 2 hr. This pattern of consumption increases blood alcohol concentration (BAC) to roughly 0.08 g/dL, the legal limit in the United States (NIAAA, 2004). Other definitions include that of the Substance Abuse and Mental Health Services Administration (SAMHSA), which defines binge drinking as more than five drinks per occasion, with heavy drinking defined as binge drinking on 5 or more days within the past month (Center for Behavioral Health Statistics and Quality, 2015).

Acute Effects of Alcohol Consumption

Effects of acute alcohol consumption can range from increased talkativeness and relaxation to clumsiness, to, at higher levels of intoxication, respiratory depression, and even death (see Vonghia et al., 2008). Broadly, effects tend to vary as a function of BAC with more severe effects occurring at higher levels of BAC. For example, relaxation is typically experienced by individuals with a BAC of less than 0.05 g/dL, whereas symptoms like respiratory depression and coma occur at BACs of 0.40 g/dL and higher (Vonghia et al., 2008). Although BAC typically increases with consumption, an individual's BAC depends on a number of factors affecting bioavailability, such as genetics, biological sex, eating prior to the drinking episode, and alcohol tolerance (e.g., Ramchandani, Bosron, & Li, 2001). Regardless, within a given drinking episode, an individual will typically experience both stimulant-like and depressant-like effects, due to alcohol's biphasic effects (i.e., stimulant-like effects on the ascending limb of the blood alcohol curve and depressant-like effects on the descending limb). However, the experience of these effects also varies as a function of individual differences (e.g., alcohol use status; King, De Wit, McNamara, & Cao, 2011).

Acute alcohol consumption can impact a number of physiological functions, which can influence health outcomes. For example, evidence suggests that alcohol consumption often yields increases in appetite and food consumption (Yeomans, 2010). Although evidence is mixed regarding the effects of alcohol intake on sexual arousal, research indicates a decrease in genital arousal, including decreased penile tumescence (see George & Stoner, 2000). Contrary to popular belief, consuming alcohol before bed may negatively impact sleep; more specifically, alcohol appears to delay the onset of rapid eye movement (REM) sleep and increase disruption in the second half of sleep (see Ebrahim, Shapiro, Williams, & Fenwick, 2013). Many individuals also experience hangovers after consuming alcohol, which may include symptoms such as headache, nausea, vomiting, diarrhea, fatigue, and decreased motor and cognitive functioning (Wiese, Shlipak, & Browner, 2000). In some cases hangover may negatively impact or prevent performance of work-related responsibilities.

Higher doses of alcohol (i.e., BAC of approximately 0.10 g/dL or higher) can impair reaction times and decision making (Vonghia et al., 2008), resulting in an increased chance of risky sexual behaviors, sexual assault, physical injury, homicidal and suicidal behaviors, and motor vehicle accidents (Cooper, 2002; see George & Stoner, 2000). Indeed, the National Highway Traffic Safety Administration (U.S. Department of Transportation, National Highway Traffic Safety Administration, 2015) estimates that approximately 28 people die each day in the United States in alcohol-related motor vehicle accidents. In sum, at lower doses, alcohol typically produces rewarding effects, such as relaxation and reductions in anxiety, whereas higher doses yield depressant-like effects and increase the risk of alcohol-related consequences. In light of this evidence, to maximize the short-term effects of alcohol and minimize consequences, it is recommended that individuals consume alcohol in a manner consistent with the 2015–2020 Dietary Guidelines for Americans, which defines moderate consumption as no more than two drinks per day for men and one drink a day for women of the legal drinking age, with some exceptions (e.g., those taking certain medications or with certain conditions, pregnant or breastfeeding women; US Department of Health and Human Services and US Department of Agriculture, 2015).

Author Biographies

Brittany E. Blanchard is currently a PhD student in clinical psychology at Texas Tech University in the Department of Psychological Sciences. Her research examines individual differences in alcohol and substance use, including use of protective behavioral strategies.

Angela K. Stevens is currently a PhD student in clinical psychology at Texas Tech University in the Department of Psychological Sciences. Broadly, her research interests include individual differences in adult problematic substance use.

Molin Shi is currently a PhD student in clinical psychology at Texas Tech University in the Department of Psychological Sciences. Her research focuses on the influences and consequences of substance-related behaviors, with an emphasis on the familial, social, and acculturative impact of substance use in minority subgroups.

Andrew K. Littlefield is currently an assistant professor at Texas Tech University in the Department of Psychological Sciences. He obtained his predoctoral training in clinical psychology at the University of Missouri and completed his clinical internship at the University of Mississippi Medical Center. Dr. Littlefield's research focuses on addictive behaviors.

Introduction

Cancer is a collection of diseases characterized by uncontrolled division of abnormal cells. In the United States, cancers of the prostate and breast are the most common cancer sites in men and women, respectively. Lung and colon/rectum cancers are the second and third most common cancers in both sexes. More than 15.5 million cancer survivors are living in the United States today; this figure is projected to rise to more than 20 million by 2026 (American Cancer Society, 2017). Treatment for cancer varies but often includes surgery to remove the tumor, chemotherapy, radiation, targeted biologic therapy, and/or hormonal therapy. Treatments can cause immediate and long-term side effects including pain, nausea, fatigue, sleep disturbance, and infertility.

Cancer mortality has declined 25% over the past two decades, primarily as a result of decreased tobacco use and improvements in cancer prevention, early detection, and treatment (American Cancer Society, 2017). Despite this trend, cancer remains the second leading cause of death in the United States, accounting for approximately 25% of all deaths, and lung cancer is the leading cause of cancer mortality in women and men. Furthermore, although cancer survival has improved overall, racial/ethnic and socioeconomic disparities in cancer deaths remain. US cancer death rates are higher in African Americans than any other racial or ethnic group. Among African Americans, rates of death from cancer are 24% higher in men and 14% higher in women compared with non-Hispanic White men and women (American Cancer Society, 2017). Causes of disparities include a complex combination of economic, sociocultural, biological, environmental, and system-level factors. Contributors to higher cancer death rates among racial/ethnic minorities and economically disadvantaged individuals include inequalities in education, income, wealth, work, housing, and barriers to receiving high-quality cancer-related healthcare services (American Cancer Society, 2017).

The Wiley Encyclopedia of Health Psychology: Volume 3: Clinical Health Psychology and Behavioral Medicine,
First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

As people live longer after cancer diagnosis, psychosocial concerns and quality of life among cancer survivors become an increasingly important focus of research and clinical attention. Research in the field of psycho-oncology examines (a) behavioral and psychosocial factors in the initiation and progression of cancer, (b) factors influencing adherence to cancer screening recommendations for early detection, (c) the biopsychosocial experience and trajectory of psychosocial adjustment to cancer, and (d) predictors of psychosocial adjustment to cancer (Holland et al., 2015). Research in psycho-oncology is also dedicated to developing and implementing psychosocial and behavioral interventions to promote health and well-being following cancer diagnosis (see *Cancer and Psychosocial Interventions* entry). Reviews of the literature suggest that these interventions, which include approaches such as cognitive behavioral therapy, relaxation, coping skills training, and supportive-expressive therapy, are effective in improving psychological functioning, fatigue, pain, and other psychological and physical health outcomes (e.g., Faller et al., 2013). This article focuses on adults with cancer; for information regarding the unique needs and concerns of children with cancer, refer to the *Childhood Cancer* entry.

Behavioral and Psychosocial Factors in the Initiation and Progression of Cancer

Behavioral factors are implicated in both cancer initiation (i.e., development of cancer in individuals with no previous tumor) and progression (i.e., cancer growth and/or spread in patients with existing disease). Indeed, more than half of cancer cases worldwide could be prevented by reducing known risk factors, most of which are behavioral (American Association for Cancer Research, 2017). Behavioral risk factors for the development of cancer include tobacco use, obesity, poor-quality diet, physical inactivity, excessive alcohol intake, risky sexual behavior, and insufficient sun protection (Spring, King, Pagoto, Van Horn, & Fisher, 2015). Although risk factors vary by cancer type, known behavioral factors associated with cancer progression, recurrence, and/or mortality include obesity, physical inactivity, poor-quality diet, tobacco use, and nonadherence to recommended cancer treatments (Gillison et al., 2012; Hershman et al., 2011; Rock et al., 2012). Cancer survivors are advised to achieve or maintain a normal weight, exercise regularly, stop smoking, and eat a healthy diet, which have the potential to improve prognosis (Brandon, Unrod, & Simmons, 2015; Rock et al., 2012).

Researchers in psycho-oncology seek to develop effective interventions to reduce the risk of cancer initiation and improve outcomes following cancer diagnosis. Interventions can target multiple levels of influences on behavior, from public policy initiatives to changing sociocultural contexts and intervening on an individual level (Spring et al., 2015). The reduction in tobacco use in the United States over the past several decades, for instance, is largely attributable to public policy and environmental interventions such as anti-smoking campaigns, clean indoor air laws, and price deterrents. Effective individual-level interventions for quitting smoking also exist, including behavioral counseling, social support, and pharmacotherapy. Despite effective interventions to reduce smoking prevalence, tobacco use remains responsible for nearly one-third of cancer deaths in the United States each year, and cancer deaths related to tobacco use continue to climb in low-income countries (American Cancer Society, 2017).

Historically, it was believed that individuals with particular personality types were more likely to develop cancer. However, no psychological factor has been demonstrated to promote the initiation of cancer (Lutgendorf & Andersen, 2015). The majority of research examines the role of psychosocial factors in the progression, rather than initiation, of cancer. Factors implicated in cancer progression include depression, distress, trauma history, and social isolation (Lutgendorf & Andersen, 2015). Psychological research has identified plausible mechanisms through which these factors may promote disease progression. For instance, psychosocial stressors can trigger activation of the autonomic nervous system (ANS) and the hypothalamic–pituitary–adrenal (HPA) axis, causing release of stress hormones such as catecholamines and glucocorticoids. Over time, chronic activation of these physiological systems can impair immune functioning and promote inflammation, which has been shown to promote tumor growth, particularly in nonhuman animal models (Lutgendorf & Andersen, 2015). Research is needed to better understand the pathways through which biopsychosocial factors might contribute to tumor initiation, growth, and spread.

Screening for Early Detection of Cancer

Early detection of cancer can improve treatment outcomes and survival. Indeed, cancer screening has contributed to a major public health advance against cancer over the past three decades. The US Preventive Services Task Force (USPSTF) issues recommendations for cervical, breast, and colorectal cancer screening based on age and gender. In issuing screening recommendations, experts must weigh the clear benefits of cancer screening (i.e., early cancer detection and intervention) against potential risks of screening.

Most individuals who are screened for cancer do not have, and will never develop, the disease. Risks of screening large swaths of the population include psychological distress and physical health consequences from follow-up investigations associated with false positives, radiation exposure from screening, and overdiagnosis (i.e., identification of pathology that is nonprogressive but is indistinguishable from progressive disease and therefore treated as progressive; Wardle, Robb, Vernon, & Waller, 2015). For instance, many prostate cancers progress so slowly that they are unlikely to cause harm within a man’s lifetime. Early identification of prostate cancer typically prompts treatment, which can cause important untoward side effects. Based on findings from randomized controlled trials, the USPSTF recently recommended against prostate cancer screening through prostate-specific antigen (PSA) testing after concluding that the risks of screening for prostate cancer through PSA measurement outweigh the benefits.

Adherence to cancer screening recommendations is suboptimal, although rates have improved over the past several decades. In 2013, 73% of American women reported mammography, and 81% reported undergoing cervical screening within the recommended period. Only 58% of women and men were up to date with colorectal cancer screening (Sabatino, White, Thompson, & Klabunde, 2015). Rates of cancer screening in the United Kingdom, which are based on national databases and therefore not subject to biased reporting, are similar (Health and Social Care Information Centre, 2013a, 2013b).

Documented barriers to cancer screening include both contextual and individual factors. Contextual factors include absence of a regular physician and/or health insurance, failure of physicians to recommend screening, language barriers, low education, and low social support for screening (Wardle et al., 2015). For these and other reasons, disparities in rates of cancer screening exist: in the United States, individuals of low socioeconomic status and Hispanic Americans are less likely to be up to date with screening than are more advantaged and non-Hispanic White Americans.

Individual-level factors that predict low rates of cancer screening include lack of knowledge about cancer and cancer screening, low perceived risk of cancer, fatalistic beliefs that cancer is incurable, and perception that screening behavior is outside the social norm (Wardle et al., 2015). Research to examine the relationship between worry about cancer and likelihood of undergoing cancer screening is mixed (Hay, Buckley, & Ostroff, 2005). Some studies demonstrate a link between cancer-related worry and higher screening behavior, whereas others find that cancer-related worry predicts lower uptake of screening. The relation between cancer worry and participation in screening may be nonlinear, such that moderate worry facilitates screening, whereas high and low levels of worry inhibit screening (Wardle et al., 2015).

To improve adherence to screening recommendations, many interventions have targeted structural and organizational, rather than individual or psychological, barriers. These strategies include improving access to healthcare, facilitating the establishment of regular relationships with physicians, and implementing public health campaigns to promote awareness about the benefits of early detection through screening. Other effective approaches for improving participation in screening for breast, cervical, and colorectal cancer include reminders for screening and one-on-one education.

Psychosocial Adjustment to Cancer

Cancer is a profound stressor that can cause significant declines in physical, emotional, and social functioning. Most people diagnosed with cancer adjust well, however. Although prevalence estimates of depression and anxiety following cancer diagnosis vary across studies, meta-analyses (e.g., Mitchell et al., 2011) suggest that more than one-third of cancer patients meet diagnostic criteria for depression, anxiety, or an adjustment disorder.

Adjustment Across the Cancer Trajectory

Longitudinal research reveals commonalities in experiences and adjustment along the continuum of the cancer trajectory, from diagnosis to long-term survivorship and/or end of life. Shortly after cancer diagnosis, anxiety is common as patients are faced with uncertainty regarding treatment options and must make difficult decisions related to treatment (Stanton & Bower, 2015). Individuals may also face challenges as they arrange for changes in employment and other life roles.

During active oncologic treatment, many patients experience significant negative side effects such as pain and fatigue (Jacobsen & Andrykowski, 2015). Other common side effects of cancer treatment include sleep disturbance, nausea, and cognitive impairment. Patients also can face challenges in communicating effectively with their medical team and their interpersonal network. During treatment, patients may feel too tired to keep family and friends updated on their health status or feel hesitant to ask for help. Many patients also must navigate changes in work and other responsibilities as they undergo treatment.

During the reentry phase (i.e., the months after primary medical treatment is completed), challenges often include resuming work, familial, and social roles despite persistent or late-emerging side effects of treatment (Stanton, Rowland, & Ganz, 2015). Fatigue, for instance, is a long-term consequence of cancer and its treatment for some. Patients can experience a sense of abandonment from the medical team and other sources of support. Fear of cancer recurrence is also common during the reentry phase. Long-term survivors may have problems with employment, enduring and late-emerging side effects of treatment, and lasting concerns about future health (Institute of Medicine [IOM], 2005).

Cancer recurrence and diagnosis of metastatic disease (i.e., cancer that has spread to distant organs) present a host of challenges for patients and their loved ones (Rainbird, Perkins, Sanson-Fisher, Rolfe, & Anseline, 2009). Metastatic cancer is usually life limiting. Treatment is often intensive and variable over time. Patients with advanced disease may face compromised role functioning and concerns about losing independence and burdening their loved ones. Patients with metastatic disease must also make difficult treatment-related decisions, which can include determining when to end treatment and prepare for the end of life.

Characterizing the Experience of Cancer

Despite the challenges associated with a diagnosis of cancer, most survivors report finding benefit in the cancer experience (Stanton et al., 2015). Facets of benefit finding, also known as posttraumatic growth, include strengthened interpersonal relationships, enhanced life appreciation, greater focus on life priorities, and a deepened sense of spirituality. Although findings are inconsistent, research suggests that finding benefit can promote improved psychological adjustment among cancer patients, with enduring effects in long-term survivorship (e.g., Bower et al., 2005).

Research also documents the challenges and distress that partners, family members, and friends of cancer patients experience. During the continuum of the cancer experience, caregivers assume varied responsibilities such as assisting patients with activities of daily living, coordinating medical care, providing emotional support, and gathering information. Rates of depression and anxiety among caregivers of patients with cancer are comparable with, or higher than, those of cancer patients themselves (e.g., Hagedoorn, Sanderman, Bolks, Tuinstra, & Coyne, 2008; Sklenarova et al., 2015). A majority of caregivers have unmet needs for support, particularly with regard to addressing fears about the patient's condition, obtaining adequate disease- and treatment-related information, and receiving emotional support for themselves (Sklenarova et al., 2015; see *Caregivers* entry).

Although many cancer patients adjust well and do not demonstrate significant deterioration in mental health, wide individual variability exists. Longitudinal studies have identified four distinct trajectories of psychological adjustment to breast cancer diagnosis (e.g., Henselmans et al., 2010). In these studies, about one-third of individuals experienced no distress throughout diagnosis and treatment. Another third showed a pattern of recovery, wherein patients experienced distress during diagnosis and active treatment, followed by a significant decrease in distress after completing treatment. A smaller group (15%) evidenced an increase in distress shortly after treatment completion (during the reentry phase). Finally, a small but notable group of individuals experienced unremittingly high distress throughout diagnosis, treatment, and beyond.

Predictors of Psychosocial Adjustment to Cancer

Specifying risk and protective factors for psychosocial adjustment to cancer builds on our understanding of trajectories of adjustment and can help identify individuals who could benefit from intervention. To this end, longitudinal research has identified demographic, cancer-related, psychosocial, and interpersonal factors associated with adjustment to cancer.

Demographic risk factors for poor psychosocial adjustment to cancer include younger age, Latino ethnicity, and low socioeconomic status (Stanton & Yanez, 2013). Chemotherapy receipt is associated with less favorable physical adjustment (Ganz, Kwan, Stanton, Bower, & Belin, 2011). Research examining the association between advanced cancer stage and psychological adjustment has yielded mixed results; research is needed to characterize the relationship between cancer stage and emotional functioning and identify potential moderators of the relationship. Personality attributes such as optimism and mastery (i.e., perceived control) are associated with more favorable adjustment, whereas neuroticism is related to poor adjustment (Henselmans et al., 2010). Negative expectancies about cancer-related outcomes contribute to increased distress.

Cancer-specific coping processes are important predictors of psychological adjustment to cancer (Stanton & Bower, 2015). Coping through approach-oriented strategies, which include emotional expression, problem solving, seeking social support, positive reappraisal, and active acceptance, predicts better psychological adjustment. Conversely, coping through avoidance of thoughts and feelings regarding cancer predicts increases in distress. Social factors also influence psychological adjustment to cancer (Michael, Berkman, Colditz, Holmes, & Kawachi, 2002). Social isolation, perceived loneliness, and lack of interpersonal support are associated with compromised adjustment.

These risk and protective factors may also influence physical health and functioning (e.g., fatigue, pain, sleep disturbance) during and after cancer. Continued research is needed to examine factors that predict both psychological and physical functioning. Research in this area will inform targeted interventions to prevent depression, anxiety, and other negative sequelae by addressing individual risk factors.

Directions for Future Research

Much of the research in psycho-oncology is composed of studies of well-educated, non-Hispanic White women with early-stage breast cancer. Research is needed using diverse samples with various cancer diagnoses and underserved groups including those with advanced cancer, socioeconomically disadvantaged individuals, and racial/ethnic minorities. Furthermore, although the majority of people with cancer are older adults, research in psycho-oncology largely focuses on middle-aged and younger adults. Research findings may not apply to older individuals with unique needs and concerns including multiple comorbid conditions, loss of independence, and pronounced side effects of treatment.

Despite the documented psychosocial needs and concerns of cancer patients, psychosocial support is not routinely provided to patients as a component of their oncology care (IOM, 2013). Recognizing the importance of psychosocial care for individuals with cancer and implemented in 2015, the American College of Surgeons Commission on Cancer (CoC) mandated universal psychosocial distress screening for cancer patients as a new patient care standard for CoC-accredited cancer programs (American College of Surgeons Commission on Cancer, 2012). Psychologists are well positioned to conduct research and make recommendations regarding appropriate screening measures, as well as to develop and disseminate evidence-based interventions for patients who screen positive for distress (see *Assessment in Health Care Settings* entry). It will also be critical for psychological researchers to investigate the potential benefits of integrated oncologic care such that patients' psychosocial needs are addressed within their existing network of cancer healthcare professionals.

Researchers in psychological science have increasing opportunities to form multidisciplinary collaborations with investigators in medicine, public health, and public policy to inform cutting-edge research and advance knowledge in the field of psycho-oncology. For instance, psychologists could assess patient-reported outcomes, including psychosocial and physical functioning, in clinical trials of new medical treatments for cancer. Psycho-oncology will benefit from adopting a biopsychosocial approach to investigate and address proactively the complex interplay of biological, intrapersonal, and interpersonal factors that influence cancer-related decision making and adjustment. A recent review regarding fatigue in cancer survivors, for example, exemplifies a biopsychosocial approach as it examines the demographic, medical, psychosocial, behavioral, and biological factors that influence cancer-related fatigue (Bower, 2014).

A recent Institute of Medicine report concluded that the cancer care system is unprepared to care for the growing—and aging—population of cancer survivors in the United States (IOM, 2013). Psychologists will have an important role—as both researchers and clinicians—in reducing the burden of cancer through prevention, early detection, and effective management of the challenges of cancer diagnosis, treatment, and posttreatment survivorship.

Author Biographies

Lauren N. Harris received her PhD in clinical psychology from the University of California, Los Angeles. Her research focuses on identifying risk and protective factors in adjustment to cancer and developing targeted interventions to improve psychosocial adjustment for cancer survivors. She is currently a postdoctoral fellow specializing in clinical health psychology at the West Los Angeles VA Medical Center.

Annette L. Stanton, PhD, is professor of psychology and psychiatry/biobehavioral sciences at the University of California, Los Angeles, and a member of the Jonsson Comprehensive Cancer Center. Her research centers on identifying contributors to biopsychosocial health in adults undergoing chronic stress, with a focus on the experience of cancer, and to translate findings into evidence-based interventions.

Ischemic Heart Disease, Depression, and Tobacco Smoking: Implications for Health Psychology

Allison J. Carroll

Department of Preventive Medicine, Northwestern University Feinberg School of Medicine, Chicago, IL, USA

Between the years 2009 and 2012, the prevalence of ischemic heart disease among US adults was estimated to be roughly 6% (Benjamin et al., 2017). High-quality evidence supports an association between ischemic heart disease and a number of behavioral risk factors, including tobacco smoking, physical inactivity, sedentary behavior, and poor diet. More recently, there has been a focus on how the development and progression of ischemic heart disease may be affected by psychological factors, including depression, anxiety, and hostility (Davidson, 2012; Kubzansky, Davidson, & Rozanski, 2005). Significant debate remains, however, regarding the nature of the association between these psychological factors and primary onset of ischemic heart disease, and many argue that the observed associations between psychological factors or personality traits and ischemic heart disease are purely moderated by one or more of the established risk behaviors for ischemic heart disease. This line of discovery provides an opportunity for health psychologists to assist in advancing the understanding and treatment of comorbid risk factors for both primary and secondary prevention of ischemic heart disease.

To illustrate the complex relationships between psychological conditions, behavioral risk factors, and ischemic heart disease, this chapter will provide an overview of the literature examining the interplay between depression, tobacco smoking, and ischemic heart disease. First, a brief discussion is provided regarding the measurement of ischemic heart disease. Second, the evidence supporting the association between depression and ischemic heart disease is outlined. Third, a description of the basis for evaluating the role of smoking in the association between depression and ischemic heart disease, and why depression and smoking are hypothesized to be synergistically associated with ischemic heart disease, is provided. The chapter concludes with an overview of the societal impact of this research and recommendations for health psychologists.

First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

Measuring Ischemic Heart Disease

There are many definitions of heart disease, but the focus of this chapter will be on ischemic heart disease (i.e., coronary artery disease or coronary heart disease). Ischemic heart disease most typically develops as a result of atherosclerosis, a buildup or blockage, in the coronary arteries that reduces blood flow to the heart. The reduction in blood flow to the heart may have consequences that range from minor physical discomfort, such as angina (chest pain), to death from myocardial infarction (heart attack). The primary reason for focusing specifically on ischemic heart disease (as opposed to cardiovascular diseases more broadly) is because coronary artery calcification (CAC), a subclinical measure that is largely specific to ischemic heart disease, has been the focus of available research studies assessing risk for primary ischemic heart disease.

CAC is the best available predictor of future cardiac events (Greenland et al., 2007). CAC is a measure of atherosclerosis, assessed by computed tomography to assess areas of calcium deposits in the coronary arteries. It is most often reported using Agatston scores, and many research studies simply report the presence of CAC (i.e., "detectable" CAC; Agatston score >0). In a 2007 report from the American College of Cardiology Foundation and the American Heart Association Task Force on Practice Guidelines, data compiled from 6 published studies with a total of 27,622 patients demonstrated that detectable CAC was associated with a 4.3-fold (95% confidence interval [CI]: 3.5–5.2) increase in the relative risk of a cardiac event over 3–5 years (Greenland et al., 2007). CAC scores are highly correlated with age, sex, and race/ethnicity, where older age, male sex, and White race are at highest risk for detectable CAC. For further information about the probability of detectable CAC by age, sex, and race/ethnicity, readers are referred to the Multi-Ethnic Study of Atherosclerosis (MESA) calcium calculator (http://www.mesa-nhlbi.org/calcium/input.aspx).

The Negative Effects of Depression on Ischemic Heart Disease

Depression Predicts Ischemic Heart Disease Incidence and Mortality

Though significant available evidence supports depression as a risk factor for poor prognosis among patients with ischemic heart disease (Lichtman et al., 2014), research supporting depression as a risk factor for incident ischemic heart disease is still developing. Emerging evidence indicates that the association between depression and the heart is quite broad. In a study of 1.9 million adults in the UK health system, a documented diagnosis of depression or a prescription for antidepressant medication was predictive of 12 different cardiovascular disease diagnoses, with hazard ratios (HRs) ranging from 1.12 (95% CI: 1.01–1.24) for abdominal aortic aneurysm to 1.70 (95% CI: 1.60–1.82) for unstable angina, even after adjusting for traditional risk factors for cardiovascular diseases (Daskalopoulou et al., 2016). In 2006, Nicholson, Kuper, and Hemingway (2006) conducted a systematic review and meta-analysis of 11 etiological cohort studies published between 1966 and 2003 evaluating the association between depression and ischemic heart disease. Nicholson et al. observed that even after studies adjusted for other risk factors, the risk of developing ischemic heart disease among individuals with depression is nearly double (95% CI: 1.5–2.4) the risk compared with those without depression (Nicholson et al., 2006).

Prospective cohort studies have provided much of the evidence for an association between a clinical diagnosis of depression and ischemic heart disease. Brown, Stewart, Stump, and

Callahan (2011) analyzed data from a prospective cohort study of older adults (≥60 years of age) followed for 13–16 years in primary care. The authors observed that compared with older adults without depression, those individuals with a history of depression were 46% more likely to experience either an acute myocardial infarction or death due to ischemic heart disease (31.9 vs. 25.7%); importantly, the two groups did not differ in rates of all-cause mortality, demonstrating specificity of the association between depression and ischemic heart disease. Similarly, in an 18-year longitudinal study of randomly selected women in Australia, O'Neil et al. (2016b) observed that a baseline diagnosis of clinical depression was associated with three times greater odds of a coronary event (cardiac death, myocardial infarction or intervention) over the next 18 years. Furthermore, adding the baseline clinical depression diagnosis to the Framingham Risk Equation, a "risk calculator" for cardiac disease and events commonly used in medical practice (https://www.framinghamheartstudy.org/risk-functions/index.php), modestly but significantly improved risk prediction of 10-year coronary events (O'Neil et al., 2016a).

Unfortunately, not everyone who suffers from depression will receive a formal diagnosis, and others may have persistent but subthreshold symptomatology. In the Whitehall II study, rather than evaluating a clinical diagnosis, Brunner et al. (2014) evaluated whether depressive symptomatology at up to six exams would predict ischemic heart disease outcomes over 24 years of follow-up. They found a dose–response relationship between number of exams with elevated depressive symptoms and ischemic heart disease, where participants with elevated depressive symptoms at two or more exams had nearly 50% increased risk of developing ischemic heart disease compared with participants without elevated depressive symptoms at any exams (HR: 1.47, 95% CI: 1.13–1.91) (Brunner et al., 2014). Taken together, the available research suggests that researchers and clinicians should consider "nontraditional" factors, particularly affective symptomatology, when evaluating risk for ischemic heart disease.

Mechanisms by Which Depression Is Hypothesized to Increase Risk for Ischemic Heart Disease

The pathophysiological mechanisms underlying the association between depression and ischemic heart disease are poorly understood at this time, though several physiological and behavioral mechanisms have been theorized. Physiologically based processes by which depression is hypothesized to promote ischemic heart disease include platelet reactivity, blood coagulation, inflammation, endothelial dysfunction, neuroendocrine dysregulation (i.e., increased sympathetic nervous system activity and decreased parasympathetic nervous system activity), cardiac rhythm disturbances (e.g., heart rate variability), and metabolic disorders (e.g., diabetes) (Davidson, 2012). Data from twin studies support this hypothesis, suggesting that certain genetic pathways that underlie both depression and ischemic heart disease may simultaneously increase risk for both conditions (Mulle & Vaccarino, 2013).

Others hypothesize that certain behaviors that are highly comorbid with depression, such as smoking and alcohol use, and those that are symptoms of depression, such as fatigue/lethargy and sleep disturbance, may account for the observed relationships between depression and ischemic heart disease. For example, Appleton et al. (2016) found that ischemic heart disease mortality associated with depression (unadjusted HR: 1.28, 95% CI: 1.02–1.62) was no longer significant after adjusting for behavioral factors (adjusted HR: 1.20, 95% CI: 0.94–1.52), including fruit and vegetable intake, physical activity, current smoking, and current alcohol consumption.

Depression and Coronary Artery Calcification

Due to the amount of time required for adults to develop ischemic heart disease or experience a cardiac event, until these mechanisms are better delineated, research progress will benefit from focusing on subclinical measures of ischemic heart disease for the purposes of evaluating the role of depression and depression treatment in the primary prevention of ischemic heart disease. The relationship between depression and CAC has been evaluated in several forms.

Persistent or recurrent depression (e.g., diagnosis of major depressive disorder or multiple episodes of significantly elevated depressive symptoms) has consistently been shown to be predictive of CAC. Women with a history of recurrent major depression, compared with those who reported only a single episode or no depression, are twice as likely to have CAC (Agatisa et al., 2005; Jones, Bromberger, Sutton-Tyrrell, & Matthews, 2003). Furthermore, the progression of CAC (i.e., the magnitude of change in Agatston scores) is directly related to level of depressive symptoms: Janssen et al. (2011) observed that the risk of CAC progression in women increases by approximately 25% for each incremental increase in depressive symptoms.

In two different studies, researchers attempted to model the longitudinal effect of the chronicity of depression on the development of subclinical ischemic heart disease by categorizing participants by the number of depressive episodes according to self-reported current depressive symptomatology assessed at multiple exams. In the Whitehall II study, Hamer, Kivimaki, Lahiri, Marmot, and Steptoe (2010) observed that individuals with two or three depressive episodes (focused only on the cognitive symptoms of depression) had approximately 2.5 times the odds of detectable CAC compared with individuals without any depressive episodes (OR: 2.56, 95% CI: 1.14–5.78). Janssen et al. (2016) similarly observed that women in the Study of Women's Health Across the Nation Heart Study with three or more depressive episodes (using a global depression score) had over two times greater odds of CAC compared with women without any depressive episodes (OR: 2.20, 95% CI: 1.13–4.28). Interestingly, in both studies, participants with only one depressive episode did not have significantly higher odds of CAC compared with individuals without any depressive episodes (Hamer et al., 2010; Janssen et al., 2016).

On the other hand, the majority of available evidence indicates that current depressive symptomatology alone does not predict CAC. Cross-sectional studies evaluating associations between depression and depressive scores and CAC have not found significant associations (e.g., Devantier et al., 2013). Likewise, when participants were only asked about past-week depressive symptoms, neither continuous depression scores in an older, multiethnic population (Diez Roux et al., 2006) nor a categorical diagnosis of depression among women (Matthews, Owens, Edmundowicz, Lee, & Kuller, 2006) was associated with greater likelihood of CAC.

Overall, it appears as though chronic exposure to and accumulation of depressive symptoms is required to increase risk for ischemic heart disease, similar to other traditional risk factors, bearing in mind that the majority of studies to date have been conducted in women. While these studies provide evidence for an association between depression and subclinical ischemic heart disease, researchers argue that the presence of depression alone does not fully explain the negative association we see with ischemic heart disease. Therefore, it becomes important to evaluate the potential role of comorbid risk factors in the relationship between depression and ischemic heart disease. To illustrate this concept, we chose to focus on the role of tobacco smoking, because it is highly comorbid with depression and because it is a strong and modifiable risk factor for ischemic heart disease, which has implications for prevention and treatment of ischemic heart disease.

The Role of Smoking in the Association Between Depression and Ischemic Heart Disease

A Brief Overview of the Comorbidity Between Depression and Smoking

A strong, bidirectional, and causal association exists between depression and smoking, where these two factors are both predisposing to and maintaining of each other. In the United States, adults with elevated depressive symptoms smoke at over twice the rate of the general population (43 vs. 22% in 2005–2008) (Pratt & Brody, 2010). Chaiton, Cohen, O'Loughlin, and Rehm (2009) conducted a meta-analysis of prospective studies in adolescents, where they found that smoking increased the odds of depression by 73% (95% CI: 1.3–2.4) and also that depression increased the odds of smoking by 41% (95% CI: 1.2–1.6). Genetic studies in identical twins also lend strong support for a biological basis of this comorbidity (Lyons et al., 2008).

Novel theories have been invoked to explain this association. One example is a transdiagnostic vulnerability framework, whereby anhedonia, anxiety sensitivity, and distress tolerance are key traits underlying the association between smoking and emotion (Leventhal & Zvolensky, 2015). A second example is an incentive learning theory, which posits that low mood (e.g., depression) increases the expected value of and therefore desire for a cigarette, which ultimately serves to maintain smoking behavior (Hogarth et al., 2015). Taken together, these theories and studies present not only an underlying genetic basis but also a behavioral or trait vulnerability to and maintenance of comorbid depression and smoking.

Smoking Predicts Ischemic Heart Disease

Research unequivocally indicates that cigarette smoking increases risk for premature ischemic heart disease morbidity and mortality in a dose-dependent manner (USDHHS, 2014). With regard to subclinical ischemic heart disease, smoking is a consistent and dose-dependent predictor of prevalence and progression of CAC (McEvoy et al., 2012). Studies have demonstrated that, among individuals with CAC, those who smoke are between four and nine times more likely to suffer cardiac death compared with their nonsmoking counterparts, which equates to an average loss of nearly 5 life years (Shaw, Raggi, Callister, & Berman, 2006).

The large list of ingredients and chemicals that compose cigarette smoke complicates the determination of any one specific mechanism by which cigarette smoking causes heart disease; discussion of all of the possibilities is beyond the scope of this chapter. Briefly, cigarette smoking stimulates the sympathetic nervous system and the heart. This stimulus induces several downstream physiological effects, including increased demand for oxygen, faster heart rate, elevated blood pressure, and greater myocardial contractility. Other suggested mechanisms include inflammation, endothelial injury, insulin sensitivity, and lipid abnormalities. Several of these mechanisms overlap with those by which depression is hypothesized to affect ischemic heart disease, providing further basis for assessing the potential synergistic association between these two risk conditions in relation to ischemic heart disease.

How Comorbid Depression and Smoking Have Been Observed to Affect the Heart

A representation of the hypothesized association between depression and ischemic heart disease is presented in Figure 1. Research evaluating the potential interactive effect of depression and

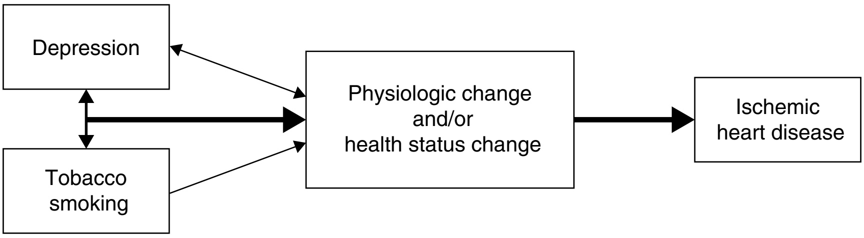

Figure 1 Hypothesized association between depression, tobacco smoking, and ischemic heart disease based on available research, where the thickness and direction of the arrows are indicative of the proposed strength and directionality of the associations. *Source*: This diagram was adapted for this chapter from Joynt, Whellan, and O'Connor (2003), figure 1 p. 249.

smoking on incident ischemic heart disease or cardiac events is limited. However, a synergistic association between depression and smoking has been observed with physical cardiac symptoms that may be indicators of future or subthreshold ischemic heart disease. For example, high heart rate variability (i.e., variability in the time interval between heart beats) is indicative of healthy cardiac function and may serve as a buffer for cardiac stress. Harte et al. (2013) observed that among adults with depression, those who smoked had lower heart rate variability than individuals who did not smoke. This finding suggests that cardiac function may be worst among adults who are both depressed and smoking compared with adults with only one or neither risk factor.

As noted above, several of the proposed mechanisms for the association between smoking and ischemic heart disease overlap with those relating depression and ischemic heart disease. Some researchers found evidence for a synergistic association between smoking, depression, and measures of these hypothesized mechanisms. Using inflammation, or the inflammatory response, as an example, Vulser et al. (2015) showed that the observed association between depressive symptoms with absolute neutrophil count was fully mediated by smoking. In another study, Stewart, Rand, Muldoon, and Kamarck (2009) argued that depressed individuals experience a dysfunction in the bodily systems that typically facilitate termination of an acute inflammatory response. They suggest that when a proinflammatory stimulus, such as smoking, is introduced to a person suffering from depression, he or she may exhibit a larger and/or more prolonged response to each exposure (e.g., each time that person smokes). The result is that, over time, these exaggerated inflammatory responses may accelerate the progression of atherosclerosis. Though preliminary, this evidence provides a basis and theory for a synergistic association between depression and smoking in relation to ischemic heart disease.

Depression, Smoking, and Coronary Artery Calcification

Only one study to date has looked for a potential interactive association between depression and smoking in relation to ischemic heart disease. Using data from the Coronary Artery Risk Development in Young Adults (CARDIA) study, Carroll et al. (2017) evaluated the association between cumulative, 25-year smoking exposure and depressive symptoms with CAC at year 25 among the 3,188 US adults. After adjusting for relevant sociodemographic, clinical, and behavioral covariates, participants with both high smoking exposure (30 pack-years) and clinically elevated depressive symptoms (a score of 16 on the Centers for Epidemiologic Studies—Depression [CES-D] scale) had nearly four times greater odds of moderate-risk CAC (scores 1–99) and over six times greater odds of higher-risk CAC (scores ≥100) compared with individuals without any depressive symptoms or smoking history (Figure 2) (Carroll et al., 2017). These findings provide preliminary evidence for a synergistic effect of depression and smoking with the onset of ischemic heart disease.

Other factors must be considered when evaluating the association between depression, smoking, and subclinical ischemic heart disease. First, subtypes of depression and clusters of depressive symptomatology (e.g., cognitive disturbance, somatic symptoms, anhedonia) may have differential associations in the relationship between depression, smoking, and ischemic

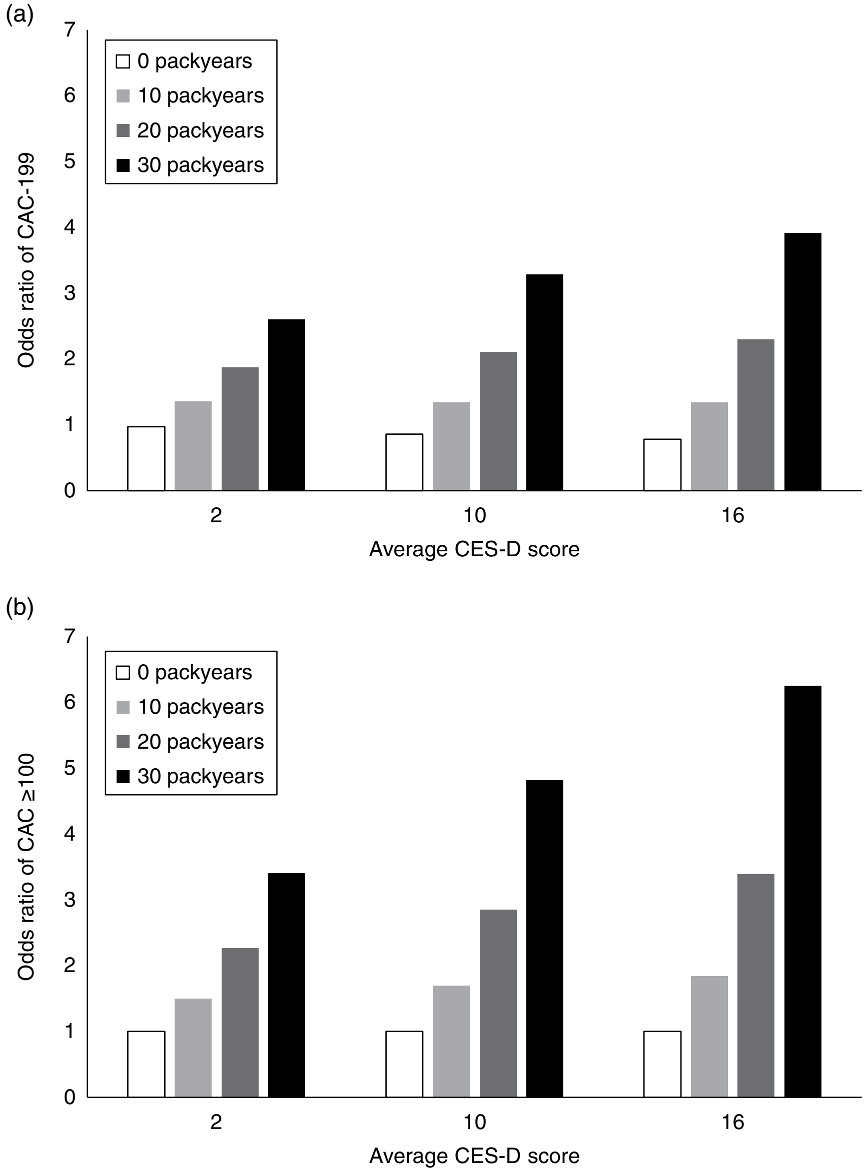

Figure 2 Odds ratios of lower-risk (Agatston scores 1–99; Panel A) and higher-risk (Agatston scores ≥100; Panel B) coronary artery calcification by depressive symptoms (CES-D score) × smoking (pack-years) relative to CES-D score = 0 and pack-years = 0, $N = 3{,}188$. *Source*: Adapted from Carroll et al. (2017).

heart disease. Second, the influence of age on ischemic heart disease cannot be ignored, given that the association between measures of subclinical ischemic heart disease and cardiac events is not strictly linear. In other words, younger individuals with detectable subclinical ischemic heart disease have lower relative risk, but higher absolute risk, of suffering a cardiac event. Finally, further study of the complex interplays between additional behavioral (e.g., alcohol use, physical activity) and/or psychological (e.g., anxiety, anger) conditions that contribute to the "Perfect Storm"—that is, the "joint presence of many co-occurring pathophysiologic processes that lead to a clinical event" (Burg et al., 2013)—remains crucial.

Societal Implications and the Role of the Health Psychologist

Ischemic heart disease accounts for approximately one in seven deaths among US adults, and the estimated direct and indirect costs of ischemic heart disease exceed $200 billion per year (Benjamin et al., 2017). Understanding the influence of psychological and behavioral factors on CAC is essential because, as of yet, there is no evidence to indicate that development of subclinical ischemic heart disease can be reversed. Therefore, preventing the development or limiting the progression of CAC is of the utmost importance. Much of the preservation of cardiovascular health could be achieved through early intervention on modifiable risk factors.

Smoking cessation swiftly and effectively reduces risk for ischemic heart disease and overall mortality (USDHHS, 2014); little is known about treating depression for the prevention of ischemic heart disease. However, one intervention study among older adults (>60 years of age) in primary care evaluated the effect of a collaborative care treatment for depression using antidepressants and pharmacotherapy on ischemic heart disease. Stewart, Perkins, and Callahan (2014) found that participants without an ischemic heart disease diagnosis who underwent treatment for their depression ($n = 85$), compared with those in usual care (i.e., encouragement to follow up with provider; $n = 83$), experienced fewer cardiac events (28 vs. 47%) over 8 years (HR: 0.52, 95% CI: 0.31–0.86). Consistent with previous research (Baumeister, Hutter, & Bengel, 2011), the authors did not observe improved mortality outcomes associated with depression treatment among individuals with preexisting ischemic heart disease. As such, an emphasis on ischemic heart disease prevention in those suffering from depression should be included in future clinical and public health efforts.

Recognizing and treating the depression–smoking comorbidity has the potential to lead to even greater advances in ischemic heart disease prevention. In an updated systematic review and meta-analysis comprising 42 smoking cessation studies, Hitsman et al. (2013) found that smokers with a history of depression had 17% (95% CI: 0.72–0.95) and 19% (95% CI: 0.67–0.97) lower odds of short-term (≤3 months) and long-term (≥6 months) abstinence, respectively. Furthermore, smokers who quit smoking experience significant improvements in negative affect (Taylor et al., 2014), contrary to popularly held beliefs. Given the recurrent, reciprocal, and relapsing nature of depression and smoking, leading experts in the field recommend a long-term and/or continuous care model using integrated evidence-based treatments for depressed smokers in order to address the high rates of relapse for both depression and smoking (Richards, Cohen, Morrell, Watson, & Low, 2013).

A number of national and global initiatives have been set forth to reduce the number of deaths due to noncommunicable diseases, including ischemic heart disease. These initiatives include the American Heart Association's Strategic Impact Goal of reducing cardiovascular disease mortality by 20% and improving cardiovascular health by 20% by the year 2020 (Lloyd-Jones et al., 2010), the United Nations Sustainable Development Goals to reduce mortality due to noncommunicable diseases by one-third by 2030 (http://www.un.org/sustainabledevelopment/health/), and the World Health Organization target to reduce mortality due to noncommunicable diseases by 25% by the year 2025 (World Health Organization, 2013). These initiatives provide an impetus for health psychologists to get involved in the prevention of ischemic heart disease, given their growing presence in primary care and other medical settings. Health psychologists may be in the best position to identify and treat these at-risk individuals to prevent development and progression of ischemic heart disease. Furthermore, health psychologists, both clinicians and researchers, can contribute to prevention efforts by developing and implementing novel targeted treatments for ischemic heart disease risk factors among at-risk patients.

Conclusion

Recognition of the role of nontraditional risk factors for ischemic heart disease is growing, especially for psychological conditions such as depression. The evidence supporting an association between depression and ischemic heart disease is tantalizing but mixed, likely related to the confounding effects of risk behaviors, and tobacco smoking in particular. As such, further research in this area is needed to fully elucidate the association between depression and risk for ischemic heart disease. Nonetheless, the available evidence indicates that health psychologists can and should play an important role in ischemic heart disease prevention through interventions designed to target and treat comorbid depression and tobacco smoking.

Acknowledgments

I would like to thank Dr. Mark Huffman for his conceptual and editorial suggestions in the development of this chapter.

Author Biography

Allison J. Carroll is a doctoral candidate in clinical psychology (behavioral medicine) at Northwestern University Feinberg School of Medicine. Her research interests include understanding the associations between multiple risk factors with chronic disease risk and evaluating clinical interventions for disease prevention and health promotion.

Neurocognitive Disorders and Health Psychology

Claudia Drossel

Department of Psychology, Eastern Michigan University College of Arts and Sciences, Ypsilanti, MI, USA

Neurocognitive disorder (NCD) describes a persistent pattern of difficulties remembering, thinking, reasoning, or problem solving that represents a decline from baseline functioning (APA, 2013). This functional decline can be due to a range of underlying conditions, some of which are reversible or stable, while others irreversible or progressive. Heterogeneous etiologies (e.g., NCD due to Alzheimer's and vascular disease) are common (see The Lancet series, "Dementia—not all about Alzheimer's," 2015). In addition to etiological subtype, NCDs are distinguished by their level of severity. When interference with activities of daily living is subtle and compensatory strategies allow independent completion of tasks, NCDs are classified as mild. Major NCDs—the focus of this encyclopedia entry—are customarily known as dementias and denote a significant disruption of activities of daily living secondary to neurodegenerative processes.

In the course of neurodegeneration, changes occur in multiple domains vital to everyday functioning, such as perception (e.g., loss of olfaction, diminished visuospatial skills, auditory processing deficits), cognition (e.g., deficits in complex attention, planning and execution of multistep actions, and learning or memory), or language (e.g., restricted conversational topics, difficulties naming common objects). Decreased motor skills and gait disturbances put the individual at risk of falls. In addition, sleep–wake rhythms may shift. While patterns of domain-specific strengths and weaknesses depend on the underlying neurological disorder as well as the person's distinct premorbid repertoire, in general, everyday tasks whose execution did not require effort or problem solving become increasingly puzzling and arduous. Adults younger than 60 years of age, whose most frequent conditions underlying the decline are alcohol-related NCD, frontotemporal lobar degeneration, or early-onset Alzheimer's disease, and their families also experience loss of employment, income, and social status.

The Wiley Encyclopedia of Health Psychology: Volume 3: Clinical Health Psychology and Behavioral Medicine,
First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

Regardless of etiology, individuals with major NCD must cope with a progressive and insidious loss of skill sets, a narrowing life space, and concomitant changes in relationships that can seem perplexing and worrisome. Because coping repertoires, available social supports, and health status other than the neurological condition vary from person to person, physiology intersects with contextual and potentially modifiable factors to create psychological presentations unique to each individual. In other words, the manner with which major NCD manifests in the life of a particular person and the specific emotional or behavioral changes it produces greatly depend upon the individual's medical and psychosocial history and his or her current circumstances. Kahn (1965) coined the term "excess disability" to describe functional impairment in excess of what would be expected based upon a person's neurological status alone. Even after more than half a century of clinical research efforts to better support affected individuals and their family and professional supports, excess disability continues to be common in NCD and indicative of care situations that inadvertently hasten decline.

Individuals with major NCD eventually depend on others for virtually all tasks of daily living, including the most basic such as eating and toileting. In the United States, responsibility for care rests upon family members (hereinafter termed "family care partners," to underline the dyadic nature of care situations). The degree to which these family care partners are prepared to understand and effectively compensate for functional loss and idiosyncratic emotional or behavioral sequelae, and to establish a 24/7 care system including respite in the form of third-party assistance, directly affects quality of care. It also affects care partners' physical and emotional health in the long run.

Given the prevalence of NCD, excess disability, and the care responsibility of families, the role of health psychology in NCD is threefold:

i To mitigate factors that contribute to excess disability when NCD is present.
ii To promote the health of care partners whose responsibility for part or full-time care places them at risk for adverse physical and emotional sequelae.
iii To prevent the onset of major NCD through policy initiatives and health behavior interventions that address known risk factors.

While age is a known risk factor for many progressive NCDs, such as late-onset Alzheimer's disease, health status and physical fitness in midlife are important predictors of later functional status and thus notable points of primary prevention. The general role of health psychology related to risk factors for major NCD—exogenous (acquired brain injury via exposure to neurotoxic substances or trauma), endogenous (vascular, metabolic), and behavioral (e.g., substance use, sedentary behavior)—is addressed elsewhere in this volume. For this reason, the current entry will focus on (1) and (2) above: the prevention of excess disability and the promotion of care partner health when NCD is present.

Prevention of Excess Disability in NCD

A subtle loss of verbal skills, including self-description and self-expression but also complex reasoning and comprehension, puts individuals with major NCD at risk of unmet physical and emotional needs as well as social withdrawal. Already in 1996, the American Academy of Neurology Ethics and Humanities Subcommittee emphasized that prevention and management of factors aggravating NCD are at the heart of care (Bernat et al., 1996). Accordingly, NCD-appropriate care includes the following:

1 Optimizing basic functioning as the foundation for quality of life by establishing:
  a Eating and hydration routines, (i) to maintain adequate nutrition given altered olfactory and taste perception and (ii) to prevent urinary tract infections, constipation, and increased confusion due to dehydration.
  b Routines for urinary and bowel functioning and implementation of voiding schedules to prevent incontinence episodes and related agitated or irritable behavior.
  c Proper detection and correction of sensory loss as decreased ability to hear or see may increase confusion, social isolation, and fear. Because cognitive decline may interfere with the effectiveness of corrective devices (e.g., individuals may develop difficulties using bi- or trifocal glasses and sophisticated binaural hearing aids or may lose their ability to switch batteries when indicated), removing barriers to correction of sensory loss is important. Often, simpler solutions are indicated, such as pocket amplifiers or glasses that only correct for myopia.
  d Access to regular physical activity, to prevent restlessness and facilitate sleep.
  e Routines that promote restful sleep and maintain the sleep–wake cycle (Cipriani, Lucetti, Danti, & Nuti, 2015).

2 Detecting and managing comorbidities. As medical providers generally rely on patients' self-report, diminishing and inadequate self-descriptive skills place individuals with NCD at risk of undetected acute illnesses and unmanaged chronic conditions. Whereas these conditions commonly reduce the cognitive efficiency of a healthy person, they tend to produce significant cognitive, emotional, and behavioral changes in individuals whose neurological functioning is compromised. Family care partners and providers may misattribute these precipitous changes to the NCD and focus on correlated emotional and behavioral changes to the detriment of detecting medical conditions that—when unmanaged—exacerbate cognitive difficulties and associated behavior problems.

  As an example, individuals with cognitive decline and diabetes may continue to be solely responsible for their diabetes medication administration and their blood glucose monitoring. Alternatively, family care partners may receive the information for diabetes management from the person with NCD. Behavioral and emotional changes may overshadow long-term hyperglycemia and short-term but potentially serious hypoglycemic episodes that are more common in individuals with diabetes and NCD. Apathy, irritability, and agitation—together with increased confusion the hallmarks of poor glycemic control in older adults—can function as active barriers to care partners assisting the person with diabetes-related self-care and requesting access to preventive medical visits. Indeed, some care partners may discount the need for diabetes care and prioritize management of behavioral and affective changes commonly associated with NCD, yet often due to preventable or manageable medical conditions.

  Other common comorbid conditions that exacerbate cognitive decline are acute and chronic pain (e.g., from urinary tract infections, toothaches, headaches, or rheumatoid arthritis), hypertension, and chronic lung and heart diseases. Because seemingly neuropsychiatric presentations can hinder the detection of acute or chronic illnesses, including cancer, health psychology plays a central role in the advocacy for proper rule-outs and adherence to chronic disease management at the intersection of physical and neuropsychiatric health.

3 Closely monitoring medication effects. Adverse events related to medications are common and may manifest as emotional or behavioral disturbances, particularly in older adults and those with already compromised central nervous system functioning (Campanelli, 2012). Individuals with NCD due to Lewy body disease, for example, are exceptionally sensitive

to treatment with antipsychotics. Referral to a geriatric pharmacist for medication review may be indicated when the person with NCD is on more than five medications, when there are multiple prescribers and potentially redundant prescriptions, when the medication regimen is suspected to worsen cognitive functioning or includes medications that are inappropriate for older adults or individuals with NCD, and when there have been changes in cognitive, emotional, or behavioral functioning that are uncharacteristic of the person and comorbid medical conditions have been ruled out. Of note, medications prescribed for the management of NCD (e.g., cholinesterase inhibitors) are known to precipitate prescribing cascades, in which the prescription drug's adverse events are diagnosed as novel conditions treated with additional medications.

4 Preventing and addressing depression and anxiety. Depression and anxiety frequently precipitate cognitive decline, potentially signaling subtle physiological changes of yet insufficient severity to disrupt activities of daily living. Once cognitive decline begins to interfere with everyday functioning, task or psychosocial demands exceed the person's skill set, and self-protective responses emerge. First among these self-protective responses are frequently avoidance of activities and general disengagement. Accordingly, depression and anxiety are the most common neuropsychiatric complaints and further exacerbate or accelerate the progressive effects of the neurodegenerative disease. Appropriate behavioral activation, that is, arranging opportunities for meaningful activities that match the person's lifetime interests and current skill level, provides the shared activities that are important to a sense of belonging and produces positive health outcomes in NCD. Inclusion of the person with NCD in daily activities, to the best of his or her abilities, is vital to maintaining quality of life.

5 Detecting and reducing substance use. NCDs are prevalent among older adults with substance use disorders, and differential diagnosis of the etiology underlying cognitive decline is difficult. Avoidant coping style, history of substance use, and psychosocial factors such as social isolation or family conflict may further increase vulnerability to substance use when cognitive decline is present (Kuerbis, Sacco, Balzer, & Moore, 2014).

6 Recognizing and managing delirium superimposed on dementia. The presence of an NCD predisposes individuals to delirium, associated with precipitous decline, hospitalization or institutionalization, and increased mortality. The practice of health psychology in inpatient medical settings often involves alerting the medical team to the rule-out of delirium and implementing non-pharmacological management strategies (Inouye, Westendorp, & Saczynski, 2014).

In summary, NCDs are complex conditions that tend to occur in medical and psychosocial contexts whose combined influence on the progression of NCDs is profound (Mast, 2011). In the United States, the everyday implementation of recommendations for care and the prevention of excess disability falls to family members, mostly women.

Promoting the Health of Family Care Partners

As family care partners assume responsibility for monitoring the safety and well-being of the person with NCD, arranging compensatory and supportive settings, assisting with basic and instrumental activities of daily living, and managing emotional and behavioral reactions to cognitive loss, family care partners' physical and mental health conditions affect how well they can meet the heavy emotional, organizational, problem-solving, and physical demands inherent in caring for a person with NCD. Family care partners' physical status and risk for clinical depression have been linked to potentially harmful caregiver behaviors, as have greater care needs and cognitive impairment of the person with NCD (Beach et al., 2005). In addition, situational constraints imposed by the need to provide supervision for safety often lead to loss of income, reduced access to preferred activities, increased social isolation, sleep deprivation, and poor health behaviors including inadequate healthcare utilization. In general, while also described as meaningful, the provision of care within the family is associated with an elevated risk of negative physical and mental health outcomes for the primary care partner, including cardiovascular disease and depression (e.g., Dassel & Carr, 2016).

Most programs to date have been developed to support family care partners in the implementation of care recommendations and do not intervene directly with the person with NCD. These programs can have single or multiple components, consisting of psychoeducation about NCD and associated skills training to enhance safety and to compensate for cognitive loss, introduction to behavioral management techniques to address behavioral or emotional changes, enhancement of problem solving and coping, or stress management including exercise. Psychotherapeutic strategies, such as cognitive behavioral therapies for depression, dialectical behavior therapy skills training, or mindfulness-based stress reduction, have also been applied. Outcome measures mostly have focused on factors that affect the ability to provide care, that is, care partner's mental and physical status. Not surprisingly, intervention effects are domain specific and vary depending on the target of the intervention. Care partners often are asked to report the frequency and the perceived impact of the difficulties exhibited by the person with NCD. It is assumed that reported reductions in frequency and/or impact of problematic behaviors translate to direct benefits of the intervention for the person with NCD. Reviews of the evidence have questioned this assumption and called for further systematic studies of patient functioning (Griffin et al., 2015; see also Schulz et al., 2002).

The progression of NCDs and the health of care partners interact with dyad or person-specific modifiable psychosocial, biobehavioral, and environmental factors within the purview of health psychology. In general, effective interventions for care partners that reduce burden and enhance mood and well-being are multifaceted and tailored to individual needs, and they require active participation (e.g., McCurry & Drossel, 2011). In addition, these interventions remove barriers to soliciting assistance (e.g., from friends or third-party agencies) and provide long-term support (Sörensen & Conwell, 2011).

Author Biography

Claudia Drossel is an assistant professor at Eastern Michigan University. Her work focuses on developing functional assessments and implementing behavioral interventions for individuals and families to increase quality of life and prevent or reduce emotional and behavioral changes associated with neurocognitive disorders.

Depression and Comorbidity in Health Contexts

C. Steven Richards[1] and Lee M. Cohen[2]

[1]*Department of Psychological Sciences, Texas Tech University, Lubbock, TX, USA*
[2]*Department of Psychology, College of Liberal Arts, The University of Mississippi, University, MS, USA*

Depression is associated with many chronic health conditions and diseases (Richards & O'Hara, 2014a). In fact, depressive comorbidity is observed so frequently in health contexts that it is important for healthcare providers to be aware of the presentation of the symptoms of depression, how to quickly assess if this is a concern with their patients, and how to structure treatment for multiple concerns simultaneously. It is also important to have an understanding of how depression can influence the course of a variety of physical illnesses (Richards & O'Hara, 2014b). In this brief entry, examples of the concurrence of symptoms of depression with chronic health conditions are provided, followed by a discussion of the implications of this body of research and scholarship.

Cancer and Depression

There is often a strong association between being diagnosed with cancer and experiencing significant symptoms of depression (e.g., see reviews by Miller & Massie, 2010; Nezu, Nezu, Greenberg, & Salber, 2014). In fact, there are large numbers of randomized controlled trials examining multiple approaches to treating depressed cancer patients. For example, Manne, Siegel, Heckman, and Kashy (2016) examined 302 female patients with early-stage breast cancer, along with their spouses. For the most distressed patients, a couple-focused and supportive version of group therapy appeared to be the most effective intervention. In contrast, among less distressed patients, a structured and skill-based version of group therapy appeared the most effective. This study successfully addressed some of the common research concerns

The Wiley Encyclopedia of Health Psychology: Volume 3: Clinical Health Psychology and Behavioral Medicine,
First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

in this area, such as including a relatively large sample and a broad array of measures. It also highlights the need for individualized treatment, based on the specific needs of the patient.

Another recent study by Desautels, Savard, Ivers, Savard, and Caplette-Gingras (2018) illustrates an alternative approach to evaluating treatment options among depressed cancer patients. This study compared the efficacy of treating breast cancer patients that had considerable depressive symptoms with either cognitive therapy or bright light therapy. The design was a randomized controlled trial, with 62 breast cancer patients, and it included pre-, post-, and 6-month follow-up assessments. Although caution is warranted because of the relatively small sample of 62 participants, the cognitive therapy group appeared to be efficacious for this group of cancer patients, compared with a wait-list control group. The bright light therapy showed some promise for reducing depressive symptoms in these patients, but it was not as consistently efficacious across all depression measures when compared with those who participated in the cognitive therapy group. Extensions of this treatment approach to larger and more diverse cancer patient samples, and with longer follow-up assessments, should prove interesting. This bright light therapy approach may be particularly helpful in circumstances where the well-tested approaches of cognitive therapy or cognitive behavior therapy are not available, or not acceptable, to cancer patients.

Hopko and his colleagues have conducted several studies suggesting that behavioral activation may be an efficacious intervention for psychosocial variables, such as depression, in samples of depressed breast cancer patients (e.g., Ryba, Lejuez, & Hopko, 2014). For instance, Ryba et al. (2014) conducted a study suggesting that the level of patient compliance with behavioral activation homework is strongly associated with reduced severity in symptoms of depression among cancer patients. The quality of the completed homework, however, appears to be less strongly associated with outcomes following this behavioral activation intervention. Hopko et al. have also found support for problem-solving interventions in this context, as have others using various methodologies among diverse samples of cancer patients (e.g., Nezu, Nezu, Felgoise, McClure, & Houts, 2003).

Many additional studies have appeared in elite academic journals, such as the *Journal of Consulting and Clinical Psychology, Health Psychology, Annals of Behavioral Medicine, The Journal of the American Medical Association (JAMA), and The New England Journal of Medicine*, that focus on depressive comorbidity among a multitude specific diseases such as cancer, heart disease, diabetes, arthritis, and neurological disease. The frequency in which this topic is included across these multidisciplinary journals underlines the importance of the topic and regularity of the concern in healthcare settings. Further, research in this area offers important treatment information and implications.

For instance, there is a rapidly expanding literature on interventions to improve several psychosocial aspects of being diagnosed with cancer, caring for someone with cancer, or functioning effectively at home and work while a family member is being treated for cancer. The treatment goals often include a reduction in diagnosable clinical depression or depressive symptoms. Thus, there are large studies supporting the efficacy of different forms of treatment among this population. Specifically, cognitive behavioral therapy and relaxation training interventions have been shown to be effective in this area (e.g., Gudenkauf et al., 2015). Mindfulness and hope components may also enhance interventions aimed at the psychosocial components of living with cancer and fears of cancer recurrence (e.g., Thornton et al., 2014).

Additionally, there are studies that also focus on the impact of cancer (and cancer treatment) on family, friends, and caregivers of cancer patients. Cancer caregivers have been shown to experience serious depressive symptoms after a loved one's cancer diagnosis. For instance, Kim, Shaffer, Carver, and Cannady (2014) illustrated that social support and caregiving stress may have implications for several years after the initial cancer diagnosis. Furthermore, these investigators continue to find that caregivers may benefit from interventions for better adjustment to long-term caregiving, even 5 years after the initial diagnosis. Finally, a randomized controlled trial by Lewis et al. (2015) suggests that an intervention of educational counseling sessions may reduce the burden of cancer and the level of negative affect for mothers with cancer. Not only did this study find that treatment helped mothers' mood, but also it helped with their parenting skills and the behavioral and emotional adjustment of their children (range of 8–12 years old).

In summary, the few examples provided, selected from a very long list of potential examples, illustrate the important progress that is being made regarding depressive comorbidity and cancer.

Treating Depressed Smokers in Smoking Cessation Programs

As another brief example relevant to the topic of this entry, we mention the rapidly growing literature on treating depressed (and anxious) smokers as part of smoking cessation interventions. Smoking and nicotine use are typically listed among the most commonly preventable causes of disease and death (e.g., Richards, Cohen, Morrell, Watson, & Low, 2013). Moreover, high rates of depressive (and anxious) symptoms are quite prevalent among patients seeking smoking cessation treatment and can in fact impede treatment progress. Therefore, research on efficacious interventions for smoking cessation that includes one or more modules on depressive symptom reduction is important (see Richards et al., 2013, for a review of treating depressed and anxious smokers in smoking cessation programs).

A recent example of this type of research is a study of the synergistic effect of a change in moderate depressive symptoms (dysphoria) and anxiety sensitivity, on post-quit tobacco withdrawal symptoms (Bakhshaie et al., 2018). This prospective research trial included 198 treatment-seeking adult smokers, who were enrolled in a smoking cessation treatment study. This large study included a broad array of measures and a 12-week post-quit assessment. The results indicated that reducing participant levels of depressive symptoms (dysphoria) and anxiety sensitivity before quitting is strongly related to the reduction withdrawal symptoms (which are highly associated with relapse to smoking) after a quit attempt. In turn, numerous studies suggest that reducing withdrawal symptoms after a quit attempt among participants in smoking cessation programs is often associated with better long-term treatment outcomes (e.g., Baker et al., 2007). Furthermore, less depression (and anxiety) post-quit attempt is also associated with a lesser probability of smoking relapse (Richards et al., 2013).

In summary, there is a rapidly developing research literature on depressive comorbidity and health-compromising behaviors such as smoking, particularly in the context of healthcare settings and treatment programs.

Depressive Comorbidity and Diversity

It is also important to discuss a couple examples of research that addresses depressive comorbidity as it relates to ethnic diversity in health contexts. For example, Le, Perry, and Stuart (2011) conducted a randomized controlled trial that illustrates the potential of a culturally sensitive cognitive behavior therapy intervention for a sample of 217 Latinas that were classified as high risk for comorbid challenges of perinatal depression, chronic health problems, and distressed relationships with their children and family. The majority of the participants were low-income immigrants from Central and South America. The cognitive behavior therapy intervention was tailored to the precise needs of this sample. Specifically, the intervention was delivered in Spanish by bilingual and bicultural staff, and it was developed to be culturally sensitive to the ethnic and economic circumstances of these participants. The participants were randomized into the adapted cognitive behavior therapy condition (eight group sessions, plus three booster sessions) or a usual-care condition. The results suggested that the cognitive behavior therapy intervention significantly reduced depressive symptoms. Major depressive episodes, however, which are more severe and rare in this sample, were not significantly reduced by this brief intervention, compared with usual care. This study illustrates that a culturally sensitive version of cognitive behavior therapy offers promise for reducing depressive symptoms in high-risk, low-income Latina women who were at risk for chronic health problems, during their pregnancy.

Another relevant example that considers the challenge of depressive comorbidity, among a diverse sample, is a study on physical activity and depressive symptoms after treatment for breast cancer (Brunet, O'Loughlin, Gunnell, & Sabiston, 2018). The early research in this area has been limited to samples of almost entirely Caucasian women, within a small age range, who were relatively well educated and mostly married or living with a partner. In contrast, this large study of 201 women with breast cancer reflected efforts to recruit a more diverse sample across a multitude of demographic variables. The investigators note that while they were somewhat successful, even more diverse samples will be important for future research. One of the major findings from this study is that more physical exercise was associated with less frequent depressive symptoms, measured in a cross-sectional manner, among women post-treatment for breast cancer. This said, not all of the predicted relationships of depression and exercise held up longitudinally.

Discussion

Depressive comorbidity is pervasive in health contexts. This has important implications for assessment, treatment, follow-up care, and long-term survivorship. Although the fields of health psychology and behavioral medicine have recently embraced the merits of recruiting diverse samples in their studies, it is clear that depressive comorbidity is frequently present in underserved populations, high-risk groups, and ethnically diverse minority populations. Unfortunately, the implications of depressive comorbidity are serious and negative. These implications include assessment and evaluation complexities, threats to effective treatment planning, poorer adherence to treatment regimens, increased rates of relapse and recurrence after treatment, more disruptions and distress in day-to-day functioning, and a more negative overall prognosis for long-term morbidity and mortality. Despite these challenges, considerable progress has been made regarding the theory, research, and practice of effectively dealing with depressive comorbidity in health contexts. Clearly, depression or depressive symptoms present concurrently with a majority of the chronic health problems and diseases that clinicians help patients cope with daily.

Included below are a few "take-home messages" that may be culled from this entry and the much broader research literature on depression and comorbidity in health contexts:

- This area struggles with clarifications and distinctions between "depressive symptoms" versus "severe clinical depression," which is defined as meeting the diagnostic criteria of major depressive disorder in the *DSM-5* (American Psychiatric Association, 2013).
- Some wonderfully ambitious and elegant studies have been designed and completed in this area. This said, any scientific, psychological, medical, and health area can be improved. For instance, future studies must include large, more diverse samples to more accurately reflect the world's population.

- The specifics of depressive comorbidity in health contexts are complex, as researchers and clinicians move from one type of comorbidity to the next, one problem to the next, and one context to the next. Therefore, extra effort and consideration may be warranted for assessment and treatment.
- The challenges of depressive comorbidity in health contexts argue for considering the merits of inter- and multidisciplinary efforts. Therefore, this seems to be an area where different disciplines working effectively together is critical.
- It appears that depression presents with almost all chronic health problems and diseases in health contexts. Therefore, it will be helpful to screen for depressive comorbidity, plan accordingly, and treat thoroughly.

Author Biographies

C. Steven Richards, PhD, is a professor of psychological sciences at Texas Tech University. His research interests include depression, clinical health psychology and behavioral medicine, comorbidity of health problems and psychopathology, self-control, and relapse prevention for depression. He has held 15 administrative positions during his faculty appointments at Texas Tech University, Syracuse University, and the University of Missouri, Columbia. Dr. Richards earned his PhD in clinical psychology at the State University of New York at Stony Brook (now Stony Brook University).

Lee M. Cohen, PhD, is dean of the College of Liberal Arts and professor in the Department of Psychology at the University of Mississippi. Dean Cohen came to UM from Texas Tech University, where he served in a number of administrative roles including the director of the nationally accredited doctoral program in clinical psychology, and the chair of the Department of Psychological Sciences. As a faculty member, he received several university-wide awards for his teaching and academic achievement. As a researcher, he received more than $1.5 million from funding agencies, including the US Department of Health and Human Services, the National Science Foundation, and the National Institutes of Health/National Institute on Drug Abuse. His research program examines the behavioral and physiological mechanisms that contribute to nicotine use, and he worked to develop optimal smoking cessation treatments. He is a fellow of the American Psychological Association and received his PhD in clinical psychology from Oklahoma State University.

Depression and Relapse in Health Contexts

C. Steven Richards[1] and Lee M. Cohen[2]

[1]*Department of Psychological Sciences, Texas Tech University, Lubbock, TX, USA*
[2]*Department of Psychology, College of Liberal Arts, The University of Mississippi, University, MS, USA*

In 1978, Richards and Perri noted, in the context of a treatment maintenance study, that psychosocial treatment effects often do not last (Richards & Perri, 1978). Unfortunately, four decades later, this is still the case. Hence, depression is an excellent example of the complex challenges faced when working with individuals to prevent relapse and recurrence (Richards & Perri, 2010a). Further, it often presents along with many health conditions and diseases (Richards & O'Hara, 2014a). In fact, depressive comorbidity is so frequently observed in healthcare settings that healthcare providers from all backgrounds need to have some understanding of this disorder as well as the impact it has on the primary medical concern for which their patients are seeking treatment (Richards & O'Hara, 2014b). In this entry, examples of depressive relapse and recurrence, concurrent with serious health conditions, are presented. Implications of this research and scholarship, as well as recommendations for preventing and reducing depressive relapse, are also discussed.

Depression: Definition and Prevalence

Depression is a chronically relapsing and recurring condition (American Psychiatric Association [APA], 2013). It is also quite prevalent, with approximately 7–10% of the adult population in the United States and other industrialized countries experiencing depression or a closely related mood disorder at a given point in time (Gotlib & Hammen, 2015; Kessler & Ustun, 2008). For the purpose of this entry, the term "depression" will be used as the general equivalent for major depressive disorder, as defined in the *DSM-5* (APA, 2013). This said, it is important to note that this use of the term "depression" is not universal. In fact, some investigators use

---

The Wiley Encyclopedia of Health Psychology: Volume 3: Clinical Health Psychology and Behavioral Medicine, First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

"depression" to indicate diagnostically subthreshold symptoms and signs, such as elevated symptom levels on a self-report measure, rather than the interview-based observational assessments that are the base of *DSM-5* diagnoses. In research settings, mingling the concepts of self-reported "subthreshold depressive symptoms," "depression," and interview-based "major depressive disorder" is somewhat controversial (e.g., see discussions in APA, *DSM-5*, 2013; Gotlib & Hammen, 2015; Richards & Perri, 2002; Watson & O'Hara, 2017).

In summary, depression is a serious and debilitating disorder, with negative implications for day-to-day functioning, disruptions in close relationships at work and at home, deterioration in chronic health conditions and diseases, and an overall negative impact on morbidity and mortality (Kessler, Scott, Shahly, & Zaslavsky, 2014). Indeed, most large national and international surveys, such as those conducted by the US National Institute of Mental Health and the World Health Organization, have indicated that serious clinical depression, such as major depressive disorder, is always high on the list of causes for day-to-day disruptions in functioning and increased disability (Gotlib & Hammen, 2015; Kessler & Ustun, 2008). Moreover, there is a large literature associating depression, and depressive relapse, with a variety of chronic health conditions and diseases. Therefore, it is important that depressive relapse is assessed over time, and when necessary, treated in health contexts in accordance with approved clinical interventions.

Studies on Relapse Prevention for Depression

Frank, Kupfer, Reynolds, and their colleagues have conducted a very ambitious series of randomized controlled trials examining relapse prevention for depression (e.g., Frank et al., 1990; Reynolds et al., 2006). These studies include long-term follow-ups and comparison of treatment maintenance interventions. Specifically, after successful completion of treatment (often 12–20 weeks), Frank and her colleagues compared various combinations of a psychosocial intervention and an antidepressant medication. The psychosocial intervention studied during both acute treatment and maintenance therapy was interpersonal psychotherapy (IPT) for depression, which is a brief form of psychotherapy that focuses on an array of interpersonal issues and skills (see Weissman, Markowitz, & Klerman, 2017 for a review of IPT). The antidepressant medications used across these studies were FDA-approved antidepressant medications (e.g., imipramine [*Tofranil*], a tricyclic antidepressant medication, or a selective serotonin reuptake inhibitor [SSRI] such as paroxetine [*Paxil*]). A review of this group's extensive body of research along with other relevant studies on IPT is available in O'Hara, Schiller, and Stuart (2010).

Several conclusions can be drawn from this important work, which utilized various combinations of IPT and antidepressant medications as relapse-prevention strategies for depressed adults. First, the continuation of maintenance treatment for depression following successful acute treatment, with IPT, antidepressant medications, or both, usually leads to reductions in the rate of depressive relapse and recurrence over multiyear follow-ups (e.g., Frank et al., 1990, 2007; Reynolds et al., 1999, 2006). For example, the Reynolds et al. study (1999) with depressed older adults found that 90% of the participants relapsed across a 3-year follow-up in the maintenance group that received a placebo during follow-up. However, only 20% of participants relapsed in the maintenance group that received IPT and antidepressant medication during follow-up. Adding to this impressive finding is the fact that it was with older adults, a population that often has chronic health conditions. This is an extremely important finding (however, compare with Reynolds et al., 2006, with even older-old adults, over 70 years of age, where the maintenance effect of long-term IPT was not particularly powerful).

Second, there is support for maintenance IPT as a stand-alone relapse-prevention strategy among adult women, which is important, as some women may be reluctant to take long-term antidepressants due to pregnancy or postpartum breastfeeding (Frank et al., 2007). Since depression and depressive relapse are highly prevalent, and frequently comorbid with other health concerns, approaches to reducing depressive relapse are very important.

Third, given findings from several randomized controlled trials and/or more naturalistic, low-cost intervention trials in point-of-healthcare clinics with depressed postpartum women, IPT interventions in the acute phase of depression treatment, and/or during maintenance treatment, appear to be helpful for depressive relapse prevention with women caring for young children (e.g., Nylen et al., 2010; O'Hara, Stuart, Gorman, & Wenzel, 2000; Serge, Brock, & O'Hara, 2015). Therefore, even in economically challenged and underserved populations, IPT apparently has potential as both an acute and maintenance treatment for depression (e.g., Serge et al., 2015).

In addition to the promising research examining the effectiveness of IPT, there is also an extensive research literature evaluating the benefits of cognitive behavior therapy (CBT), or more cognitively focused cognitive therapy (CT), as a relapse-prevention strategy in depressed adults. As with the treatment maintenance and depressive relapse-prevention research with IPT, the studies with CBT and CT have often been quite promising in support of this approach (e.g., for studies see Hollon, DeRubeis, et al., 2005; Jarrett et al., 2001; for a review see Hollon, Stewart, & Strunk, 2005). In summary, there are few, if any, evidence-based psychotherapy for depression approaches with as much evaluation using large randomized controlled trials as CBT and CT. Overall, this well-researched psychosocial intervention has also shown strong potential as a relapse-prevention strategy for depressed adults.

Finally, there has also been encouraging research investigations of mindfulness-based versions of CT (and CBT) in the area of depressive relapse prevention. Recent meta-analytic reviews of this research indicate considerable potential for mindfulness-based therapy for relapse prevention of depression. For example, a meta-analysis of over 1,200 individuals with recurrent depression, collected across nine research trials, suggested that patients receiving mindfulness-based interventions (sometimes combined with antidepressant medication) showed less depressive relapse by about 23% compared with patients who were continued on antidepressant medication but who did not receive the mindfulness therapy (Kuyken et al., 2016). Researchers, scholarly reviewers, and clinicians who work with individuals diagnosed with depression typically consider a 23% reduction in depressive relapse to be an important clinical finding (Gotlib & Hammen, 2015; Richards & Perri, 2010a).

These studies on mindfulness-based interventions were also typically conducted considering the constraints of real-world conditions, such as the use of time-limited psychological treatment. Specifically, the study designs compared 8 weeks of a mindfulness version of CT with "usual care," where "usual care" primarily consisted of antidepressant medication treatment and did not include an evidence-based psychotherapy. Therefore, this research by Kuyken et al. (2016) offers hope that mindfulness-based therapies, as with the more traditional CT and CBT therapies developed before them, may help depressed patients significantly decrease depressive relapse rates.

Examples of Depressive Relapse in the Health Context

There are many potential examples of depression and depressive relapse in the health context. Moreover, this research and clinical literature is expanding rapidly, attracting increased attention from investigators, editors, and clinicians. For example, a recent "special section" of the *Journal of Consulting and Clinical Psychology* (Davila & Safren, 2017) focused on "sexual and gender minority health." For instance, an ambitious study presented in this special section, by Choi, Batchelder, Ehlinger, Safren, and O'Cleirigh (2017), illustrates recent work on depression and depressive relapse in the context of important health behaviors. The investigators used network analysis to investigate the comorbidity of depression, PTSD, and sexual risk behaviors in the context of sexual minority men who had histories of trauma. Their sample included 296 sexual minority men who were HIV negative and living in urban environments. The findings suggested that comorbid depression and PTSD, and relapse for either disorder, were strongly related to increases in sexual risk behaviors, which in turn are often related to significant health problems and diseases (Choi et al., 2017).

Another example is a recent study by Desautels, avard, Ivers, Savard, and Caplette-Gingras (2018), which evaluated treatment options in anticipation of enhancing relapse prevention, among depressed cancer patients. This study compared the efficacy of treating breast cancer patients that had considerable depressive symptoms with either CT or bright light therapy. The design was a randomized controlled trial, with 62 breast cancer patients, and it included pre-, post-, and 6-month follow-up assessments. Although caution is warranted because of the relatively small sample of 62 participants, CT appeared to be efficacious for this group of cancer patients, compared with a wait list control group. The bright light therapy showed some promise for *briefly* reducing depressive symptoms among these patients, but it was not as consistently efficacious as CT across all depression measures or at the follow-up assessments. Moreover, bright light therapy appeared to be more vulnerable, than CT, to the enrolled patients having experiences with depressive relapse during follow-up. Extensions of this treatment approach to larger and more diverse cancer patient samples, and with longer follow-up assessments, could prove interesting. This bright light therapy approach may be particularly helpful in circumstances where the well-tested approaches of CT or CBT are not available, or not acceptable, to cancer patients.

Finally, some of the recent research that is relevant to depressive relapse investigates depression and other important health-related behaviors in the context of longitudinal research in the natural environment, rather than the randomized controlled trials that were highlighted earlier. An interesting example is the study by Trucco, Villafuerte, Hussong, Burmeister, and Zucker (2018). These investigators explored the longitudinal pathways to alcohol use and abuse among 426 adolescents who had genetic risk factors for addiction (e.g., their biological father had been charged with drunk driving and met diagnostic criteria for alcohol use disorder), which the researchers predicted would be moderated by depression and depressive relapse during the last wave of the study (adolescents aged 15–17 years). Thus, they predicted that depression would be related to more substance use and would essentially facilitate the expression of the genetic risk factors. Trucco et al. (2018) also predicted that ineffective coping methods for stress would be a moderator, related to greater substance use. It was found that ongoing depression (or depressive relapse), along with ineffective coping methods, appears to be a pathway that allows genetic risk factors to influence substance use and abuse. This study also represents some of the research trends toward excellence in clinical health psychology and behavioral medicine, noted in other entries in this volume. These trends include use of a large sample (N = 426, plus a comparison sample), which was followed longitudinally over many years (ages 3–17, in 5 waves), using multimodal and diverse measures (multi-method and multi-source) that included biological and psychological variables.

Discussion

Overview

Treatment effects often do not last. Patients and their healthcare providers are frequently surprised, and disappointed, that the psychological improvements and associated health benefits that may occur during, and soon after, acute psychological treatment will disappear over longer periods of time. Depression and depressive relapse are clear examples of this problem. Without evidence-based care, along with thorough attention to empirically supported relapse-prevention strategies, most depressed patients will experience relapse or recurrence within a few years of treatment completion. Clinical depression, such as major depressive disorder, is a chronic and relapsing condition. Recent studies suggest that depressive relapse can be reduced, even in high-risk populations such as older adults, through a combination of evidence-based therapies such as IPT, CBT, and antidepressant medication, along with maintenance follow-up care that can last several years.

In sum, four implications can be culled from this entry and the much broader research literature on depression and relapse in health contexts. Noted below are also a few of the specific relapse-prevention strategies for depression that are supported by empirical research (see Gotlib & Hammen, 2015; Hollon, Stewart, et al., 2005; Richards & Perri, 2010a, for reviews of this literature):

- This area struggles with clarifications and distinctions between “depressive symptoms” versus “severe clinical depression” meeting the diagnostic criteria of major depressive disorder in the *DSM-5* (APA, 2013; see Watson & O’Hara, 2017, for a recent discussion of assessment and diagnostic issues regarding depression). Patients, clinicians, and researchers will find it helpful to keep these distinctions in mind.
- Many of the randomized controlled trials and naturalistic longitudinal studies in this area are models of excellent research in terms of large and diverse samples, psychometrically sophisticated and multi-method measures, and long-term follow-up evaluations. This excellent research is helpful and inspiring.
- Research on relapse prevention for depression is growing rapidly. Examples of journals that regularly publish sophisticated randomized controlled trials on this topic include *Journal of Consulting and Clinical Psychology*, *JAMA Psychiatry* (formerly *Archives of General Psychiatry*), *American Journal of Psychiatry*, *British Journal of Psychiatry*, and general medical journals such as the *New England Journal of Medicine*, *JAMA*, and *The Lancet.*
- It appears that depressive relapse is likely. It seems that depression is associated with many health problems, and as such, screening for risk regarding depressive relapse, building in relapse prevention and maintenance treatment, and assessing for patient progress and durable improvement during follow-up evaluations are warranted.

Five Relapse-Prevention Strategies for Depression

1 *Teach patients effective coping skills.* Patients with severe depression will usually find it helpful to think about their personal problems more positively, regulate their emotion in a better manner, and behave more adaptively and strategically. Effective coping skills can accomplish these goals. Moreover, these coping skills may become durable (e.g., see studies by Hollon, DeRubeis, et al., 2005; Reynolds et al., 1999, 2006; for reviews see Hollon, Stewart, et al., 2005; Nezu, Nezu, Greenberg, & Salber, 2014; Richards & Perri, 2010a, 2010b).

2 *Accommodate the patient's circumstances, diversity, and membership in special populations.* As with any treatment, relapse-prevention strategies for depression will be most effective if they are tailored to the specific circumstances, diversity, and membership in special populations. For instance, a 75-year-old widowed Latina grandmother with chronic health problems, who is living in a nursing home but has frequent visits from her Latina daughter and grandchildren, may want a different relapse-prevention focus than a 29-year-old single Caucasian male, in relatively good physical health, but with chronic depression and alcohol abuse challenges. The vast research literatures on depression and health psychology include many examples where diversity, context, and special population membership make a huge difference (e.g., Davila & Safren, 2017, *JCCP* special issue; for reviews see Gotlib & Hammen, 2015; Smith, 2010).

3 *Assess carefully and follow-up thoroughly for the chronic health problems that are often associated with depression and depressive relapse.* As mentioned several times throughout this entry, depression is associated with other problems, including chronic health conditions and diseases such as coronary heart disease, cancer, arthritis, chronic pain, and neurological conditions such as multiple sclerosis. Depressive comorbidity with these health conditions usually has a negative impact on the patient, including more complicated treatment regimens, poorer adherence to medications and health promotion strategies, more risk for relapse and recurrence, and negative predictions for morbidity and mortality. Depressive relapse and recurrence will also have many negative impacts. Therefore, the comorbidity of depressive relapse and chronic health problems should be carefully assessed, thoroughly treated, monitored throughout follow-up, and considered for long-term continuation interventions, after acute treatment, which may prevent relapse (e.g., for studies see Frank et al., 1990, 2007; Nylen et al., 2010; O'Hara et al., 2000; e.g., for reviews see O'Hara et al., 2010; Richards, Cohen, Morrell, Watson, & Low, 2013; Smith, 2010).

4 *Carefully evaluate and intervene, as much as possible, with the depressed patient's social-support network.* Depression is typically a "socially based disorder," with disruption and dysfunction in close relationships at work and home being quite common in the more severe forms of depression. If a depressed patient's social world stays chaotic and not reinforcing, then it is almost inevitable that the patient will experience depressive relapse and recurrence. Depression disrupts close relationships, and dysfunctional relationships can lead to symptoms of depression (e.g., for reviews see Richards & O'Hara, 2014a; Richards & Perri, 2010a, 2010b; Stroud, Feinstein, Bhatia, Hershenberg, & Davila, 2014).

5 *Consider the patient's treatment preferences in relapse-prevention strategies.* Some patients prefer antidepressant medication regimens and consider the side effects minor or at a minimum tolerable. However, some patients dislike antidepressant medication and find the side effects very difficult to manage. A similar like–dislike relationship to treatment types can be observed with evidence-based psychotherapies. For example, many patients appreciate the strong evidence base of CBT, the relatively simple set of principles and goals, and the ease with which it can be combined with additional treatment strategies like activity scheduling, problem solving, skill building, and role-playing of challenging social interactions. Some patients, however, do not like the frequent homework assignments, the focus on cognitive errors and schema change, and the minimizing of some classic psychotherapeutic issues such as childhood and family psychodynamic issues, insight into personality styles, and transference. An analogous line of pros and cons, with different details, could be given for other evidence-based therapies, such as IPT. What is clear from the literature is that if a patient does not like their treatment, they are unlikely

to keep doing it after acute treatment ends (and this assumes they are engaged during acute treatment, which is often not the case). Thus, depressive relapse is likely to follow (e.g., for reviews see Gotlib & Hammen, 2015; Nezu et al., 2014; Richards & Perri, 2010a, 2010b).

Author Biographies

C. Steven Richards, PhD, is a professor of psychological sciences at Texas Tech University. His research interests include depression, clinical health psychology and behavioral medicine, comorbidity of health problems and psychopathology, self-control, and relapse prevention for depression. He has held 15 administrative positions during his faculty appointments at Texas Tech University, Syracuse University, and the University of Missouri–Columbia. Dr. Richards earned his PhD in clinical psychology at the State University of New York at Stony Brook (now Stony Brook University).

Lee M. Cohen, PhD, is dean of the College of Liberal Arts and professor in the Department of Psychology at the University of Mississippi. Dr. Cohen came to the University of Mississippi from Texas Tech University, where he served in a number of administrative roles including the director of the nationally accredited doctoral program in clinical psychology and the chair of the Department of Psychological Sciences. As a faculty member, he received several university-wide awards for his teaching and academic achievement. As a researcher, he received more than $1.5 million from funding agencies, including the US Department of Health and Human Services, the National Science Foundation, and the National Institutes of Health/National Institute on Drug Abuse. His research program examines the behavioral and physiological mechanisms that contribute to nicotine use, and he worked to develop optimal smoking cessation treatments. Dr. Cohen is a fellow of the American Psychological Association and the Society of Behavioral Medicine. He received his PhD in clinical psychology from Oklahoma State University.

Eating Disorders

Eliot Dennard

Department of Psychological Sciences, Texas Tech University, Lubbock, TX, USA

Eating disorders (EDs) refer to a group of disorders that are characterized by abnormal thoughts, feelings, and behaviors related to food and weight. These disorders often begin in adolescence and are much more common in females than males (American Psychiatric Association [APA], 2013). Individuals with EDs often struggle with other psychological concerns, including depression, anxiety, and substance use. Furthermore, EDs are also associated with medical complications. These factors make the treatment of EDs more complicated. This chapter includes an overview of EDs, including risk factors, comorbidity, complications, and treatment.

Types of Eating Disorders

Anorexia Nervosa

Anorexia nervosa (AN) describes a disorder characterized by self-starvation and body image disturbance. To be diagnosed with AN, an individual must meet the following criteria according to the *Diagnostic and Statistical Manual of Mental Disorders-5* (DSM-5): restriction of caloric intake leading to a low body weight, a fear of gaining weight, and body image disturbance (APA, 2013). AN is a relatively rare psychiatric disorder. Prevalence estimates of AN vary, but one recent nationally representative survey found the lifetime prevalence rates of AN to be 0.9% for women and 0.3% for men (Hudson, Hiripi, Pope, & Kessler, 2007).

Bulimia Nervosa

Bulimia nervosa (BN) is characterized by episodes of binge eating followed by purging. According to the APA (2013), to be diagnosed with BN, an individual must meet the following criteria: frequent episodes of binge eating followed by engaging in "compensatory

The Wiley Encyclopedia of Health Psychology: Volume 3: Clinical Health Psychology and Behavioral Medicine,
First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

behaviors," and self-evaluation that is heavily dependent on one's weight and size. To be considered an eating binge, the individual must feel a loss of control over eating, which results in the individual eating an unusually large amount of food in short period of time. Compensatory behaviors are designed to rid the individual of the calories just consumed and can include behaviors such as self-induced vomiting, laxative and diuretic use, and excessive exercise. These symptoms must have occurred at least once a week over the course of 3 months (APA, 2013). The lifetime prevalence estimates for BN are 1.5% among women and 0.5% among men (Hudson et al., 2007).

Binge Eating Disorder

Binge eating disorder (BED) is characterized by eating binges without the use of compensatory behaviors. There also must be distress experienced related to the disordered eating (APA, 2013). The disordered eating must have occurred at least twice a week for 6 months to be classified as BED (APA, 2013). Lifetime prevalence estimates of BED are 3.5% for women and 2.0% for men, which is higher than that of AN and BN (Hudson et al., 2007).

Other Feeding and Eating Disorders

There are several other feeding and EDs described in the DSM-5 (APA, 2013). Pica involves the ingestion of "nonnutritive, nonfood substances" (APA, 2013, p. 329). Rumination disorder involves the regurgitation of food that is either rechewed and swallowed or spit out. Avoidant/restrictive food intake disorder is characterized by an avoidance of food, including sensory stimulation related to food and concern about negative consequences of eating food. This often results in malnutrition, weight loss, and the need for nutritional supplementation. Avoidant/restrictive food intake disorder is distinguished from AN in that with avoidant/restrictive food intake disorder, there is not the same fear of weight gain nor is there body image disturbance (APA, 2013). These other feeding and EDs, particularly Pica, are often comorbid with intellectual disabilities. For the remainder of this chapter, the primary focus will be on AN, BN, and BED.

Subthreshold Levels of Eating Disorders

The current method of defining EDs in the DSM-5 uses a categorical approach, which means that individuals either meet diagnostic criteria or they do not. However, both in research and in clinical practice, individuals presenting with eating concerns often do not meet full diagnostic criteria but still experience significant distress related to food and body image. As such, disordered eating is often conceptualized as a continuum of behaviors and feelings about weight and food, rather than the traditional categorical approach. By taking a continuum approach to understanding disordered eating, EDs can be understood as all of the gray area between normal eating and severe, diagnosable EDs. In the research literature, varying levels of disordered eating presentations are often described as subthreshold EDs and partial EDs. For instance, according to Stice, Marti, Shaw, and Jaconis (2009), a subthreshold ED is defined by meeting all of the criteria for a diagnosable ED, except not at the levels specified by the diagnostic criteria. For example, an individual who engages in binging and purging behaviors less than once a week (as opposed to the once a week required by diagnostic standards) would be considered to have subthreshold BN. Similarly, an individual who only meets a subset of the required symptoms for diagnosis would be considered to have a partial ED (Stice et al., 2009).

A substantial portion of individuals that struggle with disordered eating have subthreshold and partial levels of EDs, as compared with the relatively small amount of individuals with diagnosable EDs. For example, Stice et al. (2009) found that 12% of adolescents fall somewhere on the continuum of disordered eating, which is substantially more than the prevalence of full threshold EDs, which is around 2%. Therefore, it is important for clinicians and researchers to consider the full continuum of disordered eating in both research and practice.

Risk Factors

The research literature has identified a number of factors that contribute to the development of disordered eating symptoms. Understanding different risk factors can hopefully lead to more targeted prevention efforts, as well as better treatment approaches. Although a plethora of research literature has described different risk factors for developing disordered eating, only a small portion of that is presented here.

Biological and Genetic Risk Factors

Like many psychological disorders, EDs also seem to have biological and genetic factors that contribute. In Jacobi, Hayward, de Zwaan, Kraemer, and Stewart Agras' (2004) review article of risk factors of EDs, several twin studies are cited, almost all of which found a higher concordance rate of EDs in monozygotic twins, as compared with dizygotic twins. These finds suggest that there is a genetic component to EDs (i.e., EDs are not solely caused by environmental factors). Recent advances with gene mapping have found several genes that seem linked with EDs (Jacobi et al., 2004). There will undoubtedly be further advances in understanding EDs from a biological perspective, which may lead to advances in pharmacological treatment of EDs.

Psychological, Social, and Cultural Risk Factors

The research literature provides evidence for a number of psychological and social risk factors that contribute to disordered eating. Western culture in particular prizes the female body and strongly values thinness (Striegel-Moore & Bulik, 2007). In addition, having weight concerns has been found to predict subthreshold and full threshold EDs (Killen et al. as cited by Keel & Forney, 2013). Some models even posit that cultural ideals surrounding thinness lead to having weight concerns and body dissatisfaction, which then leads to disordered eating (e.g., see Striegel-Moore & Bulik, 2007). However, individuals from other cultural backgrounds, including Latina women, also develop EDs (Marques et al., 2011). Thus the relationships among cultural variables, body dissatisfaction, weight concerns, and disordered eating are complicated and certainly not fully understood.

Several other risk factors have been supported in the literature. Both negative affect/negative emotionality and perfectionistic tendencies have been found to predict disordered eating (Keel & Forney, 2013). High levels of depressive symptoms have also been found to predict disordered eating (Dennard & Steven Richards, 2013).

Trauma has also been found to be a significant risk factor for developing disordered eating. Brewerton's (2007) review of the literature suggested that childhood sexual abuse, as well as other forms of abuse and neglect, is significantly associated with EDs, particularly BN. In addition, trauma increases comorbidity in those with EDs (Brewerton, 2007). There are many more hypothesized risk factors for the development of an ED, ranging from dysfunctional family-of-origin experiences to cognitive rigidity (see Jacobi et al., 2004 for a more complete overview). Understanding different risk factors will hopefully lead to more successful prevention and treatment efforts.

Diversity Considerations

Gender and cultural factors are an important consideration to explore in their relation to EDs. Several studies have found that the prevalence of disordered eating is similar in women of different ethnicities (e.g., Marques et al., 2011). However, the expression and cluster of symptoms may be impacted by gender and/or cultural factors. For example, one study utilized Caucasian, Latina, and African American female undergraduate students (Gordon, Castro, Sitnikov, & Holm-Denoma, 2010). Participants were asked their perception of the ideal body type for members of their cultural group. Results indicated that Caucasian women perceived that slimmer body types were ideal for their ethnicity than both Latinas and African Americans. Latinas indicated that their cultural group preferred a slimmer body than the African American participants. Participants also indicated their personal ideal body type (as opposed to ideal body types of the culture at large). There were no differences between Caucasian and Latina women on personal ideal body type. African American women had larger personal ideal body types than did the other two groups (Gordon et al., 2010). This study highlights how cultural considerations may affect body image concerns.

In addition, acculturation levels and acculturative stress may play a role in EDs in individuals from ethnic minority groups. In a sample of Mexican American women with and without EDs, a stronger orientation toward “Anglo American” culture was predictive of disordered eating, whereas a stronger identification with and orientation toward Mexican culture was not associated with disordered eating (Cachelin, Phinney, Schug, & Striegel-Moore, 2006). Acculturative stress, which is defined “as the difficulties and psychological toll that arise from the process of adapting to a new cultural context,” is also an important factor to consider (Warren & Rios, 2012, p. 4). In a sample of Latino men, acculturative stress was correlated with body image disturbance, while acculturation was not (Warren & Rios, 2012). Therefore, it may be important to consider how acculturation and acculturative stress may contribute to the development of an ED.

Gender differences also seem to impact EDs. One indicator of an ED is an individual’s dissatisfaction with his or her weight and body shape. However, this particular symptom may present somewhat differently in men than it does in women. For example, in a sample of undergraduate men and women with and without EDs, Ousley, Cordero, and White (2008) found that both men and women with EDs showed concern about body shape and tone. The women with EDs showed greater concern with weight and fat, while the men showed greater concern with muscle tone.

Gender differences are also evident in individuals hospitalized for AN. Over the period of 16 years, data from both male and female patients admitted to a hospital-based treatment program were analyzed (Gueguen et al., 2012). The males in this study presented for treatment later, had higher mortality rates, were more likely to have been overweight in the past, and were less likely to have a history of suicidality. The females in the study were more likely to be involved in a romantic relationship and living with a partner. Therefore, there may be differences in the interpersonal functioning between men and women with EDs (Gueguen et al., 2012).

Among males with EDs, sexual orientation is correlated with disordered eating. One study found that the rates of EDs are higher among men that identify as gay or bisexual than among men that identify as heterosexual (Feldman & Meyer, 2007). Further research will contribute to the understanding of how diversity-related factors impact both the development and treatment of EDs.

Complications

EDs are often associated with significant health consequences, which often necessitates monitoring by a physician. AN, in particular, often has very severe health consequences associated with malnutrition. Cardiac complications, including sinus bradycardia, decreased heart rate, and mitral valve prolapse, are often serious and are associated with at least one-third of the deaths related to EDs (Katzman, 2005). Issues with bone mass, including osteopenia and osteoporosis, are also associated with AN. The effects of losing bone mass are often permanent (Katzman, 2005). Several endocrine consequences, including amenorrhea, hypoglycemia, and thyroid abnormalities, are also potential health consequences of AN (Mehler & Brown, 2015). AN is also associated with reproductive consequences, including an increased risk of miscarriage, lower weight babies, and infertility (Mehler & Brown, 2015). Finally, in cases of severe AN, changes in brain volume can be seen using MRI technology. These changes are presumed to be a result of malnutrition (Mehler & Brown, 2015).

Cardiovascular issues, such as arrhythmias, hypotension, and bradycardia, are also associated with BN (Casiero & Frishman, 2006). Esophageal complications are also associated with BN and can even become life threatening in the case of esophageal rupture (Mehler, 2011). Many methods of purging, including laxative and diuretic use, often produce electrolyte imbalances, which require medical intervention (Mehler, 2011).

BED is also associated with health complications. One potential implication of binge eating is an increase in body weight, which in itself is associated with negative health outcomes. In one study, obese women that engaged in binge eating had higher rates of medical disorders (e.g., hypertension) than their obese counterparts that did not engage in binge eating (Bulik, Sullivan, & Kendler, 2002). One longitudinal study found that those with BED are at greater risk of developing components of metabolic syndrome (i.e., type 2 diabetes, hypertension, dyslipidemia) when compared with a comparison group individuals of similar body mass index (Hudson et al., 2010). Thus, BED seems to have health complications above and beyond the health risks of being overweight.

Individuals with EDs also have a higher mortality rate as a result of these health consequences and an increased rate of suicide. In fact, AN has the highest mortality rate of any psychiatric disorder. Mortality rates for AN have been found to be around 5% (Steinhausen, 2002). Because of the significant health consequences of EDs, early intervention and medical monitoring are crucial.

Comorbidity

EDs are associated with increased rates of comorbidity with other psychiatric diagnoses, including mood disorders, anxiety disorders, and substance use disorders. Understanding and evaluating individuals for comorbid conditions is especially important because it likely impacts both the severity of the ED and the treatment approach used. For instance, one study of adolescent females with EDs found that the participants with comorbid depression and anxiety had significantly more hospitalizations, suicide attempts, and higher scores on subscales of self-reported measures (e.g., eating concerns scores, body dissatisfaction scores, perfectionism, etc.) (Brand-Gothelf, Leor, Apter, & Fenning, 2014).

Rates of anxiety disorders in individuals with EDs are higher than in individuals without EDs. In one study, 63.5% of participants with EDs "were diagnosed with at least one lifetime anxiety disorder" (Kaye, Bulik, Thornton, Barbarich, & Masters, 2004, p. 2217). Obsessive–compulsive disorder was the most frequently diagnosed among the sample (40%), and social anxiety disorder was the next most frequently diagnosed anxiety disorder in the sample (20%). The rates of different anxiety disorders did not vary depending on ED diagnosis (i.e., AN and BN) (Kaye et al., 2004).

Many studies have found a strong association between depressive and disordered eating symptoms. The rates of comorbidity between eating and mood disorders, particularly depression, may be as high as 94% (Blinder, Cumella, & Sanathara, 2006). Among high school students, strong positive correlations have also been found between disordered eating and depression (Santos, Steven Richards, & Kathryn Bleckley, 2007). Depressive symptoms have also been found to predict disordered eating in a sample of college females (Dennard & Steven Richards, 2013).

Substance use disorders are often common among individuals with EDs, particularly among those with BN. One study found that individuals with BN were three times more likely to have substance use concerns than individuals with AN (Blinder et al., 2006). This comorbidity is particularly important, as alcohol and substance use disorders are a significant predictor of mortality for individuals with AN (Keel et al., 2003).

Treatment

Conventional wisdom suggests that utilizing a treatment team approach to treat EDs is the most beneficial. EDs are complex disorders that affect an individual psychologically, nutritionally, and medically. As such, EDs are often best treated by a team of professionals collaborating to provide holistic care. Typical members of a treatment team consist of a therapist or psychologist, nutritionist or dietician, and a physician. Therefore, individuals with EDs often receive psychotherapy, nutritional counseling, and medical monitoring. Treatment is generally not only provided on an outpatient basis but can also include partial hospitalization and inpatient/residential treatment.

Psychotherapy

The research supporting psychological therapies for the treatment of EDs, particularly AN, is disappointingly sparse. This is likely due to the low prevalence of the disorder, medical complications requiring hospitalization that interfere with study completion, extended length of time needed for treatment, and individual's negative attitudes related to recovery (Wilson, Grilo, & Vitousek, 2007). However, recent studies are beginning to show promise in treating both AN and BN with psychotherapy.

Anorexia Nervosa

Few studies have examined the efficacy of psychological therapies for AN. Many of the studies on the treatment of AN have found low recovery rates and often inconclusive results. High levels of attrition within these studies are another complication of conducting randomized controlled trials with this population (Wilson et al., 2007). Despite the limited research on treating EDs, there are several psychological therapies often used, and some of those therapies have empirical support.

One randomized controlled trial compared interpersonal therapy (IPT), cognitive behavior therapy (CBT), and nonspecific supportive clinical management therapy for women with AN. The nonspecific supportive clinical management provided support, praise, advice, and education related to healthy eating behaviors. This treatment also focused on fostering a strong therapeutic alliance between the patient and clinician. The results of the study showed that the group of patients receiving the nonspecific supportive clinical management did as well as, and even better than, those treated with interpersonal or cognitive behavioral therapy (McIntosh et al., 2005).

Another randomized controlled trial compared a novel therapy for AN, termed the Maudsley model of AN treatment for adults (MANTRA), with "specialist supportive clinical management" (SSCM) for adults with AN (Schmidt et al., 2015). The MANTRA treatment utilized elements of both CBT and IPT to target traits such as obsessiveness, avoidance, and anxiousness that are often central in AN. The treatment also incorporated aspects of motivational interviewing. The other treatment arm of the study utilized SSCM, which included clinical management (e.g., providing advice and psychoeducation) and supportive therapy. Participants completed outcome measures at baseline, 6, and 12 months. Both groups showed substantial improvement in body weight, mood, and other psychological factors at the completion of treatment. There were no differences in body mass index in either treatment group following treatment. Many of the other study outcomes, including assessments related to shape/weight concern, depression, and anxiety, were similar in both treatment groups. However, those in the MANTRA group reported higher treatment acceptability and credibility than those in the SSCM group. Furthermore, MANTRA seemed more effective in increasing body mass index in the most severely underweight participants. The results of this study suggest that a variety of therapeutic approaches may be helpful in treating AN (Schmidt et al., 2015).

Following weight restoration in underweight patients with AN, outpatient CBT has been shown to have some benefits. Pike, Walsh, Vitousek, Wilson, and Bauer (2003) utilized a sample of women who had completed inpatient treatment for AN and achieved a weight gain of at least 90% of an ideal body weight. Participants were randomly assigned to one of two treatment conditions, either CBT or nutritional counseling. Both treatments were administered individually for 50 sessions. The results found that the patients receiving CBT relapsed later in treatment (if at all) than those receiving nutritional counseling. Furthermore, the number of patients prematurely ending treatment before session 10 was higher in the nutritional counseling group. Thus, it appears that CBT is beneficial and is delaying or preventing relapse in individuals who previously completed inpatient treatment for AN (Pike et al., 2003).

Family therapy is often the treatment of choice for adolescents with AN, and it has also received considerable empirical support. One such study compared family-based treatment (FBT) with adolescent-focused therapy for adolescents with AN (Lock et al., 2010). The FBT was conducted in three phases, including a weight restoration phase, followed by a transition phase when decisions related to food and weight were given back to the adolescent, and ending with a phase designed to enhance the relationship between the adolescent and the parent. The adolescent-focused therapy arm of the study focused on helping adolescents understand, identify, and tolerate emotions, as opposed to using starvation as a means of regulating emotion. Rates of symptom remission were similar between the two therapies by the end of the study. However, at follow-up evaluations (6- and 12-month posttreatment), the FBT group had superior outcomes (Lock et al., 2010).

Despite the limited empirical support for treating AN, the American Psychiatric Association's (APA) Practice Guidelines for treating AN include "psychodynamically informed" therapy during the initial refeeding and weight gain process. Therapy should incorporate "empathic understanding, explanations, praise for positive efforts, coaching, support, encouragement, and other positive behavioral reinforcement" (p. 16). Providing these elements in therapy may increase the patient's comfort in therapy, which could potentially reduce premature termination of therapy. For children and adolescents with AN, the guidelines recommended the Maudsley model of family therapy, which is similar to the FBT previously described (APA, 2006). This approach generally requires around 20 sessions over 12 months. The initial phase of treatment helps restore weight in the patient with AN by having the parents control and regulate their child's caloric intake. In subsequent phases of treatment, the patient is gradually allowed more autonomy in his/her eating choices (Pike, Gianini, Loeb, & Le Grange, 2015). Following weight restoration, the guidelines recommend CBT to prevent relapse and note that IPT and psychodynamically oriented therapy are also often used with success in clinical practice (APA, 2006).

Bulimia Nervosa

For BN, both CBT and IPT have empirical support. Generally, CBT for BN requires 16–20 sessions. Aims of the treatment include CBT approaches to increase motivation, modify eating patterns, reduce shape/weight concerns, and reduce likelihood of relapse (Wilson et al., 2007). CBT for BN eliminates binging and purging behaviors in approximately 30–50% of cases (Wilson et al., 2007).

Several interventions are often used in CBT for BN. Initial stages of therapy often focus on increasing patient motivation and engagement in the treatment process. Self-monitoring of eating behaviors and associated behaviors, thoughts, and feelings is another initial component of CBT for BN. Another essential element of CBT for BN is psychoeducation. During this process, the clinician provides the patient with information about the harmful effects of purging, laxative use, etc., as well as how those behaviors are ineffective weight management strategies. Subsequent stages of treatment focus on addressing shape and weight concerns, dietary rules, low self-esteem, and interpersonal concerns (Murphy, Straebler, Cooper, & Fairburn, 2010).

CBT has also been shown to be superior to psychoanalytic therapy in treating BN. For example, a recent randomized controlled trial assigned 70 patients with BN to receive either 2 years of weekly psychoanalytic psychotherapy or 20 sessions of CBT (Poulsen et al., 2014). Although both treatments resulted in improvement, those receiving CBT fared much better than those receiving psychoanalytic psychotherapy. Abstinence from binging and purging behaviors was achieved after 5 months for 42% of the patients in the CBT group, compared with 6% of the patients in the psychoanalytic group. At the end of the 2-year study, abstinence of binging and purging was maintained by 44% of patients in the CBT group and only 15% in the psychoanalytic group (Poulsen et al., 2014).

The results found in randomized clinical trials using CBT for BN seem to translate to clinical practice as well. For example, Waller et al. (2014) utilized CBT to treat individuals with BN in an outpatient therapy clinic. There were few exclusion criteria, and the implementation of the therapy was less manualized than in typical randomized controlled trials. The results of the study showed a remission rate of close to 50%, which is similar to the results observed in randomized clinical trials (Waller et al., 2014). Thus, CBT seems effective in "real-world" practice as well.

Dialectical behavior therapy (DBT), which is often considered a "third-wave CBT," also shows some promise in the treatment of BN. For example, in a small study, 30 participants with BN were assigned to either 20 sessions of DBT or a 20-week wait list group. The DBT used was specifically designed to teach emotion-regulation skills. Those in the DBT group showed much greater reductions in binging and purging episodes than did their wait list group counterparts (Shafer, Telch, & Agras, 2001).

There is also empirical support for the use of IPT in treating BN. IPT was originally developed for treating depressive disorders and focuses on modifying interpersonal patterns that contribute to disordered eating (Wilson et al., 2007). One study compared a group of participants that completed CBT with a group that had completed IPT. The results showed no significant differences between the groups at the 1-year follow-up. However, measurements taken at the end of treatment showed greater improvement in the group treated with CBT (Agras, Walsh, Fairburn, Terrance Wilson, & Kraemer, 2000). Thus, IPT seems to have equivalent long-term results and may also be an effective choice for treating BN, but CBT may show quicker results.

The APA's Practice Guidelines (2006) for treating BN suggest using CBT to address acute symptoms. IPT is also recommended as a possible initial therapy, or for patients that do not respond to CBT. In adolescents, family therapy is suggested, and couple's therapy is suggested for adults experiencing conflict in romantic relationships (APA, 2006).

Medical Management

Medical monitoring by a qualified medical professional with experience treating EDs is another component of treatment. A medical provider's role includes assessing degree of malnutrition and providing medical supervision and monitoring during the individual's treatment process (Golden et al., 2015). This includes assessment and management of common physical complications of EDs (e.g., cardiac complications, electrolyte imbalances). More severe EDs often require inpatient medical treatment. Some possible reasons for hospitalization include severe electrolyte disturbances, hypothermia, food refusal, extreme low weight (i.e., weighing less than 75% of an ideal body weight), physiological instability, and suicidal ideation (Golden et al., 2015).

In addition to medical monitoring, pharmacotherapy may also be beneficial for individuals with BN. Flament, Bissada, and Spettigue (2012) reviewed randomized controlled trials utilizing monoamine oxidase inhibitors (MAOIs), tricyclic antidepressants (TCAs), and selective serotonin reuptake inhibitors (SSRIs). Results showed that all three classes of medication were more effective than a placebo in reducing binge eating (Flament et al., 2012). Topiramate, an antiepileptic drug, has been shown to reduce binge eating in individuals with BED. When compared with group of participants receiving a placebo, the individuals receiving topiramate showed a significant reduction in several outcome measures, including binge frequency and weight (McElroy et al., 2003).

Nutritional Therapy

A registered dietician is another integral part of the treatment team. Registered dieticians can provide nutritional therapy to individuals with EDs and focus on food-related issues faced by the individual with an ED. The goals of nutritional therapy are to provide the individual with psychoeducation related to nutrition, develop a meal plan, and begin to develop healthier eating patterns. Dieticians can also be instrumental in monitoring the possible effects of malnutrition (Henry & Ozier, 2006).

Partial Hospitalization

Partial hospitalization programs (PHP) are also an option for the treatment of EDs. In these programs, patients are usually provided with 8–12 hr/day of treatment that usually includes individual therapy, group therapy, nutritional therapy, and medical monitoring. In addition, patients are supervised during meal times while at the program. Patients return home on the evenings and weekends. Alternatively, some programs offer "supportive housing" during the patient's time in the PHP and while transitioning out of PHP (Tantillo, MacDowell, Anson, Taillie, & Cole, 2009).

Residential Treatment

Residential treatment programs offer more intensive treatment in a nonhospital setting. Most treatment centers adopt an integrative approach to treatment, incorporating CBT, IPT, and DBT. Individuals receive therapy in a variety of formats while in residential treatment, which includes both individual and group therapy. Many programs also implement 12-step work, art therapy, yoga, and meditation. One potential disadvantage of residential treatment is that it often requires a significant financial commitment and is sometimes not covered by health insurance (Frisch, Herzog, & Franko, 2006).

Prognosis

Although there are numerous treatment options for EDs, the prognosis is often discouraging. One longitudinal outcome study of individuals with AN found that 47.5% of the individuals in the study still met criteria for AN, BN, or ED-NOS at 12-year follow-up (Fitcher, Quadflieg, & Hedlund, 2006). Early intervention is especially important in treating EDs. As research advances, more knowledge will possibly help facilitate better methods of treating EDs.

Conclusion

Although EDs have been described as far back as the dark ages and into the Renaissance, research related to etiology and treatment of EDs is still somewhat lacking. However, research has determined several potential contributors to developing disordered eating, including biological, social, cultural, and psychological correlates. As scientific research advances, there will likely be a deeper understanding of what causes EDs, which will likely lead to more efficacious treatments. Currently, several treatment strategies indicate the possibility of a good prognosis for individuals suffering from EDs. Having professionals from multiple fields working with individuals with EDs seems to be the best approach, as these individuals have psychological, physical, and nutritional needs that must be addressed.

Author Biography

Eliot Dennard, PhD, is a counseling psychologist in private practice. She received her undergraduate degree from the University of Oklahoma and her masters and doctoral degrees from Texas Tech University. Although she primarily works in clinical practice, her previous research focused on predictors of disordered eating and gender and cultural differences in eating disorders.

Headaches

Amy Wachholtz, Adam Harris, and Amy Frers

Department of Psychology and University Health Sciences Center,
University of Colorado Denver, Denver, CO, USA

Worldwide, headache disorders are a painful and disabling condition. According to the World Health Organization, headache disorders are the third leading cause of worldwide years lost due to disability (Institute for Health Metrics and Evaluation, 2013). The experience of a headache can fall into one of two categories. The first category is called a “primary” headache diagnosis. This is due to the headache as the sole diagnosis (e.g., migraine, tension, cluster). These forms of headaches are painful, and can be very disabling, but generally are benign. In the other category, the headache is “secondary” because rather than being the primary focus of treatment, the headache is a symptom of another illness, injury, or event. There are hundreds of reasons why someone may experience a secondary headache, from benign allergy-related sinus pressure to the more serious condition of stroke.

Tension Headaches

Epidemiology

Tension-type headache (TTH) is the second most prevalent of all disorders (Vos et al., 2012). The most commonly used diagnostic criteria (see Table 1 for diagnostic criteria) for TTH is the International Classification of Headache Disorders (ICDH), created by the International Headache Society (Headache Classification Committee of the International Headache Society, 2013).The annual prevalence of episodic tension-type headache (ETTH) is estimated at 38%, and the annual prevalence of chronic tension-type headache (CTTH) is 2–3% (Schwartz, Stewart, Simon, & Lipton, 1998). Its peak prevalence is between the ages of 30 and 39, and it is slightly more common among women than men (ratio of 5 : 4) (Chowdhury, 2012).

For the 5.4% of workers in the United States who reported losing productive time due to headache, TTH accounted for about 70% of this reduction. This translates to an average of 2.9 hours per week of reduced performance at work and an annual estimated cost of

First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

Table 1 Tension-type headache diagnostic criteria.

	Infrequent episodic TTH	*Frequent episodic TTH*	*Chronic TTH*
Frequency	10+/year; <1/month	1–14 days/month for more than 3 months	15+ days/month for more than 3 months
Duration	30 min to 7 days	30 min to 7 days	Hours to days, or unremitting
Additional criteria	At least two of the following four characteristics: 1. Bilateral location 2. Pressing or tightening (non-pulsating) quality 3. Mild or moderate intensity 4. Not aggravated by routine physical activity such as walking or climbing stairs	At least two of the following four characteristics: 1. Bilateral location 2. Pressing or tightening (non-pulsating) quality 3. Mild or moderate intensity 4. Not aggravated by routine physical activity such as walking or climbing stairs	At least two of the following four characteristics: 1. Bilateral location 2. Pressing or tightening (non-pulsating) quality 3. Mild or moderate intensity 4. Not aggravated by routine physical activity such as walking or climbing stairs
	Both of the following: 1. No nausea or vomiting 2. No more than one of photophobia or phonophobia	Both of the following: 1. No nausea or vomiting 2. No more than one of photophobia or phonophobia	Both of the following: 1. Neither moderate or severe nausea nor vomiting 2. No more than one of photophobia, phonophobia, or mild nausea

$19 billion, adjusted for inflation (Schwartz, Stewart, & Lipton, 1997). The annual estimated cost of TTH for adults in the European Union is 21 billion Euros (M. Linde et al., 2012).

Etiology

A study of headache sufferers found that the most common precipitating factors they reported were stress/tension, not eating on time, lack of sleep, and fatigue (Spierings, Ranke, & Honkoop, 2001). However, these factors were reported at similar rates by both patients diagnosed with TTH and those diagnosed with migraine, so the authors note that they should be considered general causes of headache rather than causes of TTH specifically. (Permission to reproduce granted by: __________________ [copyright holder, on ______ [date].)

Stress was the most frequently reported precipitating factor, and a stressful task can induce headaches in TTH sufferers at a far greater rate than it induces headaches in those without a diagnosis of TTH (Cathcart, Petkov, Winefield, Lushington, & Rolan, 2010). This difference may be due to increased pain sensitivity in people with TTH. In studies of the effects of stress-inducing tasks on headache, CTTH patients had lower pain thresholds than healthy participants at the beginning of the experiment, and they also experienced a greater reduction in pain threshold after the stressful task (Cathcart et al., 2010; Cathcart, Petkov, & Pritchard, 2008).

Tenderness of the pericranial (head and neck) muscles is thought to play a large role in TTH. Patients with TTH have increased pericranial muscle tenderness (Aaseth, Grande, Lundqvist, & Russell, 2014). It is possible that poor posture contributes to pericranial muscle tenderness (Freitag, 2013). Additionally, there are myofascial (connective) tissue trigger points in the head and neck that may be more electrically active (and therefore more sensitive to pain) in people with TTH (Fernández-De-Las-Peñas, Cuadrado, & Pareja, 2007).

The temporomandibular (jaw) joint has also been implicated in TTH. People with temporomandibular joint dysfunction (TMJD) are more likely to have TTH (Speciali & Dach, 2015). Further, TMJD patients treated with botulinum toxin A (Botox) have displayed a reduction in TTH symptoms (Pihut, Ferendiuk, Szewczyk, Kasprzyk, & Wieckiewicz, 2016).

Treatments

Biofeedback training has been studied extensively for the treatment of TTH. A meta-analysis by Nestoriuc, Rief, and Martin (2008) analyzed 53 studies of patients with any form of TTH that were treated with biofeedback training. The interventions consisted of an average of 11 sessions. The studies used structured headache diaries to assess their primary outcome measure, headache pain, which consists of headache frequency, duration, and intensity. The analysis found a medium-to-large effect size for all studies—that is, comparisons between biofeedback and any control. There was a medium-to-large effect size when biofeedback was compared with no treatment, a medium effect size compared with placebos, and a small effect size compared with relaxation interventions. In addition, 18 studies measured follow-up headache pain. Follow-ups ranged from 3 to 60 months, and the average follow-up was 14.6 months. The authors found a medium-to-large effect size of biofeedback treatment. Some secondary measures were assessed as well: with biofeedback treatment, medication intake was reduced with a small-to-medium effect size, and there were low dropout rates that indicate a high level of acceptability for biofeedback treatment.

Relaxation training involves bringing awareness to tense muscles in the body (Sun-Edelstein & Mauskop, 2012). There are two main types of relaxation training: progressive relaxation training (PRT) and autogenic training. PRT involves intentionally tensing and releasing individual muscle groups one by one. Autogenic training uses imagery and body awareness to relax the muscles. A systematic review by Verhagen, Damen, Berger, Passchier, and Koes (2009) found mixed results for the efficacy of relaxation training for the treatment of TTH. Two of the studies reviewed found significant improvement of TTH compared with placebo and no treatment groups, and four studies found no significant difference.

Evidence is mixed for the efficacy of cognitive behavioral therapy (CBT) for the treatment of TTH, but several studies have demonstrated that CBT is more efficacious than no treatment or placebo and that it can reduce TTH by 30–50% (Christiansen, Jürgens, & Klinger, 2015). It has been suggested that CBT is most effective for patients with psychological or environmental stressors that contribute to their TTH, and some studies have found that it is more effective when combined with biofeedback and relaxation training (Freitag, 2013; Sun-Edelstein & Mauskop, 2012).

Manual therapy (e.g., massage, chiropractic therapy) is commonly used for a variety of types of pain. Lozano López, Mesa Jiménez, de la Hoz Aizpurúa, Pareja Grande, and Fernández de las Peñas (2016) conducted a systematic review of manual therapy for patients with frequent or chronic TTH. There were two primary types of manual therapy used: articulatory techniques that involve moving a joint through its full range of motion and soft tissue therapy where pressure is applied to the body as in massage. Some studies used both. There was a significant decrease in headache frequency in all studies. Headache intensity decreased in 8 of the 10 studies. Analgesic use decreased in only one of five studies. Follow-up periods were relatively short in some of the studies, limiting conclusions about the lasting effects of manual therapy.

A Cochrane review by K. Linde et al. (2016) investigated the efficacy of acupuncture for the treatment of chronic and episodic TTH. Twelve studies (2,349 participants) were included. The interventions included between 6 and 15 sessions, and the sessions occurred at least once per week. Several studies found that acupuncture reduced headache frequency and intensity for 9–29% more people than did sham treatments and control conditions. However, the studies that compared acupuncture with other forms of treatment were judged to be too low of quality to draw strong conclusions. Therefore, the research is inconclusive about the effectiveness of acupuncture compared with other treatments for TTH. A review by Hao, Xue, Dong, and Zheng (2013) similarly found mixed and inconclusive results. However, they found that electroacupuncture, in which an electrical current is passed through the acupuncture needles, may be more efficacious than manual acupuncture.

Acetaminophen (paracetamol) is a commonly used over-the-counter drug that is taken orally for headaches. A Cochrane review by Stephens, Derry, and Moore (2016) examined the results of studies of patients with frequent ETTH, most of whom took the standard adult dose of 1,000 mg. Only 5–15% more patients received a benefit from using acetaminophen compared with those who took a placebo, across 23 studies (8,079 participants). Eleven studies (5,605 participants) found no significant difference in adverse events between participants taking acetaminophen and a placebo. These findings indicate that a small but consistent group of people get a benefit from taking acetaminophen. It is unclear why this group benefits while others do not.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are another type of over-the-counter medication commonly taken for headaches. A Cochrane review by Derry, Wiffen, Moore, and Bendtsen (2015) examined the effects of a 400 mg dose of ibuprofen, a type of NSAID, on patients with frequent ETTH. Only 7–17% more patients received a benefit from using ibuprofen compared with those who took a placebo, across 12 studies (3,094 participants). Eight studies (1,645 participants) found no significant difference in adverse events between participants taking ibuprofen and a placebo. These findings are similar to those for acetaminophen and suggest that NSAIDs not only may be effective for slightly more people than acetaminophen but also not substantially better than behavioral treatments.

Selective serotonin reuptake inhibitors (SSRIs) and serotonin–norepinephrine reuptake inhibitors (SNRIs) are antidepressants commonly used to treat depression and anxiety. They are also sometimes prescribed for the treatment of chronic TTH. A Cochrane review by Banzi et al. (2015) evaluated the results of 8 studies (412 participants) that used an SSRI or SNRI to treat patients with chronic TTH. The SSRIs used were citalopram, sertraline, fluoxetine, paroxetine, and fluvoxamine; the SNRI was venlafaxine. With the exception of reduced analgesic use compared with placebo, there was no greater benefit from SSRIs compared with placebo or other antidepressants. However, all of the included studies were rated as low quality; therefore it is still unclear if these drugs reduce the frequency of TTH.

TTH is a very common disorder for people of all ages across the globe. Presently, biofeedback training, CBT, and manual therapy appear to be the most effective in reducing the frequency, duration, and intensity of TTH episodes, while acetaminophen and NSAIDs are effective for acute treatment of TTH pain for only a small percentage of TTH sufferers.

Migraine Headaches

Migraine headaches affect many people throughout the United States and the world, having a global prevalence rate of 11% (Stovner et al., 2007) and affecting 17.3% of women and 5.7% of men (Buse, Silberstein, Manack, Papapetropoulos, & Lipton, 2013). Migraines are among the top causes of reduced productivity at work (Stewart, Ricci, Chee, Morganstein, & Lipton, 2003) and contribute 1.4% of all years of life lost to disability (World Health Organization, 2001). Additionally, the amount of disability associated with migraine has been found to be comparable with that of dementia or two days after a heart attack (Steiner, Stovner, & Birbeck, 2013).

Migraine Process

There are three phases of a migraine. The first is the premonitory phase that can be thought of as the "warning" phase of a migraine and can occur several hours before the onset of the headache. About 33% of migraine sufferers experience this, and common symptoms include fatigue, gastrointestinal distress, and/or mood changes (Kelman, 2004). Those who experience the premonitory phase appear to have more headache-related complications, such as nausea and a longer-lasting headache.

The second phase is the aura phase that is experienced by about a third of people with migraines. During this period people experience visual, auditory, or motor symptoms (McCance, Huether, Brashers, & Rote, 2010). The aura may last up to an hour or longer, and roughly 90% of those who experience aura develop the proceeding headache on the same side of the head. Additionally, migraines with aura are often more mild than those without aura (Russell, Iversen, & Olesen, 1994). According to the International Headache Society diagnostic criteria, migraines can occur with or without an aura (Headache Classification Committee of the International Headache Society, 2013).

The last phase in migraine headaches is the headache phase during which actual headache symptoms occur and is characterized by unilateral, throbbing pain that worsens with movement. They are often accompanied by nausea/vomiting, and the sufferer usually has some kind of sensory sensitivity to light, smell, and/or noise. Migraines can be defined as either episodic (less than 15 attacks per month) or chronic (15 attacks or more per month for at least 3 months) (Headache Classification Committee of the International Headache Society, 2013).

Migraine Triggers

There are various triggers common in patients with migraine. Stress, weather changes, certain foods, skipping meals, too much or too little sleep or caffeine, bright sunlight, alcohol, strong odors, and menstruation can all be potential triggers for people (Wöber & Wöber-Bingöl, 2010). Additionally, certain food additives and food dyes have also been noted as potential triggers in some migraineurs (Frieri & Kettelhut, 1999).

Pathophysiology

There are many aspects of the pathophysiology of migraine headaches that are still unknown. The widely accepted theory is that during an attack, cortical spreading depression occurs, where a wave of electrical activity spreads from the occipital lobe to the cerebral cortex, which is then followed by a suppression of brain activity (Charles & Baca, 2013). This is thought to cause the aura phase of migraine; however, the reasons for migraine symptomology are still under debate. This cortical spreading depression has been found to cause increased blood flow in the middle meningeal artery that is largely involved in trigeminal and parasympathetic pathways (Bolay et al., 2002). Furthermore, cortical spreading depression has been shown to activate dural nociceptors (nerve cells that respond to painful stimuli) (Zhang et al., 2010), which is believed to cause the headache.

The etiology of migraines is thought to be largely genetic. More specifically, it seems that migraines with aura are more likely to be genetic, with children of a parent who has migraine with aura being 1.9 times more likely to develop them, compared with children of parents with migraine without aura being 4 times more likely to develop them. Interestingly, the spouse of a person with aura migraines is 1.5 times more likely to also have them, whereas there is no increased risk if the spouse has migraine without aura, indicating the possibility of more environmental factors impacting the likelihood of developing migraine with aura (Russell, Iselius, & Olesen, 1996).

Treatments

Pharmacological

Analgesics have proven to be effective for treating acute migraine attacks in many clinical trials. The typical analgesic treatments for migraine headaches include triptans, NSAIDs, and muscle relaxants (Cameron et al., 2015), and in some cases contraceptives for women who have migraines due to hormonal fluctuations (Nappi et al., 2013). Additionally, many over-the-counter medications have caffeine in them as an active ingredient. SSRIs have also been used for migraine prophylaxis; however, while they may be effective for treating anxiety/depression in people with migraines, a recent review concluded that there is not sufficient evidence that these work better than placebo for migraines (Banzi et al., 2015).

It should be noted that too much medication use can result in medication overuse headaches, a form of chronic migraine. These occur at least 15 times per month, for at least 3 months, resulting from taking triptans or opioids more than 10 days per month (or acetaminophen/NSAIDs more than 15 days per month) (Headache Classification Committee of the International Headache Society, 2013). Often, these headaches turn episodic migraines into chronic migraines, but by weaning off of the overused medication and establishing medication limits, they may be remedied. Therefore, it is recommended that patients with migraines limit medication use to two or fewer days per week, avoid opioids and butalbital, and always use the proper dosage (Tepper, 2012).

In addition to more traditional forms of pharmacological treatments, Botulinum toxin A has also shown efficacy at reducing the number of headaches in those with chronic migraines (Jackson, Kuriyama, & Hayashino, 2012). However, this has not been shown to be an effective method for episodic migraine reduction, and the associated costs are quite large compared with other prophylactic treatments.

Transcranial Magnetic Stimulation

There is some evidence that transcranial magnetic stimulation (TMS) is effective. A review by Lipton and Pearlman (2010) concluded that single-pulse TMS is effective for the treatment of migraines with aura, and a portable device manufactured by Neuralieve has been made available for the most efficient administration of TMS. It should be noted that while two studies have shown this device to be effective in treating migraines with aura, the authors were funded by Neuralieve and thus the results may warrant cautious interpretation. Furthermore, although these findings show positive results for the treatment of migraine, research has been inconclusive as to whether or not this method is effective for the prevention of migraine attacks.

Biofeedback and Psychotherapy Treatments

Biofeedback training is a type of therapy in which patients are taught to become aware of and mentally regulate physiological responses such as heart rate, skin conductance, and body temperature. Biofeedback has been recognized as an effective treatment for migraines. A review of 55 studies showed that it is most effective when home training is incorporated and blood-volume-pulse feedback appears to be more effective than peripheral skin temperature feedback and electromyography feedback. Furthermore, effect sizes are moderately large, and the effects seem to sustain over time (Nestoriuc & Martin, 2007), making this a viable treatment option for those wishing to avoid medications.

Along the same vein, there are other potential options for migraine sufferers wishing to treat their migraines behaviorally. Therefore, it is important that patients also address any mental health concerns with a trained professional. CBT focuses on challenging thoughts and changing behaviors that contribute to a person's distress. One systematic review concluded that many studies have shown that CBT can be an effective way to reduce the physical symptoms associated with migraines, although the authors note that there is not sufficient evidence for CBT to be considered an established treatment due to some methodological issues in existing studies (Harris, Loveman, Clegg, Easton, & Berry, 2015). Despite this, migraines have been correlated with several mental disorders, including depression and anxiety (Buse et al., 2013), and it seems that a large proportion of patients with chronic migraine do not utilize mental health services. Furthermore, these psychological comorbidities may go unrecognized in patients who simply attribute these disorders to their migraines (Wachholtz, Malone, & Bhowmick, 2015). Therefore, CBT may certainly improve quality of life in those suffering from migraines.

Mindfulness-based methods that focus on teaching moment to moment awareness and separation of emotions from thoughts have also found success in the treatment of migraine headaches. A recent review indicated that mindfulness-based interventions are able to reduce pain intensity (Reiner, Tibi, & Lipsitz, 2013). Additionally, it is important to note that mindfulness is a lifelong skill; therefore, pain reduction effects may compound over time (provided a person practices).

Acupuncture

Acupuncture is a treatment in which needles are inserted at various trigger points on the body. Acupuncture has been tested in several studies, and a recent review showed that it is at least as effective as prophylactic drug treatments for the prevention of migraine (Linde et al., 2009). Furthermore, fewer adverse effects have been found with acupuncture compared with drug therapy.

Emerging Treatments

There is emerging evidence that links may exist between the microbiota of a person and migraines. There are several studies that link gastrointestinal disorders with migraines (for a review, see van Hemert et al., 2014), and one recent study showed that introducing probiotics into the diets of 29 migraine sufferers significantly reduced both occurrence and intensity of migraines over a period of 12 weeks (de Roos et al., 2015). Although this was a small nonrandomized pilot study, the results warrant further research into the possibility of treating migraine with probiotics or with fecal transplantation.

Cluster Headaches

There is another class of headaches known as cluster headaches. They affect men more than women and occur in less than 1% of the population (Russell, 2004). They are characterized by severe unilateral pain, restlessness, and a recurrent pattern of attacks that may occur several times per day and last for 6–12 weeks on average, followed by a period of remission. There is also a tendency for abnormal bodily sensations to occur on the same side as the headache, such as a drooping eyelid and sweating (May, 2005). Researchers are still investigating the best treatment options for this type of headache. Neurostimulation has shown promise, but researchers are still working to determine the most effective, least invasive methods (Pedersen, Barloese, & Jensen, 2013).

Conclusion

Headaches are common, painful, often repetitive, disorders that can cause personal and professional hardship. While primary headache disorders are largely benign, headache as a secondary syndrome can be indicative of a serious disorder. Empirical comprehensive reviews identify psychobehavioral treatments as particularly effective relative to pharmacological approaches to reduce the frequency, severity, or duration of headache pain, and additional novel pharmacological and non-pharmacological treatments are in development.

Author Biographies

Dr. Amy Wachholtz, PhD, MDiv, MS is an assistant professor of psychology at the University of Colorado Denver. Dr. Wachholtz holds graduate degrees in theology, bioethics, clinical psychology, and psychopharmacology. Her research and clinical interests focus on (a) bio-psycho-social-spiritual model of chronic pain disorders and (b) the complexities of treating of comorbid pain and opioid addiction in both acute pain and chronic pain situations.

Adam Harris is a doctoral student in the Clinical Health Psychology Program at the University of Colorado Denver. His research interests include the relationship between health behaviors and mindfulness and their impact on mental health.

Amy Frers is a doctoral student at the University of Colorado Denver in the Clinical Health Psychology Program. She is interested in chronic pain and disease management, mindfulness, and the efficacy of third wave therapies for improving quality of life in these patient populations.

Multiple Sclerosis, Walking, and Depression: Implications for Health Psychology

Ipek Ensari[1] and Robert W. Motl[2]

[1]*Center for Behavioral Cardiovascular Health, Columbia University Medical Center, New York, NY, USA*

[2]*Department of Physical Therapy, University of Alabama at Birmingham, Birmingham, AL, USA*

Multiple sclerosis (MS) is an immune-mediated demyelinating disease of the central nervous system (CNS) with often co-occurring, interrelated manifestations. For example, there is evidence for the coupling of cognitive and motor functions in persons with MS such that those with worse information processing speed demonstrate worse upper extremity functioning (Benedict et al., 2011). This coupling is likely the result of damage within co-occurring regions of the CNS that subserve cognitive and motor functions, and it has clear implications for considering multicomponent interventions (Motl, Sandroff, & DeLuca, 2015). Another set of co-occurring, interrelated manifestations of MS includes walking impairment and depressive symptomology, and this has implications for intervention design and clinical practice in the field of health psychology.

Walking impairment is a common externally observable feature of MS and its progression and has meaningful consequences for daily living and mental health. The prevalence and degree of walking impairment in MS can be seen, for example, with the Expanded Disability Status Scale (EDSS) or scores on the Timed 25-Foot Walk (T25FW) and Multiple Sclerosis Walking Scale-12 (MSWS-12) (Motl & Learmonth, 2014). For example, there is consistent evidence that T25FW and 6-minute walk (6MW) performance are compromised in MS compared with controls (Motl & Learmonth, 2014). There further are epidemiological data indicating that 75% of persons with MS report significant walking impairment (Hobart, Riazi, Lamping, Fitzpatrick, & Thompson, 2003). Another study of MS patients in Europe indicated that nearly 50% reported experiencing mobility impairments within the 1st month of diagnosis

First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

and more than 90% of patients reported experiencing mobility impairments within 10 years of diagnosis (van Asch, 2011). The impairment of walking can have many unwanted consequences among persons with MS, including interruptions of daily tasks (91%), worsening of self-esteem (84%), and interference with employment (83%) and driving (87%) (LaRocca, 2011). Walking impairment may further influence family and social life among people with MS (van Asch, 2011). Collectively, the prevalence and impact of walking in MS would seemingly have relevance for mental health outcomes including depression.

Depression (Feinstein, Magalhaes, Richard, Audet, & Moore, 2014) and depressive symptoms (Jones et al., 2012) are common psychological manifestations of MS. One British survey reported that approximately 47% of the 4,178 respondents from the UK MS Registry had elevated depressive symptoms based on a Hospital Anxiety and Depression Scale (HADS) score of 8 or more (Jones et al., 2012). That same study reported that respondents with MS had mean depression symptom scores approximately 1 standard deviation (SD) higher than a reference sample without MS (Jones et al., 2012). Depressive symptoms in MS are associated with a variety of other negative consequences including pain, stress, cognitive dysfunction, and poor disease coping (Feinstein et al., 2014). Depression has been indicated to be predictive of symptoms and prospects for recovery in a variety of other diseases. Depression over illness and treatment has been linked with suicide among the chronically ill, as well as among those with MS (Siegert & Abernethy, 2005). Collectively, this would set the stage for depression resulting in physical health manifestations, including walking difficulty.

There is increasing interest in the evolving bidirectional association between walking and depression in MS, and this relationship is depicted in Figure 1. To begin, poor physical functioning and health, particularly walking impairment, brought about by MS might result in depressive symptoms and episodes (see Path a in Figure 1). Walking has been identified as one

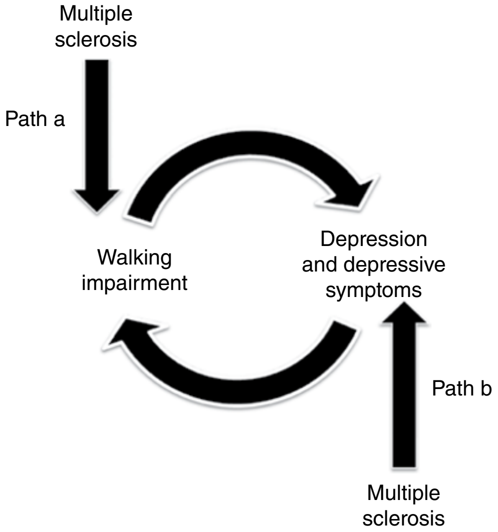

Figure 1 Proposed cyclical associations between walking impairment and depressive symptomology in multiple sclerosis (MS). MS is associated with walking impairment and depressive symptomology. Depressive symptoms might be the starting point for the worsening of disease course (e.g., walking impairment) (Path b). This might subsequently be further exacerbating depressive symptomology at a later time point (Path a).

of the most valued functions among persons with MS (LaRocca, 2011; van Asch, 2011), and its dysfunction could portend considerable consequences for mental health outcomes such as depressive symptoms. Walking impairment has been associated with loss of independence (Hirvensalo, Rantanen, & Heikkinen, 2000), and loss of independence could influence depression and depressive symptoms. Walking impairment has been associated with reduced quality of life in MS (LaRocca, 2011), and this might further reflect worse depressive symptoms. Those with MS who have walking dysfunction have reduced physical activity (Klaren, Motl, Dlugonski, Brian, & Lara, 2013), and this has been associated with depressive symptoms through a pathway mediated by mobility disability (Suh, Motl, & Mohr, 2010). Persons with MS often experience chronic pain that may interfere with walking ability and therefore increase depressive mood (Molton, Hirsh, Smith, & Jensen, 2013). Walking impairment can increase distress, and distress can result in increased depressive mood among individuals with MS (Senders, Sando, Wahbeh, Peterson Hiller, & Shinto, 2014).

On the other hand, there are multiple reasons why depressive symptoms brought about by MS might result in walking impairment (see Path b in Figure 1). Depressive symptoms have been associated with cardiovascular disease (CVD) (Joynt, Whellan, & O'Connor, 2003), and CVD has been identified as a comorbid condition associated with mobility disability in MS (Marrie et al., 2010). Depressive symptoms have been directly associated with walking impairment in large epidemiological studies of the general population of older adults, independent of sex, age, and education levels (Kivela & Pahkala, 2001). Depressive symptoms have been associated with poor patient activation (Goodworth et al., 2014), self-care (Fruewald, Loeffler-Stastka, Eher, & Baumhacki, 2001), and medication adherence in MS (Bruce, Hancock, Arnett, & Lynch, 2010), and this might influence outcomes such walking function. Depressive symptoms are further associated with reduced physical activity (Suh et al., 2010) and poorer health behaviors that are associated with walking impairment (Penninx, Leveille, Ferrucci, van Eijk, & Guralnik, 1999).

The possibility of an association between depressive symptoms and walking impairment in MS is supported empirically by previous literature conducted in other populations. For example, one prospective study reported that poor physical function at baseline predicted depression 3 years later in a sample of older adults, yet the opposite association was not statistically significant (Gayman, Turner, & Cui, 2008). Another study further reported that poor physical function at baseline predicted depressive symptoms after 1 year, regardless of improvements in physical function, in a cohort of 4,757 general practice attendees across Europe (Stegenga et al., 2012). An epidemiological study examined the association between depressive symptoms and physical function in older biracial individuals and reported that the relationship was unidirectional, whereby declining physical function predicted poorer depressive symptom scores but not the other way around (Everson-Rose et al., 2005). Collectively, those findings seemingly would support a directional association between walking impairment and depressive symptoms over time in MS, but we believe that there is a possibility of a dynamic, unfolding bidirectional association between these outcomes. That is, depressive symptoms might be associated with long-term changes in walking impairment, but this might involve intermediate steps involving a cyclical worsening of walking impairment and depressive symptoms.

Of note, the prospect of a bidirectional, cyclical association between walking and depressive symptoms is rooted in the Theory of Unpleasant Symptoms (TOUS) (Lenz & Pugh, 2003). The TOUS indicates that baseline symptoms such as depression predict performance outcomes such as walking impairments. The performance outcomes, in turn, have a reciprocal association with symptoms whereby change in walking impairment would predict change in depressive symptoms. The TOUS further identifies other variables that can predict symptoms and performance outcomes, indicating the importance of controlling for external variables (e.g., age, sex, weight, physical activity, and disability status) that might confound the relationship between walking impairment and depressive symptoms. Importantly, researchers have experienced success in applying the TOUS for studying symptomatic and behavioral consequences of MS (Motl, Snook, & Shapiro, 2008), and this would seemingly strengthen the applicability of this model for proposing an association between depressive symptoms and walking in MS.

To date, we are aware of a limited number of studies examining the association between depressive symptoms and walking impairment in MS (e.g. Motl, Balantrapu, et al., 2013; Motl, McAuley, et al., 2013; Ensari, Adamson, & Motl, 2016). One study compared performance on the 6MW and symptoms of fatigue, pain, and depression between persons with MS and controls as a precursory step before examining those symptoms as correlates of 6MW performance (Motl, Balantrapu, et al., 2013; Motl, McAuley, et al., 2013). All participants in the study completed questionnaires on symptoms of fatigue, pain, and depression and then underwent the 6MW test. The results indicated that depressive symptoms and pain were significantly, but weakly, associated with 6MW performance in the overall sample that included MS and controls. Of note, depressive symptoms did not explain the variance in 6MW performance as well as disease status (i.e., MS vs. control) or fatigue. On the other hand, the results indicated that fatigue was the strongest correlate of 6MW performance overall and in the separate subsamples of individuals with MS and healthy control participants. Fatigue partially accounted for the difference in 6MW performance between those with MS and controls. The authors concluded that targeting fatigue might be a feasible way to improve walking in individuals with MS and depression is a main contributor into elevated fatigue in MS. One limitation of this study was the sample size ($N = 66$) that might have been too small to detect effects of depressive symptoms of walking outcomes.

The other study involved a longitudinal panel design and examined the associations between depressive symptoms and walking impairment over a period of 2 years among persons with MS (Ensari et al., 2016). The researchers specifically examined the possible reciprocal relationship between depressive symptoms and walking impairment over 2 sequential 12-month periods in a sample of 269 people with relapsing-remitting MS (RRMS). Participants self-reported impairments in walking using the MSWS-12 and depressive symptoms using the HADS-D. Self-reported measures, including demographic and clinical information, were collected via questionnaire packets. The data were examined with panel analysis in *M*plus, and the model underlying the hypothesized associations is provided in Figure 2. The model hypothesized that depressive symptoms would be the starting point of this reciprocal unfolding relationship between walking impairment and depressive symptoms over time. As hypothesized, the results indicated that depressive symptoms at baseline (Time 1) predicted change in walking impairment at 1-year follow-up (Time 2), and change in walking impairment at 1-year follow-up predicted change in depressive symptoms at 2-year follow-up (Time 3) (Ensari et al., 2016). There was no evidence for the opposite pattern of unfolding relationships (i.e., walking impairment at baseline did not predict depressive symptoms at 1-year follow-up, and depressive symptoms at 1-year follow-up did not predict walking impairment at 2-year follow-up). The relationships were independent of age, sex, disease duration, disability status, BMI, and physical activity. This study provides the first evidence of a possible reciprocal relationship initiating between depressive symptoms and walking impairment over a 2-year period in a large sample of people with RRMS. The associations were independent of extraneous variables, and this partially validates the hypotheses with the TOUS model. Collectively, these findings point to a possible reciprocal association between depressive symptoms and walking impairment over

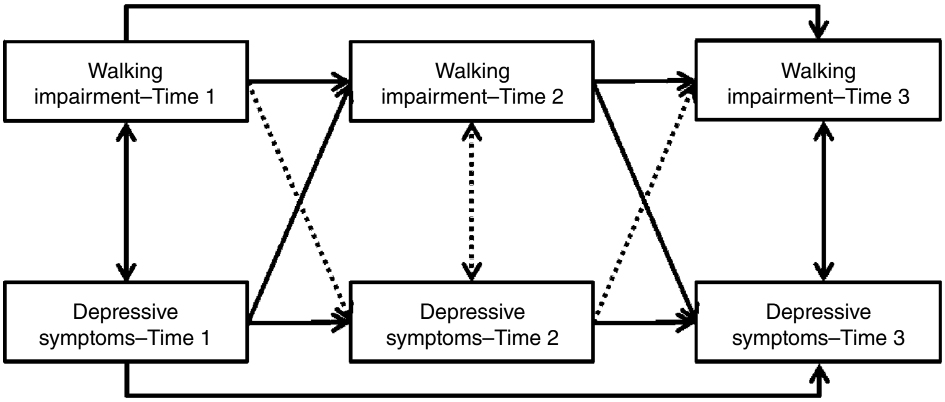

Figure 2 The tested model of longitudinal associations between depressive symptoms and walking impairment over three 1-year periods in 269 persons with multiple sclerosis. *Note*: Solid lines represent statistically significant path coefficients, whereas dashed lines represent nonsignificant path coefficients. *Source*: The figure has been reproduced from Ensari et al. (2016).

time in people with RRMS, and depressive symptoms might be the entry point for breaking this evolving pattern of associations.

The notion of physical and psychological symptoms of a chronic disease interacting with each other over time fits well within the biopsychosocial (BPS) model of health and illness (Taylor, 2012). This model was developed based on limitations of the biomedical approach that was considered a reductionist, linear cause–effect approach for explaining clinical phenomenon. The BPS model attempted to revise and improve our understanding of disease by adding the essential component of patient-related factors into the model. In essence, the BPS model maintains that biological, psychological, and social factors are all determinants and consequences of health and wellness. That is, the individual unique factors related to the patient might be exerting an influence on the symptoms and outcomes of a disease. There might be additional bidirectional influences between the biological, psychological, and social aspects of the disease as experienced by the patient. This is a more comprehensive model to explain the reciprocal relationships between psychological and somatic symptoms (i.e., depressive symptoms and walking impairment in MS). Accordingly, the possibility that changes in depressive symptoms and walking impairment interact with each other over time throughout the disease course makes sense from a theoretical perspective. Practically, it is therefore important that clinicians consider multiple interrelated manifestations when treating a patient, rather than isolating the somatic or psychological symptoms.

In a practical sense, then, it might be prudent that health psychologists working with patients who have MS consider the interactive nature between these seemingly distal (i.e., physical vs. psychological) symptoms in clinical practice. Indeed, some have recommended that screening for depressive symptoms become a routine feature of the medical management of all patients with MS (Siegert & Abernethy, 2005). Such an approach has potential benefits and is consistent with a BPS model. For example, monitoring and addressing depressive symptoms could improve treatment adherence, self-efficacy, and self-care behaviors, as well as help maintain physical activity levels in individuals with MS over time (Bruce et al., 2010; Fruewald et al., 2001; Goodworth et al., 2014; Penninx et al., 1999; Suh et al., 2010). Such improvements could aid in the prevention of future worsening of walking impairment in this population, and this might in turn reduce the likelihood of depressive symptomology worsening with disease progression.

The observation that changes in walking impairment can predict depressive symptoms over time independent of various other correlates is consistent with Lewinsohn's integrative model of depression. This model states that disease (i.e., MS) will be a risk factor for depression only when it results in functional impairment (i.e., walking impairment) and that impairment in the absence of disease is a risk factor for depression. Lewinsohn based this framework on the argument that disability and dependence, along with disease, can determine depressive symptomology and, therefore, that functional impairment must be distinguished from physical disease (Zeiss, Lewinsohn, Rohde, & Seeley, 1996). Evidently, this framework underscores the need to take into account the causal role of functional impairment when examining the causal relationship between depressive symptoms and physical disease (Zeiss et al., 1996). This model states that disease by itself only weakly increases the likelihood of depressive onset and functional impairment (e.g., walking impairment) is a stronger predictor of depressive onset. This model further suggests the presence of a linear positive association between the degree of functional impairment and the risk of depressive symptomology. Such an assumption would mean that physical disease increases the likelihood of depressive symptom onset only if it is associated with functional impairment. Indeed, previous studies have provided evidence for this in both samples of individuals with MS (Voss et al., 2002) and other samples such as older adults (Zeiss et al., 1996). Research involving older adults indicated that disease by itself was not a consistent predictor of depression. Once depressive symptoms are triggered, these mental health changes may have additional negative consequences, including further decline in functional ability (Zeiss et al., 1996). Collectively, the implications of the Lewinsohn's model combined with empirical research are in line with those of Ensari et al. (2016). This underscores the importance of screening for depressive symptoms in clinical practice when working with individuals with chronic diseases (e.g., MS), instead of only relying on monitoring the immediate consequences/impairments associated with the disease (e.g., walking impairments), as the former can initiate the worsening of the latter.

The present findings can inform the design of behavioral approaches that target depressive symptoms and walking impairment in individuals with MS and other neurological conditions. For example, based on the notion that depression might be the starting point for an unfolding cyclical relationship that involves walking impairment, researchers can test the efficacy of an intervention that primarily targets maintaining positive mood or improving depressive symptoms over a period of several months. Primarily, the changes in walking, and secondarily other walking-related functional outcomes (e.g., speed, velocity, gait), would then be the outcome measures of such an intervention. If these target outcomes improve or maintain baseline levels, then this would lend further support to the implementation of targeted interventions for treating depression and secondary physical outcomes among those with MS and other similar chronic diseases. This can subsequently provide individuals with MS more options for disease management and alleviate consequences of negative symptoms in a proactive way. Another possibility would be targeting walking in non-depressed individuals (i.e., those without clinically significant levels of depressive symptoms) to prevent/reduce the potential for depressive symptomology. This approach would be consistent with other researchers who have suggested exercise and physical activity as behavioral interventions that target walking impairment for reducing depressive symptoms in individuals with clinical and subclinical levels of depressive symptoms in the general population (e.g., Kandola & Hayes, 2020).

There are still questions that can be investigated regarding the associations between walking and depressive symptoms in individuals with MS. For example, it would be interesting to assess whether these same patterns manifest in MS patients who have concurrent formal depressive disorders. Accordingly, future studies would benefit from investigating these relationships in individuals with a clinical diagnosis of a depressive disorder (e.g., major depression). Such investigation can lead the way to better monitoring and interventions of depressive symptoms in individuals with MS and comorbid depressive disorders to hopefully prevent the progression of gait and walking impairment over time that is seen in MS. Another obvious direction would be to assess these patterns of changes across levels of neurological disability and disease course. The current literature is limited mostly to the lowest range of neurological disability, and therefore it would be important to see if higher neurological disability status interacts differently with depressive symptoms and walking impairment over time. Most of the literature so far has focused on the RRMS, and it would be beneficial to study these patterns in other types of MS (e.g., primary progressive MS) wherein ambulatory function declines considerably over time. Finally, future studies would benefit from administering objective measures of walking and clinical diagnoses of depression and examine these two variables over longer periods of time in people with MS for a further assessment of this reciprocal relationship and its stability.

We propose the novel idea and provide supportive arguments as well as models of a cyclical, bidirectional association between psychological and physical functioning symptoms over time in MS. We further provide longitudinal data supporting that these relationships likely evolve over time in MS. The coupling of these two manifestations of MS presents considerable promise for clinical research and practice that embraces the notion of helping those with MS lead the best possible life. The evidence is clear that MS is driving the coupling of depressive symptoms and walking impairment and research that better articulates the nature of this coupling will inform decisions on managing depression and walking by clinicians and practitioners.

The Impact of Exposure to Potentially Traumatic Events on Physical Health

Candice Presseau[1], Danielle S. Berke[1], Julie D. Yeterian[1], and Brett Litz[2]

[1]Massachusetts Veterans Epidemiology Research and Information Center (MAVERIC), VA Boston Healthcare System, Boston, MA, USA
[2]Department of Psychology, Boston University & VA Boston Healthcare System, Boston, MA, USA

Exposure to potentially traumatic events (PTEs), such as combat, accidents, and sexual assault, is associated with negative alterations in biology that may create greater risk of cardiovascular, gastrointestinal, and immunological problems. Unlike physical injuries that cause direct insult to various biological systems, there is no direct causal link between psychological trauma and health problems. Rather, a variety of biopsychosocial processes—some immediate, some delayed, and most chronically present—increase the risk for physical health problems. In particular, there are two modifiable pathways in the behavioral medicine arena through which PTEs can negatively affect physical health: (a) enduring dysregulation of stress reactions and (b) use of emotional inhibition strategies for regulating distress. We also discuss the potential implications of these pathways for the assessment and treatment of health problems that may develop following exposure to PTEs.

Potentially Traumatic Events and Posttraumatic Stress Disorder

Events are not inherently traumatic. Situations that involve actual or threatened death, serious injury, or sexual violence toward self or others are *potentially* traumatic. A stressor is *traumatic* if it entails sufficiently intense and functionally impairing reactions to these experiences. It is a testament to human resilience that most people that are exposed to PTEs do not experience acute or enduring traumatic stress reactions. PTEs may be chronic and repeated (e.g., ongoing childhood abuse, living in a war zone, or repeated intimate partner violence) or single incidents

The Wiley Encyclopedia of Health Psychology: Volume 3: Clinical Health Psychology and Behavioral Medicine,
First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

(e.g., a motor vehicle accident, natural disaster, or armed robbery). Rates of PTE exposure vary widely within and across specific populations (e.g., more common among male, individuals with preexisting behavioral disorders, Caucasian persons, and those of lower socioeconomic statuses; Amstadter, Aggen, Knudsen, Reichborn-Kjennerud, & Kendler, 2013; McLaughlin et al., 2013; Roberts, Gilman, Breslau, Breslau, & Koenen, 2011). However, up to 90% of the US population will experience one or more PTE(s) at some point in their lives (Kessler, Sonnega, Bromet, Hughes, & Nelson, 1995; Kilpatrick et al., 2013). As such, PTE exposure is the rule, rather than the exception, in American and other societies worldwide (e.g., Benjet et al., 2016).

In response to PTEs, individuals may develop psychopathological syndromes, including acute stress disorder, posttraumatic stress disorder (PTSD), adjustment disorders, and other trauma- and stressor-related disorders, including complex bereavement (American Psychiatric Association, 2013). Likewise, it is not uncommon for individuals who have been exposed to PTEs to experience difficulties with depression and/or substance use, which may be comorbid with trauma-related disorders (Mills, Teesson, Ross, & Peters, 2006; Rytwinski, Scur, Feeny, & Youngstrom, 2013). The most widely studied of the trauma-related disorders, PTSD, includes symptoms across four domains: (a) intrusions (i.e., dreams, intrusive thoughts and memories, strong emotional and physical reactions to trauma reminders), (b) avoidance (i.e., of thoughts, feelings, situations, or people that serve as reminders), (c) alterations in mood and cognition (e.g., loss of interest in activities, negative thoughts about self and others, difficulty experiencing positive emotions), and (d) hyperarousal (e.g., sleep problems, concentration difficulties, irritable behavior). To meet criteria for PTSD, symptoms must last for at least a month.

Lifetime prevalence of PTSD is estimated to be 5–10% in the general population (Friedman, 2015; Kilpatrick et al., 2013), meaning that roughly 1 in 10 people will meet diagnostic criteria for PTSD at some point in their lifetime. In a given year, around 8.5 million adults in the United States (or 3.5%) are estimated to meet criteria for PTSD (Kessler, Chiu, Demler, & Walters, 2005). Most individuals who are exposed to PTEs do not develop a mental illness, such as PTSD, but instead exhibit psychological and behavioral resilience (e.g., Bonanno, 2004). Resilience refers to, "the ability to *bounce back* from immediate understandably disrupted states and from initial pre-clinical responses and impairments" (Litz, 2014, p. 2).

Exposure to PTEs and Physical Health

In addition to mental and behavioral health sequelae, PTE exposure can also impact physical health. Epidemiological studies have found associations between PTEs and subjective perceptions of health and self-reported medical problems and medical records-based medical diagnoses (Pacella, Hruska, & Delahanty, 2013). Findings from the *Adverse Childhood Experiences Study* showed that the risk of developing diseases in adulthood, including cancer, diabetes, coronary artery disease, and chronic lung diseases, was highest for individuals with the greatest number of PTEs or extremely stressful experiences in childhood, even after controlling for age, gender, race, and education level (Felitti et al., 1998). Single PTEs, such as motor vehicle accidents, natural disasters, and sexual traumas, can also bring about stress reactions and subsequent health problems. For instance, sexual trauma in adulthood is associated with negative health consequences, including somatic complaints and chronic diseases (e.g., Campbell, Self, & Ahrens, 2003). Moreover, longitudinal research with older adults shows that PTEs across the life course are associated with physical health problems to varying degrees (i.e., the death of a child associated with more chronic and acute health conditions; Krause, Shaw, & Cairney, 2004).

PTSD appears to be the key set of symptoms that mediates the relationships between PTE exposure and poor health (e.g., Schnurr & Green, 2004). However, exposure to PTEs is associated with worse physical health even when controlling for PTSD and trauma-related mental health symptoms (Scott et al., 2013; Spitzer et al., 2009). Indeed, a large multinational survey found that individuals with greater lifespan exposures to PTEs were more likely to suffer from physical health conditions such as chronic lung diseases, ulcers, heart disease, and pain conditions, even after controlling for 16 other mental health conditions, including PTSD, mood and anxiety disorders, and substance use disorders (Scott et al., 2013). The authors speculated that health risk behaviors such as binge eating, smoking, substance use, and risky sexual behaviors might explain, at least in part, the relationship between PTE exposure and poor health, as health risk behaviors were also found to be elevated among individuals with greater PTE exposure. Yet, other studies have shown that the relationship between PTE exposure and health consequences is present even when health risk behaviors are accounted for (e.g., Schnurr, Spiro, & Paris, 2000). Although health risk behaviors (e.g., smoking, diet, checkups, exercise) among individuals with lifespan exposure to PTEs should be targeted in prevention efforts within healthcare settings, they are not likely to be the sole mechanism through which health problems emerge following PTE exposure. Other possible explanations for the relationship between exposure to PTEs and negative physical health outcomes include distinct, albeit potentially co-occurring, pathways of dysregulated stress responses and inhibited emotional processing that can operate in conjunction with or independently of trauma-related mental health symptoms and poor health behaviors.

Dysregulated Stress Reactions

The experience of severe stress can lead to over-activation or dysregulation of normal stress responses, thereby increasing wear and tear demands on the body in both the short and longer term. During a stressful encounter, the brain activates regulatory processes to increase the body's ability to respond to the stressor (sympathetic nervous system) and afterward to assist the body in returning to a resting state when the stressor has dissipated (parasympathetic nervous system). The brain's evaluation of a stressor triggers a cascade of reactions across several interconnected systems, including the autonomic, neuroendocrine, and immunological systems, resulting in physiological changes (e.g., increased heart rate, shortness of breath, hormone secretion) and behavioral responses (flight, fight, freeze, dissociate) with implications for physical health functioning.

Neurons, the basic building blocks of the human brain's functioning, are organized in networks that transmit signals as new experiences are encountered in the environment. Neurons are the means of communication between the brain and body and are influenced both structurally and chemically by environmental factors. The ever-changing quality of neurons, while facilitating adaptation, also enables information storage, or memory. As such, the brain and body may learn through neural circuits to habitually operate in ways that lead to physical wear and tear (e.g., persistent rapid heart rate, shallow breathing).

Neural networks are organized primarily to facilitate the maintenance of stability, or equilibrium, of the brain and body in response to change, referred to as allostasis. Hormones, neurotransmitters, and other bodily tissues are mediators of allostasis and aid in the body's functioning during daily activities, like eating, sleeping, and exercising (McEwen, 2003). When individuals are under extreme stress, the production and dissemination of allostatic mediators can lead to "allostatic load," wherein excessive demands for change accumulate and cause deterioration of the brain and body.

Allostatic load is manifested primarily in the neuroendocrine system, which includes the sympathetic–adrenal–medullary (SAM) system and hypothalamic–anterior pituitary–adrenal cortex (HPA) axis, and is responsible for hormone production and regulation. The HPA axis is the primary regulatory system for glucocorticoids, mainly cortisol. Cortisol is perhaps most intimately linked with exposure to psychosocial stress and is involved in a variety of functions, such as energy release, immunity, mental vigilance, memory, and learning (Flinn & England, 1995).

Under conditions of chronic stress, such as in war or ongoing abuse and neglect, individuals are faced with persistent threats and elevated arousal for prolonged periods. Therefore, frequent exposure to PTEs places a heavy burden on bodily systems. Persistent over-activation of the HPA system is associated with poor health outcomes, including immune deficiencies, cognitive impairment, growth and maturity delays, and psychological difficulties (Flinn & England, 1995).

It may not only be *how often* one is exposed that determines vulnerability to health effects but also *when* in the life course such exposure occurs. There are time periods during which brain development and associated functions are especially vulnerable to extreme stress and adversity. PTE exposure during critical developmental periods can change the way the brain is organized and ultimately the way it functions (Perry, Pollard, Blaicley, Baker, & Vigilante, 1995). Specifically, PTE exposure occurring during formidable developmental periods provides a neural roadmap for the brain to integrate new sensory information, thereby establishing patterns of neural activities as well as sensitization to particular information inputs. Because the primary mode of the brain under such circumstances is survival, learning related to other sensory inputs is potentially stunted.

Furthermore, given that brain systems are developed in an exceedingly complex fashion (brain stem to cortex), limited development of less complex systems is detrimental to the brain's overall functioning and capacity to engage in more sophisticated processing, such as regulation of mood and abstract thinking (Perry et al., 1995). Accordingly, state-dependent physiological and biochemical reactions can become personal attributes, or traits, that create additional vulnerabilities for neuropsychiatric symptoms (e.g., anxiety) and physical health problems (e.g., cardiovascular problems). Imagine a developing brain essentially hardwired to perceive threat and a body programmed to produce threat-related responses (e.g., heart rate, respiratory changes, and stress hormone secretion), and the potential for health problems becomes evident.

Inhibitory Emotion Regulation Styles

Exposure to PTEs may also contribute to negative health outcomes by way of inhibitory emotional coping strategies, which include attempts to avoid or escape internal experiences such as thoughts, emotions, bodily sensations, or memories (Hayes, Wilson, Gifford, Follette, & Strosahl, 1996). Individuals who attempt to cope with trauma-related emotions, thoughts, and memories by suppressing these reactions may inadvertently generate physical distress. Although the link from PTE exposure to negative health outcomes by way of emotion inhibition remains speculative, a wealth of research suggests that use of inhibitory emotional coping strategies has the paradoxical effect of increasing physiological arousal (e.g., Gross, 2002).

Research shows that individuals who engage in strategies designed to inhibit, avoid, or escape internal experiences following PTE exposure are more likely to report psychological distress and impairment (Plumb, Orsillo, & Luterek, 2004) and may be at increased risk for the onset of slow-developing multifactorial disease processes, such as cardiovascular disease (Gross, 2002). For example, in a longitudinal study of heart attack survivors divided into groups (combinations of high versus low inhibition and high versus low distress), individuals who scored highest on measures of distress and inhibition had a significantly higher mortality rate than other patients (Denollet et al., 1996). Moreover, PTE-exposed persons who attempt to avoid aversive memories by suppressing intrusive thoughts are more likely to report PTSD reexperiencing symptoms (Shipherd & Beck, 2005). Taken together, these findings suggest that use of inhibitory coping may thwart recovery from PTE exposure by perpetuating a cycle wherein individuals both experience increased distress in response to the event(s) and rely on suppressive coping styles that are physically exhausting to manage, or cope with, distress.

Because inhibition and suppression are characterized by a strategic and intentional withholding of emotional responses, such strategies require vigilant self-monitoring and the active stifling of automatic behaviors or bodily reactions (Gross, 2002). Active, effortful emotional inhibition can lead to *ego depletion*, a state in which the ability to alter responses is compromised (Baumeister, Bratslavsky, Muraven, & Tice, 1998). As such, individuals who rely on emotion suppression to cope with painful thoughts and memories of trauma may deplete their mental capacity to engage in other effortful processes, such as attention, encoding of memory, and the processing of mood inconsistent information. Arguably, the depleting effects of effortful inhibition can influence health by taxing cognitive processes essential for regulating health (Gross, 2002), including the ability to attend to subtle internal and external cues, to encode and remember important health guidelines (e.g., medication schedule), and to engage in mood inconsistent behavior (e.g., exercising when feeling apathetic or depressed).

Strategies that create distance between an individual and their emotional pain following PTEs (i.e., emotional suppression and inhibition) also have the potential to create distance between an individual and their social world. In this way, individuals who inhibit emotion in response to PTEs may experience negative health consequences due, in part, to their isolation from the health buffering effects of social support (D'Andrea, Sharma, Zelechoski, & Spinazzola, 2011). Additionally, individuals who are unresponsive to emotional cues have been shown to produce physiological activation in those with whom they socially interact. Suppression of emotional experiences has also been shown to reduce social rapport and impede relationship formation (Butler et al., 2003). These findings suggest that habitual inhibitory coping strategies may exact both personal and social consequences (Butler et al., 2003). As the absence or withdrawal of social support following PTE exposure has been shown to be one of the robust predictors of chronic psychological distress (Charuvastra & Cloitre, 2008), reliance on inhibitory coping strategies may exacerbate the physiological toll of PTE exposure on an individual's psychological and physical health by damaging social bonds. Collectively, the arguments outlined above suggest there may be complex and systemic influences of PTE exposure on physical health for individuals and those around them.

Summary, Clinical Implications, and Conclusions

In this chapter, we reviewed literature demonstrating a relationship between PTE exposure and physical health problems and identified two possible mechanisms through which PTE exposure may give rise to negative health outcomes: (a) dysregulated stress reactions and (b) inhibitory emotion regulation styles. Thus, providers may consider intervening on the mechanisms (physiological or psychological) following PTE exposure that can lead to health problems in addition to targeting health symptoms and behaviors themselves. Theory and research that explores the PTE exposure–health relationship may have implications for the optimization of healthcare interventions, as targeting underlying processes may provide benefits above and beyond those offered by medication, exercise, and diet changes.

Evidence of PTE exposure should not necessarily prompt a referral to specialty trauma-focused services, as most individuals who are exposed to PTEs will be resilient to the experience and will not suffer long-term mental health consequences. Rather, gathering information about patients' PTE exposure can be used to develop a biopsychosocial conceptualization of health problems that is informed by an appreciation for the interplay between physiological and psychological processes that may be triggered by PTEs. Addressing the intersection of mental and physical health in the context of PTE exposure may serve to enhance the effectiveness of multidisciplinary care.

Healthcare systems have been shifting toward integrative and collaborative models of care. Interdisciplinary teams and collaborative care approaches to health and wellness are common in primary, community health, and specialty care contexts (e.g., Woltmann et al., 2012). In these contexts, for certain medical problems (e.g., chronic pain, gastrointestinal distress), if patients show signs of symptom persistence despite compliance with prescribed otherwise effective treatments (or if there are compliance problems), psychologists should conduct a thorough assessment to determine the presence of exposure to PTEs and dysregulated stress responses and/or emotional inhibition. These problems can be targeted with stress management, mindfulness, and expression-promoting interventions. Unfortunately, at present there are no best practice recommendations for multidisciplinary care among subpopulations of patients who have been exposed to PTEs.

Schizophrenia

Thanh Le, Kyle R. Mitchell, Elana Schwartz,
Jessica McGovern, and Alex S. Cohen

Department of Psychology, Louisiana State University College of Science, Baton Rouge, LA, USA

Overview

Schizophrenia is a severe brain disease that is one of the most costly sources of chronic dysfunction in the world (World Health Organization [WHO], 2001). Its operational definition rests on the clinical presentation of delusions, hallucinations, disorganized behavior and speech, and negative symptoms (e.g., anhedonia, asociality, blunted affect, and alogia) (American Psychiatric Association, 2013), though virtually every function associated with the central nervous system is affected in some regard. It has a lifetime prevalence of approximately 0.5–1%, though schizophrenia spectrum disorders and subclinical traits likely affect a much broader segment of the population (MacDonald & Schulz, 2009). Despite decades of empirical attention, its cause has remained a mystery, and a cure is unlikely to manifest in the near future. Nonetheless, significant gains have been made in understanding the functional consequences of the disorder and in symptom amelioration. At present, a regimen of case management, antipsychotic medication, and various psychosocial interventions has helped reign in symptoms to a fairly manageable level for many individuals with the disease (Dixon et al., 2010). What remains is a constellation of cognitive, emotional, and motivational symptoms that impairs individual's ability to effectively function within mainstream social and vocational domains. In order to improve quality of life, improve functioning, and reduce social burden associated with schizophrenia, there is considerable effort aimed at understanding, assessing, and treating these "residual" symptoms within the disorder. This is no easy endeavor, as these efforts are pushing the very limits of translational, basic, and clinical sciences. With that in mind, the present chapter provides an overview of recent research in this domain with a particular focus on methodological, multidisciplinary, and technological advances that will hopefully improve the lives of patients with schizophrenia and their caregivers in the near future.

Cognitive Deficits

Individuals with schizophrenia experience relatively severe cognitive impairments, on the order of a full standard deviation across a wide range of basic (e.g., attention, memory), social, and metacognitive abilities. These impairments have been identified in the premorbid and prodromal stages of the disorder, among patients experiencing their first episode of psychosis, and throughout adulthood (Addington, Saeddi, & Addington, 2006; Cornblatt, Green, Walker, & Mittal, 2009). These impairments are generally unresponsive to current psychiatric medication. Importantly, cognitive impairments are one of the most robust predictors/concomitants of functional outcome both concurrently and prospectively. More specifically, deficits in basic cognitive abilities are reliably and highly associated with lower quality of life, poorer social skills, higher unemployment rates, difficulty with independent living, less time spent in the community, and reduced success following rehabilitation programs (Green, Kern, Braff, & Mintz, 2000). Furthermore, studies examining the effects of composite cognitive measures have found that cognitive impairment may account for 20–60% of the variance in real-world outcomes even after accounting for psychotic and other psychiatric symptoms (Green et al., 2000). These findings coupled with a review of the extensive literature have led some investigators to propose that cognitive impairments are the most important factor for understanding long-term disability associated with the disorder (Cornblatt et al., 2009).

While it is clear that schizophrenia is associated with severe cognitive deficits, the true nature of the cognitive dysfunction remains unclear. Traditionally, test batteries partition global cognition into separate domains such as memory, attention, executive functioning, and more. Partly due to this fact coupled with hopes of informing tailored interventions, many studies have provided evidence that discrete cognitive domains are largely responsible for social, occupational, and other dysfunctions (Green et al., 2000). However, other investigators challenge this view of specificity. For example, prior studies have shown that traditional domains of cognitive function are highly interrelated, indicating that the selective deficits observed exist against a backdrop of generalized cognitive deficits (Dickinson, Ragland, Gold, & Gur, 2008). This specific versus general issue raises fundamental questions about the neural underpinnings of cognitive impairments and has direct implications for assessment practice and intervention design. Additionally, investigators are focused on identifying mechanisms and mediators that may explain *how* basic cognition is related to functional outcome and identify further treatment targets. Social cognition, broadly defined as the ability of individuals to correctly identify and adaptively make sense of others' thoughts, emotions, intentions, and social cues, has emerged as a likely mediator as it requires basic cognitive skills and has obvious links to social behaviors. The rapid growth in the study of social cognition has led to important findings: social cognition has stronger relationships with social functioning than cognition (Fett et al., 2011), and some aspects of social cognition (e.g., social perception and social knowledge) fully mediate the relationship between cognition and social problem solving and work skills (Addington et al., 2006). More recently, metacognition has also been examined as a potential mediator between basic cognition and everyday outcomes. Metacognition can be defined as a spectrum of mental activities that involve thinking about thinking and, more specifically, describes the ability of an individual to recognize and hold specific thoughts and feelings of complex representations of self and other over time (Lysaker et al., 2011). Similar to social cognition, metacognition has demonstrated relationships to occupational and social functioning (Lysaker et al., 2011), and aspects of metacognition (e.g., mastery) have been found to fully mediate the influence of cognition on social contact and empathy (Lysaker et al., 2010).

Given the ubiquitous influences of cognitive impairments in schizophrenia, current efforts to understand the exact nature of these substantial and persistent deficits have led to unprecedented cooperation between multiple federal agencies, private pharmaceutical companies, and academia. For example, various stakeholders, including researchers, the National Institute of Mental Health (NIMH), the Federal Drug Agency (FDA), and industry, started two initiatives—the Measurement and Treatment Research to Improve Cognition in Schizophrenia (MATRICS) and the Cognitive Neuroscience Treatment Research to Improve Cognition in Schizophrenia (CNTRICS)—that resulted in the development of consensus cognitive test batteries assessing domains of cognition central to schizophrenia. More specifically, the MATRICS initiative (Nuechterlein et al., 2008) focused on identifying tasks with established psychometric properties to include in a standardized test battery that would be utilized in clinical trials aimed at ameliorating cognitive dysfunction in schizophrenia. In contrast, the CNTRICS initiative (Carter & Barch, 2007) focuses on leveraging cognitive neuroscience-based methods and technologies (e.g., neuroimaging, electrophysiology, and animal paradigms) to isolate cognitive functions that may be conflated in more traditional batteries, such as the MATRICS, where a single cognitive task may tap multiple cognitive processes (e.g., visual scanning, attention, problem solving, etc.). Researchers have also investigated the heritability and genetic component of common cognitive deficits, or endophenotypes, shared by individuals with schizophrenia and their healthy relatives. Studies such as the Consortium on the Genetics of Schizophrenia (COGS), a multisite NIMH-sponsored collaboration, are making groundbreaking discoveries on the genetic architecture on these endophenotypes that can foster a better understanding of pathophysiology of schizophrenia, improve early identification of the illness, and guide the development of preventive interventions (Swerdlow, Gur, & Braff, 2015). Lastly, cognitive remediation (CR) (discussed below), which involves the systematic use of methods aimed at improving cognitive functioning through the practice of cognitive exercises on either computer-based or paper-and-pencil tests, have been found to improve cognitive outcomes, with small to moderate effect (Revell, Neill, Harte, Khan, & Drake, 2015).

Emotion Abnormalities

Individuals with schizophrenia experience a range of emotion abnormalities, including abnormalities in emotion regulation, emotion recognition, and emotion experience and expression. Meta-analytic studies examining emotion perception indicate that individuals with schizophrenia evidence deficits on the order of one standard deviation below controls (Kohler, Walker, Martin, Healey, & Moberg, 2010). Individuals with schizophrenia also show abnormalities in emotion regulation, or the ability to influence the timing and intensity, as well as how they experience and express these emotions (van der Meer, van't Wout, & Aleman, 2009). These individuals report higher trait negative and lower positive affect than controls (Kring & Elis, 2013). Whereas healthy controls typically employ healthy emotion regulation skills like suppression or reappraisal of negative emotions, individuals with schizophrenia use fewer healthy skills and use more unhealthy skills like avoidance of negative emotion (van der Meer et al., 2009). Individuals with schizophrenia also exhibit deficits in measures of verbal, facial, and acoustic emotional expression (Kring & Elis, 2013), but the exact nature of these deficits is unclear at the present time.

Of the myriad of emotional abnormalities, anhedonia, or a reduction in capacity to experience pleasure, is a poorly understood but crucial emotion deficit in schizophrenia. Anhedonia is evident in a number of neuropsychiatric disorders. In schizophrenia, anhedonia is part of a subset of symptoms consistent with reductions in normal functioning or negative symptoms. These symptoms are a negative prognostic indicator, and in particular anhedonia is associated with deficits in social and occupational functioning (Kring & Elis, 2013). Despite the range of functional impairments associated with anhedonia, researchers have only recently begun to address these symptoms. Emerging research indicates that anhedonia in schizophrenia is not merely an extension of the symptoms seen in other neuropsychiatric disorders. In fact, recent research indicates that anhedonia is a complex and unique set of deficits that until recently have been difficult to explain, leading researchers to coin the term the "emotion paradox." This pattern of deficits consists of deficits in trait hedonic response, but intact in-the-moment hedonic responses (Cohen & Minor, 2010).

A number of cognitive, affective, and neurobiological mechanisms have been proposed to understand anhedonia in schizophrenia. These mechanisms include deficits in autobiographical memory as well as abnormal activation of semantic memory networks that lead to inaccuracies in recall of past pleasurable experiences (Cohen, Najolia, Brown, & Minor, 2011). Another potential cognitive mechanism posits that abnormalities in working memory contribute to dysfunctional beliefs about or representations of pleasure (Strauss, 2013). Deficits in inhibition of negative emotion are a potential mechanism, which suggests that deficits in emotion regulation contribute to self-reported anhedonia (Cohen & Minor, 2010). A number of brain regions are of interest; however, current literature focuses primarily on reward processing circuitry and implicates areas including the ventral striatum (Dowd & Barch, 2010). The results of these studies posit that deficits in reward processing are of primary concern in schizophrenia. Prior research has been informative in clarifying areas of deficit in schizophrenia, but greater fidelity is necessary in understanding the mechanisms associated with this symptom. Informed by our current understanding, future research integrating basic affective neuroscience, behaviorally based research, and self-report and interview data are likely to be instructive in advancing our understanding of anhedonia in schizophrenia.

Motivation and Effort Deficits

Avolition, a deficit in initiation and persistence in goal-directed activities, is a particularly deleterious symptom of schizophrenia. Of note, avolition in schizophrenia is sometimes used interchangeably with decreased drive, amotivation, or apathy (Foussias & Remington, 2010). This symptom may manifest as setting or engaging in less effortful goals, such as more often choosing to watch TV as opposed to goals that require more forethought and planning such as creating a meal for several people. At its worst, individuals high in avolition may become so withdrawn as to appear inert or catatonic.

Avolition and the other negative symptoms respond poorly to existing medications and other treatments (Kirkpatrick, Fenton, Carpenter, & Marder, 2006). Presence and severity of avolition predict worse functioning in terms of daily living skills independent of depressive, cognitive, positive, and other negative symptoms (Foussias & Remington, 2010). Avolition is not merely a withdrawal reaction to onset of psychosis; in fact, it is one of the most commonly described prodromal ("prepsychotic") features of schizophrenia and is prevalent through onset of the first psychotic episode and through chronic phases of illness (Faerden et al., 2009; Kirkpatrick et al., 2006). Importantly, this deficit in pursuing and maintaining goal-directed activities occurs despite these individuals reporting in the moment that they enjoy the activities at similar levels to healthy controls when they do engage in them (Cohen & Minor, 2010). Given the prevalent, persistent, and pernicious nature of this symptom, it is critical to better understand the underlying mechanisms that contribute to this deficit and to have reliable, valid, and practical measures of this deficit.

It has become increasingly clear over the last decade that motivation and effort is a complicated and multifaceted construct. One promising objective measure of avolition comes from a strong body of translational evidence directly linking disrupted dopamine functioning in areas sensitive to reward information (e.g., striatum) to reduced willingness to exert effort to obtain larger rewards (see Fervaha, Foussias, Agid, & Remington, 2013). Whereas rodents are typically willing to exert greater effort (e.g., climb over a barrier) to obtain a more desirable reward (e.g., more or tastier food pellets), under a variety of manipulations that decrease dopamine in these key reward areas, rodents tend to prefer the easier choice with a smaller reward (e.g., no barrier for fewer or less "tasty" food pellets; Fervaha et al., 2013). These behavioral patterns mirror findings in humans wherein individuals with schizophrenia tend to prefer more perfunctory tasks over more laborious tasks even when the payoff may be greater. Several effort-based decision-making paradigms have been developed for use in humans, including the Energy Expenditure for Rewards Task (EEfRT) (Treadway et al., 2012) and Balloon Effort Task (Gold et al., 2013). In these tasks, individuals are asked to make several choices between varying low-effort/low-reward (e.g., \$1 for 20 button presses) and a high-effort/high-reward (e.g., \$7 for 100 button presses) options where the high-effort reward value (e.g., \$3, \$7) and probability (e.g., 50, 100%) of reward receipt are varied. This type of paradigm has been shown to activate the same reward pathways as those in the animal models (Treadway et al., 2012). Most importantly, mounting evidence suggests that a similar pattern of effort-based performance deficits found in animal models is evident in schizophrenia; that is, individuals with schizophrenia tend to opt for the low-effort/low-reward choice more often than healthy controls but only under conditions where high-effort rewards were highest and where probability of reward receipt was highest (i.e., under conditions where it would seem to be most "worth it" to exert the extra effort; Barch, Treadway, & Schoen, 2014; Gold et al., 2013). This pattern has been interpreted to mean that individuals with schizophrenia have deficits in their ability to translate reward-relevant information about costs and benefits of allocating effort into goal-directed behavior. This pattern has been associated with negative symptoms or apathy and with worse community and work functioning (Barch et al., 2014; Gold et al., 2013).

Implications for Assessment: Present and Future

Historically, investigators have collected data on dynamic psychological processes through single-occasion interview-based measures or self-report-based measures in a laboratory or clinical setting. However, such measures have a number of drawbacks that challenge both their reliability and validity. For example, individuals with schizophrenia show moderate to severe cognitive deficits across a number of domains directly relevant to autobiographical recall and introspection, including but not limited to impairments in delayed memory, attention, and executive functioning (Green et al., 2000). Additionally, retrospective self-reports are vulnerable to biases such that both psychiatric and healthy populations are more likely to report personally relevant, recently occurring, or mood congruent events (Trull & Ebner-Priemer, 2009). Ecological momentary assessment (EMA) is a powerful and innovative assessment strategy that avoids these common measurement shortcomings and instead captures in-the-moment assessment of personal experiences that are known to changes over time (Trull & Ebner-Priemer, 2009). Modern EMA techniques employ electronic mobile devices (e.g., smartphone or personal data assistants) to deliver a preprogrammed signal that prompts individuals to complete self-report questionnaires that focus on current of very recent states or behaviors. EMA data are more ecologically valid than those collected from traditional retrospective assessment strategies because they repeatedly assess individuals in their normal daily environment and reduce the effect of recall bias that is normally associated with delayed self-reporting.

Several studies have shown that many individuals with severe psychiatric and functional impairment can and will use EMA techniques successfully given the opportunity and appropriate training (Granholm, Ben-Zeev, Fulford, & Swendsen, 2013; Oorschot, Kwapil, Delespaul, & Myin-Germeys, 2009). EMA methodologies have also made important contributions to further our understanding of the emotions, clinical symptoms, and behaviors in individuals with schizophrenia. For example, Gard, Kring, Gard, Horan, and Green (2007) employed an EMA study to help resolve the "emotional paradox" of anhedonia in schizophrenia and found that while patients exhibited deficits in anticipating pleasure from future events, they also exhibited intact consummatory (or in-the-moment) pleasure for current activities. The authors suggest that although patients often self-report appropriate responses to emotional stimuli while experiencing them in the moment, they tend to report less pleasure when describing noncurrent emotions often elicited from trait questionnaires using a retrospective or prospective format. Furthermore, EMA also enables for the examination of dynamic prospective relationships between variables within individuals, thus providing information about directional effects that can inform and enhance interventions for schizophrenia (Granholm et al., 2013). EMA is just beginning to be applied to clinical assessment (Cohen & Elvevåg, 2014).

Implications for Treatment: Present and Future

Current traditional psychosocial treatments aimed at improving cognitive impairments, emotion, and motivation symptoms for individuals with schizophrenia have had limited success thus far. With respect to psychosocial treatment, a recent review and meta-analysis (Revell et al., 2015) of CR administered for approximately 12 weeks (range 8–105) for a total of about 40 hr (range 12–156) found a small positive effect of CR on global cognition. Additionally, traditional antipsychotic medication has not proved to be as beneficial for negative symptoms and cognitive deficits; thus, recent research has examined effects of other drugs such as oxytocin and galantamine. Oya, Matsuda, Matsunaga, Kishi and Iwata (2016) conducted a meta-analysis of seven oxytocin augmentation therapy (OAT) randomized controlled trials in individuals with schizophrenia and found that OAT was superior to a placebo in only a few general scores on a measure of positive and negative symptoms. Limited preliminary research on galantamine has demonstrated positive effects on delayed memory, attention, and processing speed, as well as alogia and social cognition (Koola et al., 2014). Current psychosocial standards of treatment require many resources (e.g., overall cost and time), and the paucity of information for new drug approaches highlights the need for interventions that utilize novel treatment delivery systems and are feasible, flexible, and cost efficient.

Small effect sizes aside, another issue with treating residual symptoms of schizophrenia, particularly psychosocial treatments, involves the cost. Recently, Kazdin and Blase (2011) advocated for a shift in psychotherapy research and practice to aid in the reduction of the mental illness burden by finding new ways to deliver mental health services to those needing but not receiving treatment. For example, interventions that can be administered by a nonprofessional or peer mental health worker may serve as a viable alternative given the cost associated with a doctoral or master's level clinician provide individual treatment. A recent meta-analysis of randomized control trials (Fuhr et al., 2014) examined the effects of peer-delivered interventions compared with treatment as usual (TAU) or to treatment delivered by a licensed healthcare professional among individuals with a severe mental illness. The researchers found small effects of peer-delivered interventions on quality of life and hope, which suggest that peer-led interventions may be equivalent to professionally delivered interventions at improving clinical symptoms. Alternatively, there have been recent efforts to disseminate therapeutic interventions through mobile devices (e.g., smartphones, tablets) to individuals with schizophrenia. Granholm, Ben-Zeev, Link, Bradshaw, and Holden (2012) designed a mobile text message intervention to target medication adherence, socialization, and auditory hallucinations and was administered three times per day, 6 days a week for 12 weeks. This study reported improvements in all of the treatment domains for many of the consumers as well as an 83–86% valid response rate. In another recent study, Ben-Zeev et al. (2014) utilized a smartphone intervention designed to provide illness management support to individuals with schizophrenia. Participants received three prompts per day for 1 month that provided tailored interventions. In this study, participants utilized the smartphone on 86% of the days they had the device, and reductions in positive, global, and depressive symptomatology were evident. More research is needed to understand the clinical efficacy of these peer-led and mobile interventions, though preliminarily results suggest that peer-delivered and mobile applications appear to be a feasible and promising option in conjunction with or as an alternative for traditional therapeutic approaches.

Conclusions

By almost any criterion, schizophrenia is among the most debilitating of psychiatric disorders and has profound influence on the lives of people with the illness. While symptoms such as hallucinations and delusions are modestly tractable, "residual" symptoms (e.g., cognitive, emotion, and motivation) endure beyond acute episodes and are prognostic of nearly every facet of daily functioning. Our goal in this chapter has been to summarize our understanding of three complex residual symptoms of schizophrenia. First, we documented that basic, social, and metacognitive impairments have a highly deleterious effect on social and functional outcome. Second, we illustrated that anhedonia in schizophrenia does not reflect a reduced capacity to experience pleasure in the moment, but rather reflect deficits in anticipating and retrospectively reporting degree of pleasure. Third, we presented compelling evidence that disrupted dopamine functioning and effort valuation may underlie avolition. Furthermore, translating theories and methodologies from cognitive and affective neuroscience, genetics, and emerging technologies (e.g., mobile devices) have enabled investigators to more accurately pinpoint the mechanisms underlying these symptoms. The routine use of interview and self-report measures, translational laboratory measures, and EMA may be the only way to ensure comprehensive coverage of domains that needed to be targeted during treatment.

To conclude, the search for effective schizophrenia treatment continues. Schizophrenia research is continuously evolving and incorporating scientific, methodological, and technological advances. Increased collaboration among various stakeholders and vast resources allocated in an effort to understand and treat the illness has also been observed. Despite the challenge of curing schizophrenia, there is cause for optimism so long as innovative researchers and clinicians continue to leverage contemporary translational research and emerging technologies in the search for the next-generation treatment.

Author Biographies

Thanh Le graduated from the University of California, San Diego, in 2011 and is a graduate student who works with Dr. Alex Cohen at Louisiana State University. His interests include utilizing behavioral and mobile assessments to understand the cognitive and affective mechanisms underlying social functioning impairments in serious mental illness.

Kyle R. Mitchell graduated from the University of Texas at Austin in 2012 and is a graduate student who works with Dr. Alex Cohen at Louisiana State University. His interests are affective abnormalities, their relationship to neurocognitive systems in individuals with schizophrenia spectrum disorders, and the application of biobehavioral systems to understanding this relationship.

Elana Schwartz earned a bachelor's degree in psychology at the University of Maryland, College Park, and completed a master's degree in clinical psychology at Towson University under Dr. Kerri Goodwin. Ms. Schwartz is currently working on a PhD in clinical psychology at Louisiana State University mentored by Dr. Alex Cohen.

Jessica McGovern, MA, is a graduate student in the PhD clinical psychology program at LSU. Her broad interests are in the interactions between emotion, cognition, and symptomatology in schizophrenia spectrum disorders as they relate to understanding the underlying neural mechanisms.

Alex S. Cohen, PhD, is the director of the Affective Science and Psychopathology Laboratory at Louisiana State University. He is a licensed clinical psychologist and is an active researcher on understanding residual symptoms of schizophrenia.

Obesity

Michael G. Perri, Melissa H. Laitner, and Aviva H. Ariel

Department of Clinical and Health Psychology, College of Public Health and Health Professions, University of Florida, Gainesville, FL, USA

Scope, Seriousness, and Etiology of Obesity

Prevalence of Obesity

Obesity is characterized by increased body weight caused by an excess accumulation of fat. In adults, it is defined operationally as a body mass index (BMI) (weight in kilograms divided by height in meters squared) of 30 or greater. Individuals with BMIs of 25 or greater but less than 30 are described as "overweight." During the course of the twentieth century and continuing into the first decade of the current century, the United States witnessed a remarkable rise in the prevalence of obesity. The obesity rate rose from an estimated prevalence of less than 5% in 1900 to more than 36% in 2011–2014, with most of the increase occurring from 1970 to 2010 (Helmchen & Henderson, 2004; Komlos & Brabec, 2011; Ogden, Carroll, Kit, & Flegal, 2014; Ogden, Carroll, Fryar, & Flegal, 2015).

Over the past 40 years, a sharp increase in the prevalence of obesity has also been observed worldwide. Closely associated with economic development, higher rates of obesity have been identified not just in the affluent nations of North America and Europe but also in a broad array of low- and middle-income countries across the globe, particularly in China and India. The World Health Organization (WHO) (2014) estimates that more than 600 million people (approximately 13% of the world's adult population) are obese and that most people in the world now live in countries where overnutrition and obesity are responsible for more deaths than malnutrition and underweight.

In the United States, data from the National Health and Nutrition Examination Survey (NHANES) indicate that approximately 37% of adults are obese (Ogden et al., 2015) and an additional 34% are overweight (Ogden et al., 2014). Among adults 20 years and older, the prevalence of obesity has risen steadily since the 1970s. Currently, 34.3% of men and 38.3% of women are obese (Ogden et al., 2015). An examination of prevalence in 2011–2014 (Ogden et al., 2015) by race, ethnicity, and gender revealed the following pattern.

The Wiley Encyclopedia of Health Psychology: Volume 3: Clinical Health Psychology and Behavioral Medicine, First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

The highest rates were observed in non-Hispanic Black adults (56% for women; 37.5% for men) and Hispanic adults (45.7% for women; 39.0% for men) followed by non-Hispanic Whites (35.5% for women; 33.6% for men) and lowest in non-Hispanic Asians (11.9% for women; 11.2% for men).

In children and adolescents ages 2–19 years, obesity is defined as a BMI at or above the 95th percentile of the Centers for Disease Control and Prevention (CDC) sex-specific BMI-for-age growth charts from 2000 (Kuczmarski et al., 2000). Across all ages of young people, the prevalence of obesity in 2011–2014 (Ogden et al., 2015) was 17.1% among girls and 16.9% among boys. Data from 2011 to 2012 (Ogden et al., 2014) indicate an additional 14.4% of girls and 15.3% of boys were overweight (defined as BMI-for-age > 85th percentile and <95th percentile of the CDC growth charts). In 2011–2014 (Ogden et al., 2015), the highest rates were seen in Hispanic youth (22.4% for boys; 21.4% for girls) and non-Hispanic Black children and adolescents (20.7% for girls; 18.4% for boys), followed by non-Hispanic White youth (15.1% for girls; 14.3% for boys), and lowest in Asian children and adolescents (11.8% for boys; 5.3% for girls).

Consequences of Obesity

Evidence documenting the deleterious impact of excess weight on health and longevity continues to accumulate. Obesity is directly associated with an array of health complications, including the spectrum of cardiovascular diseases and associated risk factors including ischemic heart disease, angina, myocardial infarction, heart failure, sudden death, stroke, hypertension, dyslipidemia, insulin resistance, and type 2 diabetes, as well as asthma, osteoarthritis, and certain cancers (breast, colorectal, endometrial, kidney, pancreatic, liver, and gallbladder; Jensen et al., 2014).

BMI is positively associated with premature death, disability, and reduced quality of life. Estimates suggest the number of obesity-related deaths per year in the United States may be as high as 400,000 (Mokdad et al., 2003). Obesity exacts a toll not just in terms of morbidity and mortality; it also has substantial economic and psychosocial effects. Obesity accounts for 20.6% of the nation's health expenditures, an amount in excess of $200 billion dollars per year (Cawley & Meyerhoefer, 2012). Medical costs for obesity increase with degree of obesity such that people with a BMI > 40 accrue costs that are two- to threefold greater than normal weight individuals (Arterburn, Maciejewski, & Tsevat, 2005). The social and psychological effects of obesity are profound and include social discrimination, personal distress, decreased emotional well-being, and overall lower health quality of life (Puhl & Heuer, 2010).

Genetic and Environmental Contributors

The determinants of obesity include genetic and environmental factors and their interaction. Several genetic profiles have been identified that suggest body weight is linked to inherited biological factors that regulate energy and expenditure (Albuquerque, Stice, Rodríguez-López, Manco, & Nóbrega, 2015). However, few specific genes have been identified that put an individual at increased genetic risk for obesity, and the expression of genetic influences on body weight appears to be mediated by the interaction between inherited genetic profile and environmental exposure (Rosenquist et al., 2015).

During the latter half of the twentieth century, a variety of important environmental and cultural changes with the potential to influence the expression of genetic predisposition to weight gain occurred. These included (a) major modifications in industrial mechanization that reduced energy expenditure across a broad array of occupations; (b) the adoption of an automobile-centered way of life and changes to the built environment that discouraged walking; (c) the rise of fast-food restaurants and the ready availability of low-cost, energy-dense foods provided in larger serving sizes than home-cooked meals; (d) the increased proportion of women in the workforce and the greater number of meals eaten away from home; and (e) the introduction and widespread adoption of screen-based entertainment and information exchange technologies (e.g., televisions, personal computers, and the Internet). The confluence of these changes created an "obesogenic environment"—an environment that promoted high energy intake and low energy expenditure. Among genetically susceptible individuals in the population, this combination may have produced increased body weights, thereby contributing to the rise in the prevalence of obesity (Swinburn, Egger, & Raza, 1999). Many of these same factors that contributed to the rise in the prevalence of obesity in the United States are now at play in low- and middle-income countries throughout the world, resulting in the growing global prevalence of obesity (WHO, 2014).

Treatment Options

In the United States, an array of options is available for the management of obesity. These include self-help approaches, commercial weight-loss programs, behavioral or "lifestyle" treatments, pharmacotherapy, and bariatric surgery.

Self-Help Approaches

The majority of people attempting to lose weight do so on their own. However, while anecdotal reports of success are common, empirical studies show on average the degree of weight loss achieved via self-help is quite modest. For example, a recent meta-analysis of 23 studies of self-help approaches to weight management (Hartmann-Boyce, Jebb, Fletcher, & Aveyard, 2015) showed a mean loss of 1.8 kg at 6 months and no changes at 1 year.

Recent technological advances have made Internet and mobile health (mHealth) programs for weight management widely available to help people lose weight on their own. Indeed, numerous devices and applications are available to assist people in tracking and modifying their physical activity, dietary intake, and body weight. However, very few high-quality studies exist to provide empirical support regarding the efficacy of Internet and mHealth interventions for self-management of obesity. Recent reviews suggest that interactive mHealth technologies can enhance the effectiveness of in-person weight-loss intervention, boosting mean weight losses by 1 kg, but the effects of Internet and mHealth programs as stand-alone interventions appear to be minimal (Kodama et al., 2012; Okorodudu, Bosworth, & Corsino, 2015).

Despite the limited effectiveness of self-help programs in general, some individuals achieve and maintain substantial weight reductions. For example, the National Weight Control Registry (NWCR) (Wing & Phelan, 2005) tracks a cohort of obese individuals who have lost 30 pounds or more and maintained that loss for at least 1 year. Understanding factors associated with success among NWCR participants may offer insights into effective self-help strategies for weight management.

Most NWCR members reported using a combination of strategies including decreased energy intake (e.g., reducing fats and sugars, portion control, and counting calories) and increased physical activity (e.g., walking, swimming, and strength training) to achieve their initial weight reductions. To maintain their losses, individuals in the NWCR report participating in approximately 1 hr/day of moderate-intensity exercise, consuming fewer than 1,400 calories per day, eating the same foods on weekdays and weekends, consuming a healthy breakfast, exerting high levels of control over their eating, and self-monitoring through weekly weighing and/or daily tracking of food intake. The NWCR participants appear to be a relatively unique group of people, and it is unclear how representative they are of the obese population. Nonetheless, the approaches they employ for managing their weight may be useful guides for others dealing with obesity.

Commercial Weight-Loss Programs

Although many overweight and obese individuals seek treatment through commercial weight-loss programs, research regarding the effectiveness of such programs remains relatively limited. In a recent systematic review of 45 studies including 39 randomized controlled trials, Gudzune et al. (2015) found Jenny Craig® and Weight Watchers® had 12-month mean body weight reductions that were 4.9 and 2.6%, respectively, greater than controls. Nutrisystem® showed 3.8% greater body weight loss at 3 months compared with controls, but there was limited information available regarding its longer term effectiveness. Very-low-calorie programs (<800 kcal/day) including Health Management Resources®, Medifast®, and OPTIFAST® had initial mean body weight reductions that were 4.0% or more than what was accomplished with dietary counseling, but beyond 6 months this advantage was reduced. Atkins® low-carbohydrate diet showed 0.1–2.9% greater mean weight losses at 12 months compared with counseling, and insufficient information was available regarding the effects of SlimFast®. Thus, there is empirical evidence to suggest that commercial programs can elicit greater weight losses than control conditions, particularly during the first 3–6 months of treatment.

Behavioral "Lifestyle" Interventions

Since the early 1970s, behavioral or "lifestyle" interventions have employed principles derived from learning theory, particularly operant and social cognitive theories, to elicit and maintain changes in eating and activity patterns and thereby produce weight loss. Participants are taught an array of behavior modification strategies to decrease their energy intake and increase their energy expenditure. Goal setting for daily caloric intake (e.g., 1,200 kcal/day) and physical activity (e.g., 30 min/day of walking), coupled with daily self-monitoring of foods consumed and minutes of exercise completed, comprise the foundation of behavioral interventions (Butryn, Webb, & Wadden, 2011). Other behavioral modification strategies employed include stimulus control (decreasing environmental triggers for eating), self-reinforcement (rewarding oneself for progress), cognitive reframing (replacing negative thoughts with positive ones), assertiveness training (learning how to decline offers of food), and problem solving (systematic brainstorming to deal with barriers to progress; Wadden, Webb, Moran, & Bailer, 2012). Following an initial phase focused on inducing weight loss, an extended care phase, consisting of 6–12 months of less frequent contacts delivered via face-to-face or telephone, is commonly employed to help participants maintain the behavioral changes and weight losses achieved during initial treatment (Perri et al., 2008).

Obese adults who participate in a behavioral lifestyle intervention lose an average of 8–10% of their initial body weight over the first 4–6 months of treatment with a gradual regaining of weight after treatment ends (Perri et al., 2014; Wadden et al., 2012). Extended care "maintenance" programs appear helpful in slowing or delaying weight regain (Perri et al., 2008).

The landmark Diabetes Prevention Program (DPP) (DPP Research Group, 2002) demonstrated the effects of lifestyle treatment on the prevention of disease. Overweight and obese adults (*n* = 3,234) at risk for diabetes achieved an initial weight loss of 7% and maintained approximately half that amount over 3 years. The lifestyle participants showed a 58% reduction in the incidence of diabetes compared with a placebo control condition, whereas a medication group that received the antidiabetes medication metformin had a 34% decrease. Ten-year follow-up data from the DPP study indicated that the cumulative incidence of diabetes remained lowest for participants in lifestyle treatment compared with those who received metformin or placebo (DPP Research Group, 2009). During the 10-year follow-up period, participants in the lifestyle program on average returned to their baseline weights. Nonetheless, the 10-year incidence of diabetes for the lifestyle participants was 16 and 34% lower than for those in the metformin and placebo conditions, respectively. The DPP researchers concluded that the years spent at a lower weight reduced the overall risk for diabetes among the lifestyle participants (DPP Research Group, 2009).

Further documentation regarding the beneficial health effects of behavioral interventions for weight loss comes from the Look AHEAD study (Look AHEAD Research Group, 2013), the largest (*n* = 5,145) and longest (maximum follow-up = 13.5 years) randomized controlled trial of behavioral treatment for weight loss. The Look AHEAD lifestyle program produced a mean body weight reduction of 8.6% at the end of the first year followed by a gradual regaining of weight over the next 4 years and the maintenance of losses of approximately 4–5% in subsequent years (Look AHEAD Research Group, 2014). At year 8, the participants sustained on average more than half of their initial losses, and the majority successfully attained body weight reductions of 5% or more. Although the Look AHEAD study was not successful in its aim of reducing cardiovascular mortality and morbidity (perhaps due to the greater medication use by participants in the comparison condition), the study was successful in reducing cardiovascular risk factors, insulin use, sleep apnea, and depression and in improving participants' quality of life, physical functioning, and mobility (Look AHEAD Research Group, 2010, 2013).

Collectively, the findings regarding behavioral interventions for obesity indicate that they can produce weight changes of sufficient magnitude to improve health with no risk of serious side effects. Limitations of behavioral treatment include a regaining of lost weight and the limited availability of state-of the-art interventions in most communities.

Pharmacotherapy

The 2013 Obesity Management Guidelines developed by the American Heart Association, the American College of Cardiology, and the Obesity Society (Jensen et al., 2014) suggest that individuals with a BMI > 30 (or a BMI > 27 with an obesity-related comorbidity) may be appropriate candidates for pharmacotherapy *as an adjunct to a comprehensive lifestyle intervention*. Currently, there are five weight-loss medications approved by the Food and Drug Administration (FDA) for long-term use. Each medication, its mechanism of action, and weight changes commonly associated with its use in clinical trials are described briefly below.

Orlistat (Xenical®)

Orlistat inhibits lipase, the enzyme in the gastrointestinal tract responsible for fat digestion, and reduces the absorption of fats by approximately 30%. Pooled data from a meta-analysis (Rucker, Padwal, Li, Curioni, & Lau, 2007) showed a mean weight reduction with orlistat of approximately 8.6 kg compared with 5.5 kg for dietary counseling plus placebo. This finding suggests that the incremental weight-loss benefit of orlistat is approximately 3.1 kg. Common side effects associated with orlistat include gastrointestinal distress, including fecal urgency and fecal incontinence.

Naltrexone/Bupropion (Contrave®)

Naltrexone/bupropion is a combination of two FDA-approved drugs, naltrexone and bupropion. Naltrexone is an opioid antagonist used to treat alcohol and opioid dependence. Bupropion is a norepinephrine–dopamine reuptake inhibitor approved as an antidepressant and also used for smoking cessation. Results from a clinical trial that directly examined the effects of behavioral treatment plus placebo versus behavioral treatment plus naltrexone/bupropion showed that among all randomized participants there were 56-week mean weight losses of 4.9 and 7.8 kg, respectively, indicating an incremental benefit of naltrexone/bupropion of approximately 2.9 kg (Wadden et al., 2011). Nausea, constipation, headache, and vomiting are common side effects of the use of naltrexone/bupropion.

Lorcaserin (Belviq®)

Lorcaserin selectively stimulates the 5-HT_{2C} receptor for serotonin and thereby suppresses appetite and increases satiety. In randomized trials (e.g., Smith et al., 2010), lorcaserin has produced mean weight reductions of 6.0–6.6% compared with losses of approximately 3% for diet plus placebo. Hence, the incremental weight-loss benefit of lorcaserin appears to be 3.0–3.6%. Common side effects include headache, dizziness, fatigue, nausea, dry mouth, and constipation. While chemically similar to fenfluramine (a weight-loss drug discontinued due to its association with heart valve disease), the use of lorcaserin has not been associated with an increase in heart valve problems.

Phentermine/Topiramate (Qsymia®)

This compound is a combination of the stimulant phentermine, which is approved for short-term use in weight management, and the antiseizure/antimigraine drug topiramate. Phentermine is a centrally acting appetite suppressant that works in a manner similar to amphetamine. Topiramate appears to assist in weight loss by inhibiting orexigenic glutamate signaling and increasing energy utilization. A randomized controlled trial (Gadde et al., 2011) of the standard dose of phentermine/topiramate showed an incremental benefit of a 6.6% weight loss versus placebo. Dizziness, nausea, and fatigue are common side effects associated with the use of phentermine/topiramate.

Liraglutide (Saxenda®)

Liraglutide, the newest drug to be approved by the FDA for weight loss, is a glucagon-like peptide-1 (GLP-1) receptor agonist that mimics an intestinal hormone that signals satiety. A lower dose of liraglutide (marketed as Victoza®) is used as a treatment for type 2 diabetes. Randomized trial data presented to the FDA suggest that 1 year of treatment with liraglutide produces body weight reductions of 4.0–5.4% above the weight losses accomplished with diet plus placebo (FDA, 2014). Common side effects include nausea, hypoglycemia, and diarrhea, and there is some concern that the use of liraglutide may be associated with acute pancreatitis.

In summary, an array of medications are now available that may enhance the effectiveness of lifestyle treatments for obesity. Each of these pharmacological agents increases weight loss, and each is associated with notable side effects. Moreover, the withdrawal of previous weight-loss drugs from the market serves as an object lesson that serious adverse effects may become apparent only when a drug is used in larger populations for longer periods of time than in the FDA approval process.

Bariatric Surgery

Surgery may be an appropriate option for adults with a BMI > 40 (or a BMI > 35 with an obesity-related comorbid condition) who have not responded sufficiently to behavioral treatments with or without pharmacotherapy (Jensen et al., 2014). The four types of operations that are commonly offered in the United States are described below.

Adjustable gastric band

In the "gastric banding" procedure, the surgeon places a small band around the top of the stomach to create a pouch that limits the quantity of food that can be ingested, which helps the patient feel full after eating a small amount. The feeling of satiety is governed by the size of the opening between the pouch and the remainder of the stomach. The gastric band contains a circular balloon that allows the surgeon to increase or decrease the size of the opening between the upper and lower portions of the stomach according to the needs of the patient. Gastric banding generally produces slow and steady weight losses that are larger than what is commonly achieved with behavioral interventions but smaller than other bariatric surgery procedures. Mean body weight reductions of 14–16% are commonly observed 1–3 years after surgery (Colquitt, Pickett, Loveman, & Frampton, 2014). While gastric banding has fewer complications than other procedures, it has the highest rate of reoperation (>30%), often related to slippage or malfunctioning of the band.

Roux-en-Y gastric bypass

Gastric bypass, long considered the "gold standard" of bariatric surgeries, involves a complex set of procedures that entail the restriction of food intake coupled with changes in the absorption of nutrients. The surgeon first creates a small pouch at the top of the stomach. Next, the small intestine is connected directly to the pouch so that after food leaves the pouch, it bypasses the remainder of the stomach, the duodenum, and a portion of the upper intestine. Transporting food directly from the pouch into the small intestine changes how the digestive tract absorbs food, resulting in reduced absorption of nutrients and calories consumed. Gastric bypass is more complicated to perform than gastric banding, requires a longer hospital stay, and has a greater risk of near-term surgical complications, but it produces much larger weight losses than gastric banding. Patients commonly lose 30–35% of their body weight within 1 year, and this degree of weight reduction is typically maintained well at follow-ups of 3–10 years (Colquitt et al., 2014). The metabolic and weight-loss effects of gastric bypass typically include partial if not full remission of type 2 diabetes. The disadvantages of gastric bypass include malabsorption of vitamins and minerals (often requiring supplementation) as well as adverse reactions to the consumption of sugary or starchy foods that can cause rapid heart rate, dizziness, abdominal pain, and vomiting.

Vertical sleeve gastrectomy

This irreversible procedure (known as the "gastric sleeve") is performed by removing approximately 80% of the stomach. What remains is a tube-like pouch that holds a considerably smaller volume than the normal stomach, thereby decreasing the amount of food that can be consumed. The gastric sleeve induces large, rapid weight loss comparable in magnitude (>30% of body weight) at 1 year to the gastric bypass (Colquitt et al., 2014). The gastric sleeve also produces favorable changes in the gut hormones that suppress hunger, increase satiety, and improve blood sugar control. Overall, the gastric sleeve appears to be as effective as gastric bypass with respect to weight loss and its impact on type 2 diabetes. Moreover, the rates of complications associated with the gastric sleeve, while higher than gastric banding, are lower than gastric bypass.

Biliopancreatic diversion with a duodenal switch

This surgery, commonly referred to as the "duodenal switch," is a complex procedure that entails (a) removal of a large portion of the stomach (to increase satiety), (b) rerouting food away from much of the small intestine (to limit the absorption of nutrients), and (c) modifying how bile and other digestive juices influence digestion (to decrease further the absorption of calories). Unlike the other procedures described previously, over time the duodenal switch allows patients eventually to resume eating "normal" amounts of food while experiencing long-term weight losses that are larger than those produced by gastric banding, gastric bypass, and the gastric sleeve procedures (Colquitt et al., 2014). The "duodenal switch" results in beneficial changes to gut hormones (which also occur in the bypass and sleeve procedures) and appears to be the most effective surgical treatment for diabetes. The duodenal switch has higher complication rates and greater risk for mortality than alternative procedures—factors that must be carefully considered by prospective patients.

Bariatric surgery offers individuals with severe obesity the opportunity to achieve very large weight losses that are generally well maintained over the long run and are associated with dramatic improvements in many of the comorbidities associated with severe obesity. The major disadvantages associated with bariatric surgery include the potential for perioperative and postoperative complications that could extend hospitalizations, require additional surgeries, and, in rare cases, result in death. The significant changes in eating patterns associated with most bariatric procedures pose important challenges to many patients. Behavioral counseling is often recommended before and after surgery to help patients prepare for and deal with the significant lifestyle changes dictated by bariatric surgery.

Clinical Guidelines

The American College of Cardiology, the American Heart Association, and the Obesity Society have developed a comprehensive set of guidelines for the treatment of obesity in adults (Jensen et al., 2014). The guidelines, written as advice to providers of medical care, recommend that primary care providers measure height, weight, and waist circumference in overweight and obese adults, at least annually. Counseling to lose 3–5% of body weight is recommended for patients with a BMI > 25 who are at increased risk for cardiovascular disease (i.e., those with elevated blood pressure, prediabetes, or hyperlipidemia). A comprehensive, high-intensity (i.e., >14 sessions over 6 months) lifestyle program led by trained interventionists is recommended for adults with a BMI > 30. Individuals who are unable to achieve or maintain moderate weight losses after participating in a comprehensive lifestyle intervention may be appropriate candidates for pharmacotherapy (for adults with BMI ≥ 30 or ≥27 with a comorbid condition) or bariatric surgery (for adults with BMI ≥ 40 or ≥35 with comorbid condition). In recommending treatment, clinicians are encouraged to consider an individual's age, severity of obesity, comorbid conditions, behavioral health history, and treatment preference.

Conclusions

The current global epidemic of obesity has focused attention on the need to better understand, manage, and control this serious threat to public health. An array of cultural and environmental changes associated with economic success and increasing affluence have promoted higher food consumption and decreased energy expenditure, thereby potentiating a genetic predisposition to obesity in much of the population. In the United States, the rise in the prevalence of obesity has resulted in increasingly larger portions of healthcare expenditures devoted to the treatment of obesity and its comorbidities.

At the individual level, most people with obesity prefer to manage their weight on their own. Some subgroups, such as the NWCR participants, show dramatic success in the self-management of obesity, but generally there is scant evidence to support the effectiveness of self-help approaches for obesity management. Some commercial weight-loss programs offer resources likely to result in tangible but modest weight reductions. Among professionally delivered interventions, behavioral lifestyle interventions reliably produce weight changes of sufficient magnitude to improve health, and an array of medications are now available that may enhance the effectiveness of lifestyle treatments. For individuals with severe obesity, bariatric surgery offers the opportunity to achieve very large weight losses accompanied by significant improvements in many of the comorbidities associated with severe obesity.

Despite progress that has been made in the treatment of obesity, numerous challenges remain. For large segments of the population, access to obesity treatment is limited by governmental regulations and lack of coverage by health insurance policies. Furthermore, little research has addressed the important issues of dissemination and implementation of obesity treatment in community settings. More research is needed to deal with the problem of poor weight-loss maintenance and how an improved understanding of the interplay between biological and behavioral factors that contribute to obesity might be utilized to develop innovative and more effective treatments. Finally, greater attention needs to be given to the prevention of obesity and how governmental policies might modify the environmental factors responsible for the global rise in the prevalence of obesity.

Author Biographies

Michael G. Perri, PhD, is the Robert G. Frank Endowed Professor of Clinical and Health Psychology and dean of the University of Florida College of Public Health and Health Professions. His research focuses on the development, evaluation, and dissemination of cost-effective programs for the management of obesity. Findings from the 20+ randomized trials conducted by his team have had a significant impact on theory, research, and clinical care related to the behavioral treatment of obesity.

Melissa H. Laitner, MS, is a PhD candidate in the Department of Clinical and Health Psychology at the University of Florida where she is concurrently completing a master's degree in public health. Her research interests include behavioral treatment for obesity, health disparities, and health policy. Her dissertation research focuses on examining potential disparities between rural and urban communities in regard to obesity, diabetes, and prediabetes.

Aviva H. Ariel, MS, is a PhD candidate in the Department of Clinical and Health Psychology at the University of Florida where she is concurrently completing a master's degree in public health with a concentration in social and behavioral sciences. Her research interests include holistic health promotion, body image disturbance, and behavioral interventions for weight management and disordered eating.

Overview

The first non-edited and comprehensive textbook in health psychology was published by Gatchel and Baum (1983). At that time, the field of health psychology was simply an array of basic and sometimes fragmented different areas (e.g., clinical psychology, cognitive psychology, experimental psychology, neuropsychology, physiological psychology, social psychology, etc.). These areas, though, began to touch upon important biobehavioral and medical content topics new to the field, such as adherence to medical regimens, promoting healthy lifestyles, rehabilitation approaches to disability, and the prevention and treatment of chronic pain, just to name a few. At about this time, when the term health psychology was still a relatively new one, a series of five edited volumes were published under the title, *Handbook of Psychology and Health* (Baum & Singer, 1982, 1987; Baum, Taylor, & Singer, 1984; Gatchel, Baum, & Singer, 1982; Krantz, Baum, & Singer, 1983). The books in this series focused on specific topic areas including pain. As subsequently noted by Baum, Revenson, and Singer (2001) in their handbook, this earlier series was published over several years just as health psychology became firmly established in its own right. There have been numerous other such handbooks published since then. Moreover, the quite diverse areas of how health psychology and medical illnesses are interrelated were perfectly aligned with the very important and influential Institute of Medicine's (IOM) report on *Living Well and Chronic Illness: A Call for Public Health Action* (Institute of Medicine, Committee on Living Well with Chronic Disease: Public Action to Reduce Disability, Improve Functioning and Quality of Life, 2012). This major IOM report was written as "… a guide for immediate and precise action to reduce the burden of all forms of chronic illnesses through the development and implementation of cross-cutting and coordinated strategies to help Americans live well…" (A-1). One such illness category was

First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

chronic pain. Indeed, one of the most frequently cited reasons for patients in the United States to seek medical care is due to pain. Recent estimates reveal that 25.3 million American adults (11.2%) suffer from daily (chronic) pain and 23.4 million (10.3%) report "a lot of pain" (Nahin, 2015). Moreover, according to earlier statistics from the National Academy of Sciences (Gaskin & Richard, 2011), the societal costs of chronic pain and related disability in the United States alone is $560–$635 billion each year. Unfortunately, many chronic pain conditions cannot yet be successfully treated. More clinical research is still needed to develop better treatment methods. Thus, social, economic, and biobehavioral research have become increasingly important in medicine and in the general related area of health psychology.

The above subsequently led to another very influential IOM report, "Relieving Pain in America" (Institute of Medicine of the National Academy of Science, 2011), which highlighted the urgent need for the development of better methods for pain management because the ever-increasing costs associated with current treatment approaches cannot be sustained. This important focus has been further reinforced by National Institutes of Health's (NIH's) recent "National Pain Strategy: A Comprehensive Population Health-Level Strategy for Pain" (https://www.federalregister.gov/articles/2015/04/02/2015-07626/solicitation-of-written-comments-on-draft-national-pain-strategy). The mission of the strategy is to "Enhance pain research efforts and promote collaboration across the government, with the ultimate goals of advancing fundamental understanding of pain and improving pain-related treatment strategies." It was also charged to develop "a comprehensive population level health strategy for pain prevention, treatment, management, education, reimbursement, and research that includes specific goals, actions, time frames, and resources" as recommended in the IOM report on "Relieving Pain in America." The proposed strategy also emphasizes the use of the biopsychosocial model of pain, which is the underpinning of interdisciplinary pain assessment and treatment.

The result of the new area of health psychology led to the replacement of the outdated *biomedical reductionism*, or a "dualistic" perspective that the mind and body function separately and independently, to a more heuristic *biopsychosocial approach* to medicine, initially introduced by Engel (1977) and that further emerged in the 1980s. In the context of pain, the biopsychosocial model views it as the result of a dynamic interaction among biological, psychological, and social factors that perpetuate and may even worsen the clinical presentation. Gatchel and others (Gatchel, 2004, 2005; Gatchel, McGeary, McGeary, & Lippe, 2014; Gatchel & Okifuji, 2006; Gatchel, Peng, Peters, Fuchs, & Turk, 2007; Gatchel & Turk, 1999; Turk & Monarch, 2002), for example, have further advanced this health psychology/biopsychosocial perspective of pain.

The Biopsychosocial Model of Pain

As earlier reviewed by Gatchel and Okifuji (2006), traditional interventions for chronic pain had predominantly involved monotherapies, such as surgery, injections, and a wide array of pharmacotherapeutic approaches. However, as Turk and Gatchel (2002) began to highlight, a more comprehensive interdisciplinary approach was needed to address both the physical and psychosocial factors involved in chronic pain. A major outgrowth, in turn, was the development of the biopsychosocial model. As briefly discussed earlier, this model views pain as the result of a dynamic interaction among biological, psychological, and social factors that perpetuate and may even worsen the clinical presentation. Each patient experiences pain uniquely, and a range of psychological and socioeconomic factors can interact with physical pathology to modulate that patient's report of symptoms and subsequent pain-related disability. This model has been very influential in the area of pain, especially with the resultant development of treatment- and cost-effective interdisciplinary pain management programs (Gatchel et al., 2007; Gatchel & Okifuji, 2006), to be reviewed later. Such programs, based upon the biopsychosocial model, have been found to be the most heuristic approach to understanding and assessing chronic pain (Gatchel et al., 2007). Indeed, the influential IOM report (Institute of Medicine of the National Academy of Science, 2011, p. 35) states that "Today, most researchers and clinicians who specialize in pain issues use the '**biopsychosocial model**' [denoting the combination of biological, psychological and social/family/cultural contexts of pain to understand and treat chronic pain (Gatchel et al., 2007)]."

The biopsychosocial model focuses on both disease and illness, with illness being viewed as the complex interaction among biological, psychological, and social factors (Gatchel, 2005). As succinctly summarized by Turk and Monarch (2002), *disease* is usually viewed as a pathophysiological event that results in a disruption of some anatomical/physiological structure or organ system functioning. *Illness,* on the other hand, is usually viewed as a more *subjective* experience that a specific disease is present. *Illness*, therefore, basically refers to how a "sick" individual and possibly members of his/her family accommodate and react to the resultant symptoms of possible disability and limited activities of daily living. As Turk and Monarch (2002) further point out, the distinction between disease and illness can basically be viewed as similar to the difference one can make between *nociception* and *pain*. Essentially, *nociception* refers to the stimulation of nerves that transmit signals to the brain about potential tissue damage. In contrast, *pain* is the subjective perception that results from the sensory input to the brain. Moreover, such input is usually "filtered" through a number of layers (e.g., past learning experiences, psychosocial influences, genetic predispositions, etc.). Therefore, because the biopsychosocial model of chronic pain views each individual as experiencing pain uniquely, it is important to evaluate the different dimensions of this interactive process (Gatchel, 2004). Other comprehensive reviews of the biopsychosocial model of pain can also be found elsewhere (Gatchel, 2004; Gatchel et al., 2007, 2014; Turk & Monarch, 2002).

Interdisciplinary Pain Management

The biopsychosocial model of chronic pain was one of the first models designed to accommodate the complexity of the chronic pain experience. As the model began to permeate academic and clinical medicine, so, too, did multicomponent models of pain management care. To date, the interdisciplinary pain management approach stands as one of the best and most efficacious examples of comprehensive pain management (Gatchel et al., 2014). Before exploring interdisciplinary care in greater detail, one must first be able to draw a distinction between *interdisciplinary* and *multidisciplinary* care. In an excellent review of interdisciplinary pain management models, Turk et al. (2010) carefully explained how interdisciplinary and multidisciplinary models differ. They appropriately highlight that, although the two models may both include components that match the dimensions of the biopsychosocial pain conceptualization, a truly interdisciplinary pain management program is more integrated and all treatment components are administered "under one roof" at the same pain management facility. In contrast, multidisciplinary care may be delivered by different providers at different facilities, thus decreasing integrative care and constant communication among providers "under one roof." Integration of pain management services is essential and can manifest in multiple ways, although most agree that coordination of care through daily team-based communication "under one roof" and common treatment goals is the key to effective integrative pain management (Gatchel et al., 2014). Interdisciplinary pain management teams will often include pain medicine physicians, nursing staff, clinical health psychology, and physical/occupational therapy providers who synthesize their care through effective leadership and commonly developed goals to create a comprehensive treatment program, with the resultant effectiveness greater than the sum of its parts (Okifuji, 2003).

A number of published studies describe the effectiveness of interdisciplinary pain management models in multiple pain populations (Gagnon, Stanos, van der Ende, Rader, & Harden, 2013; Gatchel et al., 2014). Indeed, a PubMed search for "interdisciplinary pain management" returned 50 published studies between 1995 and 2015, most of which demonstrate significant benefit of interdisciplinary pain management programs for pain of various etiologies. Despite a wealth of supportive research outcomes, interdisciplinary pain management programs are widely unavailable to many pain patients. Numerous barriers prohibit both the implementation of comprehensive pain management programs and the long-term follow-up needed to ensure that gains are maintained. First, some have noted that third-party payer reimbursement policies have played an important role in limiting the availability of more comprehensive pain management options (Gagnon et al., 2013). This is quite surprising in light of the staggering cost of chronic pain over time and the substantial socioeconomic gains that are possible through interdisciplinary care (Lippe & Polatin, 2014). Others have noted that interdisciplinary programs may not be utilized as well as they could be because many pain treatment providers prioritize simple palliative pain management (e.g., medications) over interdisciplinary options. Breivik, Eisenberg, O'Brien, and OPENMinds (2013) have noted that palliative pain relief options may be preferred because chronic pain patients and their most oft-seen medical providers (e.g., non-specialty physicians) are either not aware of more effective treatment options or are not familiar with the data supporting interdisciplinary pain management. There is some hope that increased US congressional attention to the pain management crisis, and federal policy calling more interdisciplinary healthcare options, will alleviate these concerns in the future (Gatchel et al., 2014).

In order to truly improve the availability of interdisciplinary pain programs, there needs to be some agreement on the necessary components. In a "Letter to the Editor" in the journal, *Pain*, Kaiser, Deckert, Kopkow, Schmitt, and Sabatowski (2014) pointed out that there is no broadly accepted definition of multidisciplinary or interdisciplinary pain programs (including the level of emphasis required for psychosocial intervention). This has resulted in heterogeneity in interdisciplinary pain programs under study, making it difficult to examine the state of the research meta-analytically with much refinement. Some have stressed a need to establish common outcomes across pain programs that can be used to uniformly examine the important components of pain management (i.e., key ingredients) for translation (Deckert et al., 2015). In fact, the NIH have developed the *Patient-Reported Outcomes Measurement Information System* (PROMIS) (http://www.nihpromis.org/) in order to encourage all pain practitioners to use the set of outcome measures. Regardless, most who study interdisciplinary pain management seem to agree that psychosocial intervention is vital if a pain management program wants to holistically address the biopsychosocial model (Gatchel et al., 2014). Numerous studies have uncovered psychosocial constructs of pain (e.g., pain catastrophizing, pain acceptance, fear avoidance, etc.) that contribute to the pain management process (Vowles, McCracken, & Eccleston, 2007), and subsequent studies have found that these concepts may mediate the relationship between pain experience and mood (Weiss et al., 2013). In light of these findings, interdisciplinary pain programs must appreciate the value added by the clinical health psychologist in order for the treatment team to be successful.

Functional Restoration Programs

Despite the heterogeneity of interdisciplinary pain programs, there are a few models under study with more definite composition and a more definite role of clinical health psychology. Of these, functional restoration (FR) programs represent some of the most well researched, with a strong emphasis on return to function and the pursuit of long-term socioeconomic goals (e.g., reduced medical visits for pain management, increased employment, increased retention of employment). The mechanics of FR pain and disability management typically include an emphasis on both physical capacity and psychosocial functioning (Mayer, McGeary, & Gatchel, 2004). Health psychology is a prominent component of FR. In fact, the recommended FR treatment team should always include a psychologist, along with a pain management physician, nurse, and physical or occupational therapist. These providers must work in an interdisciplinary fashion to quantify function across all relevant rehabilitation domains (e.g., functional capacity, mood, pain coping) and to develop an integrated treatment program that targets these domains synergistically (Gatchel & Okifuji, 2006). Treatment begins with a comprehensive assessment battery (i.e., quantify function), and the resulting data are used to identify treatment targets. As an interdisciplinary program, FR's goals are determined collaboratively across all providers and are agreed upon by patients who are given regular feedback about their assessment and shown evidence of physical *and* psychosocial progress over the course of the intensive FR program. Again, the clinical health psychologist plays a key role in the FR treatment process. For example, the psychologist helps mitigate emotional disruption (e.g., depression) that may affect physical function and/or engagement in rehabilitation with other FR team members (Heiskanen, Roine, & Kalso, 2012) and helps the patient learn how to effectively track goals and communicate with other healthcare providers to ensure that their clinical needs are met and that they are progressing toward their goals. They also teach the patient effective pain management strategies that can be used to overcome self-limiting functional activity, which helps maximize the benefits of physical rehabilitation (Gatchel et al., 2014).

Over the past 30 years, numerous studies have confirmed the efficacy and effectiveness of FR pain management models, often showing significant gains beyond those demonstrated in one-dimensional programs of physical/physiotherapy or biomedical care (Mayer et al., 1987; Steiner et al., 2013). As studies of FR have progressed, research surrounding these interdisciplinary programs has started to expand, with increasing emphasis on the effectiveness of FR in managing orthopedic/musculoskeletal pain and common comorbidities (including sleep, non-orthopedic pain conditions, and psychiatric disorders) that typically present with chronic pain. For example, Hartzell et al. (2014) found that patients with chronic musculoskeletal pain and comorbid fibromyalgia show a significant improvement in fibromyalgia symptoms after completing an FR program (e.g., 41% of completers no longer met criteria for fibromyalgia after completing treatment). Asih, Neblett, Mayer, and Gatchel (2014) found a significant improvement in insomnia among FR program completers, although the presence of insomnia was a predictor of program completion, and more severe insomnia symptoms persisted beyond treatment. As noted above, interdisciplinary pain management programs (including FR) can contribute to significant reductions in some emotional distress conditions (e.g., depression), but there are fewer data supporting the application of FR to more complex psychosocial presentations like posttraumatic stress disorder (PTSD) (McGeary, Moore, Vriend, Peterson, & Gatchel, 2011). This is particularly relevant because of the increasing attention paid to PTSD and pain-related comorbidity among military members and veterans who served as part of the post-9/11 war effort.

Chronic pain and PTSD have been found to co-occur quite frequently in some military populations. Specifically, Lew et al. (2009) report that over 58% of veterans assessed for trauma and pain in a VA Polytrauma Network Site presented with comorbid pain and PTSD and the presence of PTSD in the context of pain can have significant and deleterious effects on response to pain management intervention (McGeary et al., 2011). Little has been done to examine treatments for pain and PTSD comorbidity, but there is solid evidence suggesting that FR programs are generally effective for military service members with chronic pain (Gatchel et al., 2009), and some psychosocial interventions work quite well for military PTSD (McLean & Foa, 2014). Thus, it stands to reason that a comprehensive interdisciplinary pain management program (like FR) could incorporate effective psychosocial treatment components for PTSD to develop an efficacious treatment option for this significant problem. Large-scale studies of interdisciplinary pain and PTSD management are underway, but some smaller studies have already started to show the benefits of combined treatments for this comorbidity (Plagge, Lu, Lovejoy, Karl, & Dobscha, 2013).

Conclusions

The field of health psychology has grown significantly over the past several decades, and few subspecialty fields have benefitted more from this growth than chronic pain. As the field of healthcare providers who work with chronic pain increasingly adopts and expands the biopsychosocial model, greater integration of treatment will likely follow. Indeed, recent changes in legislation and the growing body of evidence supporting integrated treatment for pain bode well for the growth of interdisciplinary models. Research on psychosocial variables in the pain experience and pain management has rapidly expanded over the past 30 years, and health psychology is now widely acknowledged as a vital component of interdisciplinary pain management teams. This growth is likely to continue as pain management intervention and research start to apply the biopsychosocial model to even more complex chronic pain presentations (e.g., comorbid pain and PTSD).

Author Biographies

Dr. Robert J. Gatchel, PhD, ABPP, is the Nancy P. & John G. Penson endowed professor of clinical health psychology at the University of Texas at Arlington. He is internationally known for his research on biopsychosocial pain management, and his scientific contributions have resulted in numerous awards including an NIH Senior Scientist Award and the Gold Medal Award for Life Achievement in the Application of Psychology from the American Psychological Association.

Dr. Don McGeary, PhD, ABPP, is an associate professor in the Department of Psychiatry and a ReACH scholar at the University of Texas Health Science Center at San Antonio. He is the principle investigator of several federally funded studies of chronic pain and psychiatric comorbidities with a particular emphasis on managing pain-related polymorbidities in military service members and veterans.

Perinatal Depression

Rachel Vanderkruik, Elizabeth Lemon, Laura River,
and Sona Dimidjian

Department of Psychology and Neuroscience, University of Colorado Boulder, Boulder, CO, USA

The transition to motherhood can be both a risky and rewarding time for women physically, interpersonally, and psychologically. Nearly 20% of mothers worldwide are affected by depression during pregnancy or the postpartum (i.e., the "perinatal" time period) (Gavin et al., 2005). Perinatal depression represents a significant public health issue for women and families. Here, we will review the conceptualization and classification, correlates and consequences, risk and contributing factors, and detection and management of depression during pregnancy and the postpartum.

Conceptualization and Classification

There is considerable variability in the severity and duration of symptoms of depression that may be experienced during the perinatal period. For example, postpartum blues, or "baby blues," are fleeting feelings of depression and anxiety that many new mothers experience within the first 10 days after giving birth. In contrast, the term "depression" is often used in clinical contexts to refer to an episode of major depression. The diagnostic criteria for major depression are the same during pregnancy and the postpartum as in other times of life; thus, it is important to underscore that terms such as "perinatal depression" do not indicate a distinct clinical disorder but rather the occurrence of depression during this specific life phase. Major depression is indicated by the presence of at least 2 weeks of depressed mood or loss of interest or pleasure in activities, for most of the day, nearly every day, accompanied by at least four additional symptoms (i.e., sleep disruption, change in appetite, psychomotor agitation or retardation, fatigue, feelings of worthlessness or guilt, problems with concentration or decision making, or thoughts of death or suicide). Further, these symptoms must cause functional impairment.

The Wiley Encyclopedia of Health Psychology: Volume 3: Clinical Health Psychology and Behavioral Medicine,
First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

Depression during the perinatal period is captured in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition, as a specifier of major depressive disorder. To receive a diagnosis of major depressive disorder with "peripartum onset," a woman must meet all of the criteria for a major depressive episode, and the onset of depressive symptoms must have occurred during pregnancy or within 4 weeks after delivery. There is inconsistency within the field, however, about this time restriction, with many defining postpartum depression as onset up to 12 months following delivery.

A recent review of 16 longitudinal studies found that the average rate of antenatal depression is 17% and the average rate of postpartum depression is 13% (Underwood, Waldie, D'Souza, Peterson, & Morton, 2016). The point prevalence of antenatal depression is 11% in the first trimester, and 9% in the rest of pregnancy, using DSM criteria for diagnosis (Gavin et al., 2005). Postpartum depression has a period prevalence of up to 19.2% of women within 3 months of delivery; the point prevalence of postpartum depression has been recorded as highest in the third month postpartum (13%), followed by a point prevalence of about 10% during the fourth through seventh months postpartum, and 7% thereafter, also using DSM criteria (Gavin et al., 2005).

There is significant comorbidity between postpartum depression and anxiety. Women who have a history of postpartum depression, or who are experiencing current symptoms of postpartum depression, are also at risk for the onset of mania/hypomania (bipolar disorder), although this has been understudied. While rare, symptoms of psychosis may co-occur with perinatal depression, particularly in the postpartum, potentially increasing the severity of the disorder.

Correlates and Consequences of Depression During Pregnancy and the Postpartum

Perinatal depression is associated with increased risk of negative correlates and consequences for the overall health, well-being, and developmental trajectories of both mother and offspring, as well as a broader impact on society.

Mothers

Depression during pregnancy has been associated with maternal physical health problems, compromised immune function, and preeclampsia (Field, 2011). Postpartum depression is linked to increased risk of factors that interfere with parenting, including persistent negative affect, increased self-focus, and negative perceptions of oneself and others (O'Hara & McCabe, 2013). Many women who experience depression in pregnancy also experience postpartum depression. Perinatal depression also poses risk for future episodes of depression (O'Hara & McCabe, 2013).

Offspring

Depression during pregnancy is associated with an increased risk of preterm delivery, low birth weight, reduced breastfeeding initiation rate, heightened infant distress and sleep disturbance, and emotional and behavioral problems in childhood (Field, 2011). Depression during the postpartum has been associated with heightened infant distress and sleep problems, as well as compromised infant self-regulation, stress, and arousal, and poor cognitive functioning and emotional and behavioral disorders in infancy and childhood (e.g., O'Hara & McCabe, 2013).

Society

Beyond the risks to individual women and their families, depression presents challenges from public health and economic perspectives. Lifetime costs of perinatal depression have been estimated at 23,151 British pounds for mothers (US$30,805.56 as of time of writing) and 52,577 British pounds for children (US$70,808.07), based on costs of healthcare, as well as reduced productivity and quality of life (Bauer, Knapp, & Parsonage, 2016).

Risk and Protective Factors

Demographic Factors

We lack a clear and consistent picture of the demographic factors associated with depression during pregnancy and postpartum. Younger maternal age has been associated with increased depressive symptoms during pregnancy and postpartum, as has older maternal age during pregnancy (e.g., Biaggi, Conroy, Pawlby, & Pariante, 2016); however, this association has not been consistently reported in all of the studies included in these reviews. Similarly, belonging to a minority race/ethnicity may be associated with increased rates of depression during pregnancy (Biaggi et al., 2016), but the association was not consistent across all studies included in this review. Few studies have examined the association of race/ethnicity with depression in the postpartum period, although it does appear that there are racial/ethnic disparities in rates of postpartum depression (Liu & Tronick, 2013).

Socioeconomic status (SES) is likely an important factor. There is some evidence that low SES has a small effect on the development of postpartum depression, yet varying criteria used to define "low income" contribute to inconsistent evidence of this relationship. Several reviews of demographic risk factors for antenatal depression have identified unemployment, low income, and low educational attainment to be associated with depression during pregnancy; however these associations were not found in all studies reviewed (Biaggi et al., 2016; Lancaster et al., 2010). Having Medicaid or other public insurance versus private insurance is more consistently associated with increased likelihood of antenatal depressive symptoms (Lancaster et al., 2010). Additionally, there is some evidence that women who live in rural areas may face heightened risk for postpartum depression, perhaps because they have less access to care.

Biological and Health Factors

There has been growing interest in identifying the pathophysiology of depression during pregnancy and postpartum. Much of the work to date has examined the roles of stress and reproductive hormones as risk and protective factors. The evidence for the role of cortisol in the development of perinatal depression is mixed; however, most studies support an association between elevated cortisol and brief mood fluctuations during pregnancy and postpartum "blues"; in contrast, blunted cortisol is likely related to postpartum depression, particularly when it is more chronic (Yim, Tanner Stapleton, Guardino, Hahn-Holbrook, & Schetter, 2015). Some data suggest that oxytocin may be an important player in the pathophysiology of postpartum depression, with evidence of an inverse relationship between oxytocin and depression severity (Yim et al., 2015). Several studies have found heightened sensitivity to estrogen fluctuations in perinatal depression (Yim et al., 2015). Moreover, genetic factors appear to influence depression differently depending on the point in time in the perinatal period that the symptoms emerge (Yim et al., 2015). Understanding the contribution of hormonal factors to the timing and course of depression during pregnancy and the postpartum will be an important direction for future research.

Recent research has begun to explore how the development timing of perinatal depression influences child outcomes, as well as how mechanisms of maternal depression may shape the somatic and behavioral health of the child. Such attention to the sensitive periods of when a woman may be at greatest risk for depression, hormonal factors, or exposure effects of perinatal depression on the offspring has implications for design and administration of interventions. Emerging research is using magnetic resonance imaging to examine the neurobiological profile of postpartum depression, which appears to be similar to major depression in the general population, and is also examining the relationship between inflammation and perinatal depression as a promising direction for future research.

Finally, several health-related behaviors may also influence risk for perinatal depression. Physical activity during and after pregnancy may be associated with a reduced risk for postnatal depression, yet more research is needed to identify an optimal dose of physical activity for such risk reduction. The evidence relevant to breastfeeding as a potential risk factor has been equivocal: some data suggest that not breastfeeding is associated with postpartum depression; however, others suggest that this association may be due to other risk factors such as income, stress, and social support. Additionally, postpartum depressive symptoms have been positively associated with unhealthful behaviors such as smoking and poor maternal diet. There is limited evidence to suggest an association between postpartum depression and deficiencies in biopterin, homocysteine, zinc, and vitamin B_{12}; more robust evidence supports an association between low vitamin D levels during pregnancy and increased risk for postpartum depression, and there is insufficient evidence to support a link between postpartum depression and levels of maternal iron, selenium, or omega-3 fatty acids (DHA and EPA) (e.g., Serati, Redaelli, Buoli, & Altamura, 2016). Finally, sleep disturbance during the postpartum period may be associated with postpartum depression, although the direction of the relationship is unclear.

Psychosocial Factors

There is strong evidence supporting an association between stressful life events (e.g., losing a job, moving) and elevated symptoms of depression during pregnancy (Lancaster et al., 2010). Support for an association between experiencing stressful life events during the perinatal period and depression in the postpartum has been mixed, with some studies finding a weak association (Yim et al., 2015) and others finding that the experience of multiple stressful life events from the start of pregnancy to shortly after childbirth is associated with depressive symptom severity and increased risk for postpartum depression (Lancaster et al., 2010). A more consistent association has been identified between chronic stressors and postpartum depression. Parenting stress, and in particular caring for difficult infants (e.g., because of temperament, crying, and colic), is consistently associated with elevated levels of depression in the postpartum period, as are general life stress, perceived stress, and feelings of overwhelm (Yim et al., 2015). However, daily stressors are not consistently associated with depression during pregnancy (Lancaster et al., 2010).

Social support has been identified as a key factor in protecting against depression among pregnant and postpartum women. Women with poor social support may be at greater risk for antenatal depressive symptoms or postpartum depression (Lancaster et al., 2010). Lack of intimate partner support may predict depression during pregnancy, particularly in the context of intimate partner violence, whereas support from an intimate partner and overall relationship satisfaction are associated with lower levels of perinatal depression (e.g., Pilkington, Milne, Cairns, Lewis, & Whelan, 2015). Specific partner factors including emotional closeness, low levels of conflict, effective communication, and sufficient emotional and instrumental support are associated with lower depression during pregnancy and the postpartum (Pilkington et al., 2015). Non-cohabitation with an intimate partner was associated with increased risk of depressive symptoms during pregnancy (Lancaster et al., 2010), but not all findings included in this review were consistent. There also appears to be a relationship between an unwanted or unplanned pregnancy and postpartum depression, and the prevalence of depression among women with unintended pregnancies may be as much as two times higher (e.g., Abajobir, Maravilla, Alati, & Najman, 2016).

Clinical History and Comorbidity

A family history of depression and having experienced a previous episode of depression, especially a past perinatal depressive episode, are predictors of perinatal depression. Experiencing anxiety before or during pregnancy increases the risk of developing depression both during pregnancy and postpartum. Experiencing depression during pregnancy also substantially increases the risk of developing postpartum depression (Biaggi et al., 2016; O'Hara & McCabe, 2013; Underwood et al., 2016). A history of childhood sexual abuse is associated with perinatal depression, although the association is more consistently seen during pregnancy than postpartum (Wosu, Gelaye, & Williams, 2015). Substance abuse during pregnancy and the postpartum is also associated with increased rates of depression, although the direction of the relationship is unclear (e.g., Forray, Gotman, Kershaw, & Yonkers, 2014). Body image and eating concerns also may increase risk for perinatal depression. A recent review reported a consistent but weak association between body image dissatisfaction and the onset of perinatal depression (Silveira, Ertel, Dole, & Chasan-Taber, 2015). A history of eating disorders, particularly bulimia nervosa and binge eating disorder, increases risk for perinatal depression.

Detection and Management

Screening and Engagement

Recently, there has been increasing attention to the importance of screening for depression during pregnancy and the postpartum period. American Congress of Obstetricians and Gynecologists (ACOG)'s Committee on Obstetric Practice recommends that physicians screen women for depression and anxiety symptoms at least once during the perinatal period with a validated tool. ACOG also stated that the screening should include appropriate follow-up procedures, including the provision of therapy or a referral to receive treatment. Similarly, the US Preventive Services Task Force (USPSTF) recommended that all adults should be screened for depression, including at-risk populations of pregnant and postpartum women, again highlighting a call for adequate systems to ensure appropriate follow-up and treatment (Siu et al., 2016). It has been recommended that practitioners take advantage of women's routine antenatal and infant checkups to screen for elevated depressive symptom severity.

Recently, a systematic review was conducted for the USPSTF surrounding the effects of depression screening and treatment for pregnant and postpartum women (O'Connor, Rossom, Henninger, Groom, & Burda, 2016). Based on six trials, the authors reported an 18–59% relative reduction in the risk of depression at follow-up after participation in programs involving depression screening, with or without additional treatment components, compared to usual care. These data suggest that screening pregnant and postpartum women for depression may reduce depressive symptoms.

There are several instruments that have been validated for use during pregnancy and the postpartum period to screen for depression. A commonly used instrument is the Edinburgh Postnatal Depression Scale (EPDS), which consists of 10 self-reported items, takes less than 5 min to complete, has been translated into 12 languages, requires a low reading level, and is easy to score. The Patient Health Questionnaire 9 (PHQ-9) is another brief screening tool often used for perinatal depression.

Research has explored common barriers to treatment-seeking behaviors for perinatal women. Women are more likely to prefer non-pharmacologic (i.e., psychotherapeutic) treatments for depression, rather than antidepressant medication (Battle, Salisbury, Schofield, & Ortiz-Hernandez, 2013). Additionally, research has found that depressed perinatal women often experience a high level of decisional conflict, or uncertainty, as to how to treat their depression. Such decisional conflict is associated with a lower likelihood to engage in treatment (Battle et al., 2013). There have been recent efforts to explore models of screening, support for treatment decision making, and therapeutic care that increase the likelihood that women who may benefit from mental health support will be screened and receive treatment (e.g., medical home models, integration into primary care, engaging patients in treatment decision making, including mental health providers in OB-GYN clinics).

Prevention and Treatment

Services are available that can help to prevent perinatal depression. There is evidence that interventions based in cognitive behavioral therapy (CBT), mindfulness-based cognitive therapy (MBCT), and interpersonal therapy (IPT) are effective in reducing the risk of depression during the perinatal period. Some women with an elevated risk for perinatal depression (i.e., women with a history of depression) may benefit from prophylactic treatment with a selective serotonin reuptake inhibitor (SSRI) antidepressant to prevent perinatal depression.

Both pharmacological and non-pharmacological interventions are effective for treating depressed pregnant and postpartum women. Recent guidelines published by the American Psychiatric Association (APA) and ACOG provide instructions for mental healthcare providers regarding appropriate treatment with pharmacotherapy as well as considerations for safety with respect to the use of pharmacotherapy during pregnancy (Yonkers et al., 2009). A growing body of research describes the efficacy and safety of antidepressant medication for depression in pregnancy; however significant gaps still remain. There may be small increases in the risk of preeclampsia, postpartum hemorrhage, or miscarriage, as well as adverse infant outcomes (e.g., preterm birth, pulmonary hypertension, small for gestational age), associated with second-generation antidepressant use during pregnancy (O'Connor et al., 2016).

Recent guidelines also indicate that some forms of psychotherapy should be considered as a treatment, either in place of, or to augment, pharmacotherapy. CBT, IPT, and behavioral activation (BA) therapy demonstrate promise in ameliorating perinatal depressive symptoms. In their review, O'Connor et al. (2016) pooled results for the benefit of CBT for pregnant and postpartum women with screen-detected depression and found an increase in the likelihood of remission compared with usual care. A variety of promising delivery methods for treating perinatal depression exist, including Internet-based therapy and peer-delivered psychological interventions in addition to delivery by mental health professionals.

Some work has examined complementary and alternative medicine (CAM) interventions for perinatal depression. Numerous CAM treatments have been studied, including omega-3 fatty acid, folate, and St. John's wort supplements, exercise, and bright light therapy, as either monotherapies or adjunctive treatment for women during the perinatal period (for a review see Deligiannidis & Freeman, 2014). Further study is needed to examine the efficacy and safety of these CAM treatments for perinatal depression.

Summary

It is not uncommon for a woman to experience depression during pregnancy or the postpartum, particularly in the presence of risk factors such as a history of depression, low social support, or other stressors in her life. The consequences of untreated perinatal depression are substantial for both mothers and offspring, as well as for society as a whole. Healthcare providers should consider the identified risk and protective factors for women during the perinatal time period to assess the level of a woman's risk for experiencing perinatal depression and current severity of symptoms or disorder. There has been a strong focus on efforts to screen perinatal women for depression during the perinatal period, yet additional work remains to ensure that women receive the follow-up support and care that may benefit them after they are screened. There are effective interventions available through a variety of delivery methods for both the prevention and treatment of perinatal depression. Consideration for perinatal mental health should be a top priority in order to promote women's health, as well as the healthy development of children born to women with depression.

Author Biographies

Rachel Vanderkruik is a doctoral student in the clinical psychology program at the University of Colorado Boulder. She received a BA in biology from Bowdoin College and an MSc from Harvard T. H. Chan School of Public Health. Her research interests focus on increasing access to mental health services for women during the perinatal period and disseminating evidenced-based interventions for mental and behavioral health issues.

Elizabeth Lemon is a doctoral student in the clinical psychology program at the University of Colorado Boulder. She received her BA in psychology from Humboldt State University, California, and her MA in psychology from Boston University. Elizabeth's research interests focus on mood and anxiety disorders during pregnancy and the postpartum period, as well as developing new ways to access and deliver clinical care to decrease barriers to mental health services.

Laura River is currently a doctoral student in the child clinical psychology program at the University of Denver. She received her BA in psychology from Pomona College. Her research interests center on parent–child and romantic attachment during the transition to parenthood, as well as interventions promoting parent and infant well-being.

Dr. Sona Dimidjian is an associate professor in the Department of Psychology and Neuroscience at the University of Colorado Boulder. Her research focuses on cultivating enduring well-being for women and children. She is a leading expert in the treatment and prevention of depression, focusing on the mental health of women during pregnancy and postpartum. She received her BA in psychology from the University of Chicago and her PhD in clinical psychology from the University of Washington.

Suicide in the Context of Health Psychology

Maryke Van Zyl-Harrison, Tanya Hunt, Rebekah Jazdzewki, Yimi Omofuma, Paola Mendoza-Rivera, and Bruce Bongar

Department of Clinical Psychology, Palo Alto University, Palo Alto, CA, USA

Health psychology is a multifaceted subfield of psychology that aims to understand the human experience by combining two traditional theoretical approaches: natural science and human science (Marks, Murray, & Evans, 2005). The natural science approach focuses on studying human behavior through experimental studies, while the human science approach focuses on exploring the underlying meanings of human behavior (Marks et al., 2005). Through the combination of these two approaches, health psychology is able to study how biology, social conditions, and psychological stress intertwine and shape human behavior (Kaplan, 2009).

Health psychology currently covers a broad range of practice within the discipline of psychology. Throughout the last several decades, there have been numerous attempts to describe the activity, within the context, of what is now called health psychology. Some of the terms previously used have included behavioral medicine, psychosomatic medicine, and medical psychology. Behavioral medicine is the interdisciplinary field related to the development and combination of behavioral and biomedical science, knowledge, and procedures involving prevention, diagnosis, treatment, and rehabilitation of health and illness (Schwartz & Weiss, 1978). This definition was purposefully intended to not subscribe to any one specific theoretical orientation or discipline. Those involved in this field includes various health professionals like health psychologists, nurses, nutritionists, physicians, and members of other fields who decide to engage in the practice, teaching, development of policy, or research related to the combination of behavioral and biomedical disciplines regarding health and disease. Psychosomatic medicine refers to the interdisciplinary practice of examining the interaction between social, psychological, and behavioral components of physiological processes. Medical psychology refers to both the practice of psychology within a medical school facility and the

study of psychological factors associated with all the components of diagnosing and treating physical health illness and disease. The relationship between physical and psychological symptoms can be addressed on individual, group, and systematic levels.

The American Psychological Association (APA) formally recognized health psychology as a specialty over 20 years ago (Belar & Deardorff, 2009). Health psychology entails the use of scientific knowledge and research regarding psychological factors concerning the interaction of thoughts, emotions, personality, and biopsychosocial factors adaptation to illness and disease, disability, rehabilitation, and health promotion involving individuals, groups, and the healthcare system.

Health Psychology Theory of Suicide

The purview of health psychology includes the examination of environment, cultural factors, mental distress, health habits, impulsivity, substance use, coping skills and resources, and chronic stress levels as divisions of mechanisms that may lead to risky or unhealthy behaviors (Taylor, Repetti, & Seeman, 1997). Health psychology evaluation of the underlying factors of risky behavior can assist in identifying factors that can lead to suicidal behaviors. However, reducing suicide behaviors includes not only reducing problematic behaviors but also increasing positive behaviors. It must be mentioned that cultural factors can also impact the acceptance of suicidal behaviors. Therefore, understanding the effect of culture, healthy environments, support systems, resilience, and coping skill can lead to the formulation of protective factors and safety plans that may prevent or reduce suicidal behaviors.

The role of psychology in health is quite prominent as the literature suggests that most health models hypothesize that psychosocial stressors negatively impact the physical and mental health of individuals (Watson & Pennebaker, 1989). For example, a review by Leeb, Lewis, and Zolotor (2011) found that severe psychological distress during childhood was positively correlated with future negative physical health outcomes (e.g., chronic pain, respiratory illness, cancer), psychological disorders (e.g., depression, anxiety, PTSD), and increased suicide risk. Considering that suicide is regarded as the tenth leading cause of death in the United States (CDC, 2015), the field of health psychology has heightened its efforts to the understanding and reduction of factors that lead to an increased risk of suicide. Particularly, two health psychology theories, the biopsychosocial perspective and the lifespan perspective, may be used to understand the topic of suicide from a health psychology perspective.

Biopsychosocial Perspective

The biopsychosocial perspective is a scientific model that considers the development of illness and recovery due to the interaction of biological factors, such as genetics; psychological processes, like mood and personality characteristics; and social factors, including culture and ecology (Engel, 1980). Evaluating all the elements that impact a person both positively and negatively allows for a more comprehensive understanding of the development and maintenance of illness, recovery, and well-being. The biopsychosocial perspective combines all these previously independent factors of health and disease and recognizes that the nonphysiological elements of a person can change the person's physiological reaction, resulting in vulnerability to the development of disease. In addition, these nonphysiological elements can impact the course of the illness (Jackson, Antonucci, & Brown, 2003). This perspective is of particular value when considering the increasing intersectionality of populations. Hoffman (2000) discussed how the biopsychosocial perspective can potentially explain some trends concerning the issue of suicide. According to Engel's (1997) biopsychosocial model, physical health is affected by biological, cultural, and psychological variables (Marks et al., 2005). This perspective (which is one of the main influences of health psychology) may help to understand why suicide rates are increasing among patients with chronic illness, as well as why there appears to be an increased awareness about how psychosocial factors play a role in suicide (Hoffman, 2000). Hoffman (2000) suggested that, even though humans seem to be living longer, they are experiencing more chronic illness and a poorer quality of life. Therefore, this decreased quality of life may have led to an increased motivation to commit suicide and to a change in how societies view suicide, which has led to policy changes regarding the legitimacy of physician-assisted suicide (e.g., Oregon's *Death with Dignity Act*) (Hoffman, 2000).

Lifespan Perspective

The lifespan perspective relates to the study of the consistency and transformation of development that occurs throughout the course of life. This perspective stipulates that no particular age period can be considered the primary attribute to the regulation of the developmental process. Essentially the lifespan perspective maintains that during all stages of life, the developmental processes are always at work and can occur at any time during a person's life from birth to death. The system of changes that occur during development can differ in terms of time, direction, and order (Baltes, 1987). A theoretical aspect of the lifespan perspective is the gain/loss argument, which is a product of the belief that function declines as humans age. However, it has been proposed that any change within the adaptive capacity is a form of development, regardless if the change is positive or negative, suggesting that all growth and change is a combination of desirable and undesirable effects (Baltes, 1987). Another theoretical foundation of the lifespan perspective is plasticity, meaning an individual's development is based on testing the environmental limits and experiences, suggesting that humans are molded by the limitations of their cultural environments (Baltes, 1987). The lifespan perspective can also be taken to explain suicide trends (Hoffman, 2000). According to this perspective, people are more likely to be subjected to illness and isolation as they become older; thus, research shows that suicide might be seen as a more acceptable solution to chronic illness and poor quality of life among elderly individuals who have a harder time dealing with the vicissitudes associated with aging (Hoffman, 2000). However, more research is required to address how lifespan issues may affect the views and perceived consequences of suicide.

Suicide in the Context of Primary Care Medicine

Since suicide tends to be viewed as a mental health issue, clinicians in primary care medicine are often less prepared to respond to suicidal thoughts or behaviors. There are clear gaps in the training of primary care clinicians when it comes to the assessment and treatment of suicide. It is important to consider possible psychological causes of physical complaints, particularly those that are challenging to explain using medical reasoning. Additionally, physical illness, particularly chronic illness, may lead to a sense of hopelessness and suicidal ideation. Ultimately, a patient-centered integrative care approach compliments an enhanced awareness of culturally based expressions of psychological distress.

Training

Keeping in mind the trends indicating an increase in suicide rates among chronically ill individuals (Hoffman, 2000), one could imagine that the issue of suicide is likely to be prevalent in primary care practices. Indeed, a study by Luoma, Martin, and Pearson (2002) found that, while only one in five victims of suicide reached out to mental health providers within 1 month of committing suicide, approximately 45% of suicide victims sought primary care providers within 1 month of committing suicide. The tendency to turn to primary care physicians for mental healthcare could present a potential problem if primary care physicians are not properly trained to identify or treat suicidal individuals. According to Sudak et al. (2007), even though the Accreditation Council for Graduate Medical Education requires training programs to provide students with suicide-related didactic content, less than 50% of the training directors that participated in their study demonstrated confidence or satisfaction with the adequacy of their programs' suicide prevention training. Another potential problem that stems from the limited suicide prevention training received by primary care physicians is that they are not mandated to obtain suicide-related continuing education, yet they have the capacity to prescribe psychotropic medications to depressed patients, which may in turn exacerbate their suicidal ideations (Stuber & Quinnett, 2013). Literature shows that antidepressants like selective serotonin reuptake inhibitors (SSRI's) are linked to increased suicide attempts, particularly among children and young adults (Fergusson et al., 2005; Ghaziuddin, Merchant, Dopp, & King, 2014). These findings are particularly important since suicide is the third leading cause of death in the United States for individuals between the ages of 15 and 24 (Swanson, McGinty, Fazel, & Mays, 2015, p. 370).

Common Presentation

Since primary care is the first line of defense against suicide, it is important to consider the warning signs and common presentations of risk that primary care physicians may come in contact with. Suicidal ideation may be presented in ways that are not merely psychological, but present as somatic symptoms. Individuals endorsing suicidal thoughts often present comorbid mood and substance use disorders (MacLean, Kinley, Jacobi, Bolton, & Sareen, 2011). Older adults who are suicidal tend to seek out their primary care physicians with complaints of somatic symptoms related to physical illness or functional impairment, rather than depressive symptoms (Conwell et al., 2000). Similarly, Asian American patients tend to present psychological distress as somatic symptoms like headaches or stomach pain. Individuals from different cultures may express suicidality in different ways. It is important for clinicians in primary care to be aware of these atypical presentations of psychological distress, particularly suicide, in order to accurately assess suicidal ideation.

Furthermore, an awareness of the differences in suicide rates as well as the commonly used means of suicide among individuals who share a cultural identity could enable the early detection of suicide risk in primary care. It is important to note that suicide is the eighth leading cause of death among American Indian/Alaskan Natives and the tenth leading cause of death among Caucasians in the United States. Elderly Asian/Pacific Islander women over the age of 65 have higher suicide rates than any other ethnic group in the same age range (Chu, Hsieh, & Tokars, 2011). African American adolescent boys and Latina adolescent girls have been shown to have higher suicide rates, suicidal ideation, and attempts than their same-aged Caucasian peers, and ideation, attempts, and completions among LGBTQ individuals have been consistently higher when compared with nonsexual minority populations (Silenzio, Pena, Duberstein, Cerel, & Knox, 2007).

Mind–Body

Physical pain can not only present negative physical sensations but also emotional distress. Medical and psychological problems can sometimes mask one another. While some patients may report medically unexplained physical symptoms (MUPS) (Weiland et al., 2015), oftentimes categorized under somatic symptom disorders in the Diagnostic and Statistical Manual of Mental Disorders (DSM), others can experience medical illnesses that first present as psychological symptoms. Some patients may present with mental symptoms, such as depression and anxiety, which are caused by, or exacerbated by, physical diseases such as pancreatic carcinoma, diabetes, heart disease, arthritis, kidney disease, HIV/AIDS, lupus, multiple sclerosis (MS), and hypothyroidism. As psychologists, it is important to conduct thorough interviews at the start of treatment, which includes gathering a medical history, making a referral for a physical evaluation to rule out medical conditions that may be impacting their symptoms, and being aware of changes in patient presentation in terms of appearance, emotional state, physical state, and symptomatology. Conversely, some patients may present in primary care with MUPS. Research indicates that up to 50% of patients who present in general or specialist care are MUPS patients (Weiland et al., 2015). Many of these patients report not feeling understood or empathized with and can develop symptoms of depression and anxiety as a result (Weiland et al., 2015). Furthermore, medical specialists may subject these patients to different tests, for fear of missing a medical cause, and may find these patients difficult to handle (Weiland et al., 2015). Patient-centered communication can help improve patient outcome and overall experience. As part of a multidisciplinary team, psychologists can help develop training programs for specialists in other disciplines on how to assess patients who have MUPS (Weiland et al., 2015).

Impact of Suicide on Health

Suicidal ideation affects individual health, while acts of suicide affect community health. Suicidal ideation is correlated with an increase of substance use. Past suicidal ideation or suicidal attempts increase the likelihood for opioid misuse (Ashrafioun, Bishop, Conner, & Pigeon, 2017). Suicidal attempts are also strongly associated with later alcohol, nicotine, and cannabis dependence (Agrawal et al., 2017). General physical health is also affected by suicidal ideation. Perceived health decreases as suicidal ideation increases (Kim, Hong, Yook, & Kang, 2017). Exposure to a peer suicide in one's community increases the likelihood of another suicide in the community, a phenomenon called suicide contagion (Randall, Nickel, & Colman, 2015). Suicidal contagion is especially impactful for adolescents and in indigenous communities (Goodwin-Smith, Hicks, Hawke, Alver, & Raftery, 2013; Randall et al., 2015). The continuous exposure to death by suicide crumbles social well-being within the community and brings added distress to already vulnerable populations (Goodwin-Smith et al., 2013).

Health Psychology Preventing Suicide

Many general health diagnoses, such as cancer, cardiac disease, chronic pain, diabetes, functional bowel disorder, and erectile dysfunction, have been linked to an increase in stress levels, physical and psychological pain, as well as an increase in risk of suicide among patients. Common mental illnesses, such as depression, panic attacks, bipolar disorder, and posttraumatic stress disorder (PTSD), are often associated with a risk of suicide. Furthermore, there is a growing body of research highlighting the direct or indirect correlation between unhealthy behavior and diseases. With clinical psychology being a field focused on the study of behavior, and psychologist being trained and equipped to manage suicide crisis, it therefore stands to reason that incorporating mental healthcare in the treatment of individuals diagnosed with general health problems, at an early stage, can help reduce the risk of death by suicide.

Individuals diagnosed with terminal or chronic illnesses such as cancer, cardiac diseases, or chronic pain often report experiencing feelings of hopelessness (Ahn et al., 2015; Suarez et al., 2015), which is correlated with an increased risk of suicidal behavior (Hirsch, Visser, Chang, & Jeglic, 2012). Evidence-based psychological treatment approaches, such as cognitive behavioral therapy (CBT) and dialectical behavior therapy (DBT), have strong research backing as treatments that help reduce suicidal cognitions, behaviors, and feelings of hopelessness (Comtois & Linehan, 2006; Mewton & Andrews, 2016). Having psychologists as part of treatment teams for patients with terminal or chronic illnesses can help reduce the risk of suicidal behavior, as psychologists can provide the vital support required to treat suicidal ideation.

Identification of Risk

Assessment of suicide risk in patients in primary care occurs similarly to risk assessment in the mental health field. Assessment tools such as the Beck Depression Inventory and Hospital Anxiety and Depression Scale (Aiello-Laws, 2010) can be used. However, some assessment tools used by psychologists can be cumbersome and lengthy and may not be appropriate for use in the primary care setting. Highlighted as a core knowledge and skill, it is important for clinicians to be competent in selecting appropriate evidence-based screening measures for primary care settings. Psychologists can assist members of the treatment care team, such as nurses, who have more interactions with the patients, in incorporating brief measures that can be included in routine appointments. These measures may assist the treatment team in monitoring for illnesses like depression, anxiety, or insomnia, which can co-occur with medical diagnoses, as well as risk-related symptoms like hopelessness. Some medication may lead to impulsive or suicidal behavior or have side effects that increase depressive symptoms. As highlighted above, it is imperative that clinicians be aware of the different side effects of the medications that their patients are taking and that they monitor the patient's response to their medications frequently throughout treatment.

Integration

Integrated care can be defined as unified care experienced by patients, when a team of behavioral health and primary care providers, in collaboration with the patient and their family, using an organized and cost-effective method, work together for the purpose of providing patient-centered care. The healthcare system is steadily moving toward a more integrated approach to treatment, incorporating biological, psychological, and social factors in patient care. The Joint Principles of the Patient-Centered Medical Home (PCMH), published in 2007, highlighted the need for personal, coordinated, and comprehensive healthcare by a team of clinicians, addressing all of a patient's needs, further emphasizing the importance of integrated behavioral healthcare. One of the key aspects addressed by integration is unification of records. Integration allows for the availability of shared medical records, collaborative decision making, and shared responsibility of patient care. Barriers to communication between healthcare professionals are reduced, allowing for improved treatment of the patient as a whole, incorporating different aspects of the patient's life in their treatment as is applicable.

Traditionally, the role of psychologists was to assess, diagnose, and treat psychopathology. However, over previous decades, psychology in healthcare has expanded to be multifaceted, from understanding the development and maintenance of illness and disease to determining the development and impact of individuals' and communities' health behaviors (Sarafino & Smith, 2014). Health psychology has provided psychological interventions aimed to address and understand health behavior, provide a basis for clinical care, promote research, and inform program and public policy implementation. The role of psychology within the field of health originates from the premise that individuals' psychological processes are interrelated to biological processes. The understanding associated with what and how all behaviors, including health-related ones, are influenced is invaluable to the medical care system. This idea has led to the development and implementation of psychologically driven interventions to promote health. This multisystem approach combining psychological and physical aspects has proven to be successful in improving functioning and well-being.

Though significant progress has been made, there remains a high level of stigma surrounding mental health. Integrated care reduces the focus on mental health and increases the emphasis on the overall well-being of the patient, thereby reducing the stigma surrounding mental health treatment. Furthermore, the patient-centered approach helps to empower patients by increasing their involvement in their own care and fostering a sense of control over their treatment. The population of the United States is increasingly growing more diverse and older. Therefore, the field of health psychology must continue to refine and adapt conceptual models, research methods, and resources for application that are influenced by these variations.

Changes over Time

Suicide prevention in healthcare has expanded from targeting individuals in crisis to a preventative approach that involves the community in outreach and prevention efforts. Stakeholders in the community are now being trained to identify suicidal community members. Social relationships are being utilized in suicide safety plans to facilitate resilience. Media campaigns not only target at-risk individuals but also are beginning to offer information about how to be an advocate for a suicidal peer. These new developments are utilizing the community's unique risk and resilience factors to create suicide prevention programs.

WHO Global Goals

The Millennium Development Goals (MDGs) were created in 2000 by a collective of 189 countries. The objective was for countries and partners to work together in order to globally reduce poverty, gender inequality, child mortality, and diseases such as HIV/AIDS and to improve maternal health, environmental sustainability, and global partnerships, with targets set for 2015. Many of these goals relate to health, whether directly or indirectly. One of the goals outlined by the MDGs and the World Health Organization (WHO) is the reduction of suicide. In an effort to sustain and expand upon the MDG's of 2000, the UN presented a list of 17 sustainable development goals (SDGs), to be met by 2030. Specifically, these SDG's resolve to reduce premature mortality related to noncommunicable diseases by one third to promote mental health and well-being. The objective is to achieve a 10% reduction of suicide by 2020 (World Health Organization, 2013). To reach this goal for suicide, smaller goals to increase mental health were set by the WHO. With this objective in mind, countries are encouraged to use expanded mental health treatments in order to prevent suicide. The inclusion of noncommunicable diseases and the explicit mention of mental health serve as an indication that mental health and well-being are of increasing importance on the agenda of global development.

Future Directions

The inclusion of mental health, particularly suicide, in the WHO recommendations toward improved global health, indicates how significant the issue of suicide is from a health perspective. As a result, several policy changes have been implemented by national and global organizations in an attempt to enhance suicide prevention efforts worldwide. The WHO and the US Joint Commission on Accreditation of Healthcare Organizations (JCAHOs) have employed specific recommendations that aimed to improve suicide risk assessment and treatment. Some of these recommendations included conducting suicide risk assessments on any individual over 10 years old that presented with either a medical or psychological condition, as well as being responsible for deglamorizing suicide in the media (Dua et al., 2011).

WHO Recommendations

Over time, recommendations from the WHO for suicide prevention have evolved from an individualistic approach to one that begins with the community and then reaches inward. In 2000, the WHO focused their recommendations on demographic risk factors. These recommendations were focused on those with a high risk of suicide. The recommendations consisted of detecting such individuals and managing individual risk by asking targeted questions and referring them to a psychiatrist or hospital. The WHO expanded suicide prevention in 2001 with the recommendation of increased research, training for mental health workers, and public awareness campaigns. An ecological orientation became the framework in 2003 for suicide prevention. This involves intertwining organizations such as schools, companies, and regions to create health networks (Kickbusch, 2003).

The current recommendations consist of surveillance, prevention, and evaluation. The WHO recommends surveillance of patterns of suicide in communities and suicidal behavior in individuals. Additionally, it suggests that community patterns such as suicidal contagion should be observed and recorded. The common behaviors of suicidal individuals should also be documented in order to increase knowledge of risk factors. Knowing how communities and individuals react in regard to suicide creates opportunities for more accurate prevention strategies.

The WHO has three levels of prevention strategies: universal, selective, and indicated. Universal prevention strategies reach the entire population. This type of strategy is effective for reaching low-risk individuals and educates non-suicidal individuals in order to create a supportive network. A mental health stigma awareness campaign is an example of a universal prevention strategy. Selective interventions target specific vulnerable populations, such as those who are unemployed, adolescents, and people with mental illnesses. Selective interventions focus on training for stakeholders in communities that are vulnerable to suicide. One such intervention would be training high school teachers how to identify and appropriately support a suicidal student. The general training of teachers is a selective intervention, but this specific action of the teacher is an indicated intervention. Indicated interventions directly target individuals that have a high risk for suicide. Integrating a public health approach into the prevention plan is recommended by the WHO. This shows a commitment to suicide prevention from the government. Restricting suicide means and increasing access to mental health services are common interventions that governments have implemented successfully to reduce suicide.

Finally, the aforementioned prevention strategies need to be evaluated in order to ensure effectiveness. The outcome being measured should be clearly outlined before the intervention is administered. Important evaluation metrics include the rate of suicide, suicide attempts, and suicidal ideation. The population being evaluated should be considered when choosing an outcome to measure. Suicidal ideation should be used instead of suicide in a small population since suicidal ideation is more common and enough data is available to conduct statistically significant evaluations.

Joint Commission Recommendations

The Joint Commission developed their own set of recommendations to reduce suicide mortality nationally in the United States, which addressed the provision of suicide screenings, assessing for safety needs, and providing resources like crisis hotline numbers for discharged patients (Czyz et al., 2016). Recently, the Joint Commission's recommendations were updated to include "safety planning, discharge, treatment, and follow-up care" (p. 175), among other things (Czyz et al., 2016)

The Joint Commission's recommendations for preventing suicide are targeted for healthcare professionals. Their approach begins with assessing all patients with an evidence-based screening tool and observing high-risk individuals through their history of suicide. Patients in a suicidal crisis should not be left alone. The emergency department or psychiatric unit should be immediately called, and possible suicidal means, such as bandages, elastic tubing, and plastic bags, should be kept away. Lower-risk individuals should be given referrals to outpatient mental health providers, introduced to the suicide hotline, have lethal means restricted, and develop a safety plan. Even after discharge, suicidal prevention should continue. Safety plans are most effective when friends and family are involved. Therapists also have a direct role after discharge. The Joint Commission recommends therapies that directly target suicidal ideation like Cognitive Therapy for Suicide Prevention and Collaborative Assessment and Management of Suicide.

The Joint Commission had specific recommendations for suicide in the hospital setting. These were based differences between psychiatric hospitals and medical hospitals. Medically ill patients who committed suicide were older and more likely to be employed and married compared with the psychiatric patients. Since medically ill patients are more likely to commit suicide in the hospital, the Joint Commission recommends increased suicide assessment for patients in the medical hospitals. A systemic collection of data on suicides and suicide attempts in hospital settings should also be created to fill the gap of information for this issue.

As a recommendation for assessing suicide in primary care, be aware that individuals who are part of ethnic and sexual minority subgroups may be at higher risk for suicide, particularly those with multiple minority identities. Be cognizant that culture affects how suicidal ideation is expressed, which methods for suicidal behavior are chosen and which stressors are more salient. Keep in mind that a mental illness diagnosis is not an adequate indication of risk for suicide and that it may be necessary to consider culturally specific stressors and the social environment within the patient's cultural context.

Recommendations for Future Research

Successful integration of psychologists in primary care requires an understanding and acceptance of patient-centered care by healthcare providers. More research focusing on how to optimize the systems to ensure that every aspect of a patient's life is duly addressed is important. This includes research into and the development of policies that ensure that the practice, training, and financing of behavioral health services are included in benefit or insurance plans for patients.

Suicidal behavior can occur at different stages in an individual's life and in conjunction with different medical illnesses as well. Research has shown that individuals are more likely to visit their primary care providers prior to seeking out professionals for mental health-related problems (Luoma et al., 2002). It is therefore crucial for primary care providers to be equipped to assess for mental illness and risk-taking behavior in patients. Future research should look into evaluating treatment models in primary care settings, particularly focusing on risk assessment and crisis intervention for patients.

Integrative Care

Although public health organizations like the WHO and the US JCAHO have advanced how healthcare professionals manage patients exhibiting suicidal behavior, there remains plenty of room for improvement. To continue achieving progress, the best option appears to be for mental health providers and healthcare providers to take an integrative approach and collaborate in the management of their shared patients. Though healthcare practitioners are the experts on physical health, they do not always have the necessary training or the time to conduct psychological assessments and provide psychotherapy to their patients (Nash, McKay, Vogel, & Masters, 2012). Therefore, psychologists are pivotal members in this contemporary concept of multidisciplinary teams. In integrated primary care, effective psychologists must possess the knowledge and skills to serve as consultants, teachers, and supervisors for primary care providers, as well as properly assess patients, provide psychotherapy, remain up-to-date in evidence-based practices, evaluate progress, and serve as case managers.

Author Biographies

Maryke Van Zyl-Harrison, MA, is a doctoral candidate in clinical psychology with an emphasis in diversity and community mental health at Palo Alto University. Maryke earned her bachelor's degree from Stellenbosch University in South Africa and her masters in marriage and family therapy from Pepperdine University in Los Angeles. She has worked to address HIV/AIDS, substance abuse, and suicide risk among underserved communities. Maryke works with children with serious medical diagnoses and adults with chronic pain. Most recently, she serves as coordinator of a special interest group on risk, resilience, and reasons for living within the International Association for Suicide Prevention.

Tanya Hunt is currently working on earning her PhD in clinical psychology with an emphasis in diversity and community mental health at Palo Alto University. Her areas of concentration also include culture, trauma, and health psychology. She earned her BBA from the University of Kentucky. Tanya has over 20 years' experience working with marginalized populations. She has provided services in employment and substance abuse counseling, as well as adjudicating claims based on mental and physical health. Tanya is currently providing mental health services including addressing health disparities to a diverse population within an integrated healthcare setting.

Rebekah Jazdzewski, BA, is currently working on her doctorate in clinical psychology with an emphasis in adult trauma at Palo Alto University. Rebekah earned her bachelor's degree from Point Loma Nazarene University where she studied coping mechanisms in underserved populations. Currently, she is working with Native American tribes to study suicide prevention and resilience. Rebekah also serves as a student therapist at the Gronowski Center, working as a therapist in community mental health.

Yimi Omofuma, MA, is currently pursuing her doctorate in clinical psychology with an emphasis in trauma at Palo Alto University. Yimi earned her bachelor's degree from Southern Illinois University, Carbondale, Illinois and her masters in forensic psychology from Fairleigh Dickinson University in New Jersey. She currently works at an Early Intervention Clinic, providing emergency psychology for recently traumatized individuals. Furthermore, Yimi serves on the board of the Imani Foundation, a nonprofit organization currently dedicated to working with women and children who are survivors of abuse in Nigeria.

Paola M. Mendoza-Rivera, BA, is currently pursuing her PhD in clinical psychology with an emphasis in forensic psychology at Palo Alto University. Paola achieved her bachelor's degree in general psychology as well as a second bachelor's degree in criminal justice from the University of New Haven in West Haven, Connecticut. Currently, she is working on building her resume and developing her practical clinical skills at Palo Alto University's Gronowski Center. Paola is serving as a student therapist in the Gronowski Center's Clinica Latina, a bilingual specialty clinic that specializes in treating underserved Latinx populations.

Bruce Bongar, PhD, ABPP, FAPM, CPsychol, CSci, is currently the Calvin Distinguished Professor of Psychology at Palo Alto University and has previously served as consulting professor of psychiatry and behavioral sciences at Stanford Medical School. Dr. Bongar received his PhD from the University of Southern California and maintained a private practice for 25 years. Dr. Bongar is past president of the section on Clinical Crises and Emergencies of the Division of Clinical Psychology of the American Psychological Association. Dr. Bongar has also been a winner of the Edwin Shneidman Award from the American Association of Suicidology for outstanding early career contributions to suicide research and the Louis I. Dublin Award for lifetime achievement in research on suicidology.

Adherence to Behavioral and Medical Regimens

Tricia A. Miller[1,2], Summer L. Williams[3], and
M. Robin DiMatteo[2]

Introduction

Patient adherence (also called compliance) involves the degree to which patients follow treatment recommendations as directed by their healthcare provider. Although empirical evidence demonstrates that quality health outcomes depend heavily upon patients' adherence to recommended treatments, 25% of patients, on average, are nonadherent to prevention and disease management activities (DiMatteo, 2004). These activities include taking medications as prescribed, keeping medical appointments, engaging in regular disease screening, and following specific diet and exercise regimens (DiMatteo, Haskard-Zolnierek, & Martin, 2012; Martin, Williams, Haskard, & DiMatteo, 2005). For patients with chronic disease, adherence can be as low as 50% or less (Vermeire, Hearnshaw, Royen, & Denekens, 2001).

Patient nonadherence can be intentional or unintentional. "Unintentional nonadherence" describes situations in which patients incorrectly believe they are adherent, or try to be adherent but fail, whereas "intentional nonadherence" describes the purposeful choice to dismiss treatment or change the regimen without consulting the provider (Lehane & McCarthy, 2007). Whether purposeful or accidental, nonadherence contributes to suboptimal health outcomes. Research has identified some clinical factors that may influence patient nonadherence, such as the complexity of the regimen prescribed, and patients' existing beliefs about the recommended treatment and the severity or seriousness of the disease condition (DiMatteo, Haskard, & Williams, 2007).

Patient nonadherence also places an appreciable economic burden on the US healthcare system. Empirical evidence suggests that as many as $100 billion dollars are wasted annually

due to the cost of preventable hospitalizations (Cutler & Everett, 2010). Failure to properly adhere to treatment can also cause unnecessary complications or disease progression, with significant increases in the cost of care (Dunbar-Jacob, Schlenk, & McCall, 2012).

Current research suggests that improving adherence requires patients' knowledge and understanding of their disease and treatment regimen, a collaborative and trusting therapeutic partnership between patients and health professionals, and satisfaction with care.

The purpose of this chapter is to highlight the importance of patient adherence, discuss several factors that affect treatment adherence, and examine the Information–Motivation–Strategy Model (IMS Model) as a way in which clinicians and healthcare professionals can improve their patient's adherence behaviors.

Factors that Affect Patient Adherence

Several factors influence whether or not patients engage in disease management and adherence behaviors. Decades of research have identified both real and perceived doubts about the expected benefits and efficacy of treatment, potential financial constraints, and the lack of resources as factors that significantly affect treatment adherence (DiMatteo, Giordani, Lepper, & Croghan, 2002; Zolnierek & DiMatteo, 2009). Socioeconomic factors, financial constraints (e.g., cost of medications), and patient characteristics can also negatively affect adherence (Peltzer & Pengpid, 2013).

Some of the unique demands of patients' prescribed treatment regimens have been associated with lower rates of adherence. These include the number of medications prescribed, the frequency of dosing, and the specific routines of administering medications for complex treatments. Patient nonadherence can be has high as 70% for treatment regimens that are complex and/or require complex lifestyle changes (Chesney, 2003). Dezii, Kawabata, and Tran (2002) found that for patients with type 2 diabetes, adherence was higher for patients on a one-medication-per-day regimen compared with patients who were on a three-medication-per-day regimen. Forgetting to take (or how to take) prescribed medications also contributes to patient nonadherence. Over 56% of patients forget details of their medical instructions shortly after leaving their physician's or healthcare provider's office (Martin et al., 2005). Thus, it is important that healthcare providers explain specific steps of their patient's treatment regimens, review the most important details of their patient's treatment, and use written instructions to encourage patients to ask questions and recall important information.

Patients' level of health literacy can also affect treatment adherence (Gazmararian, Williams, Peel, & Baker, 2003; Zaghloul & Goodfield, 2004). Health literacy is defined as a patient's ability to appropriately obtain, process, and understand basic health information needed to make health decisions (Baker, 2006; Schillinger et al., 2003). The Institute of Medicine (2004) estimates that more than 90 million people in the United States lack the necessary health literacy skills needed to understand and act on health information given by their providers. Patients with low health literacy often use fewer preventive services, incur higher medical costs, have more limited understanding of their treatment regimen, and have poorer health status than those with higher health literacy (Gazmararian et al., 2003; Schillinger et al., 2003; Schillinger, Bindman, Wang, Stewart, & Piette, 2004). Thus, low health literacy increases health disparities and negatively impacts patients' self-management and collaborative care (Schillinger et al., 2004). The interpersonal dynamics of the clinician–patient relationship can also influence patterns of adherence behaviors. For example, patients who feel that their physicians communicate well with them and actively encourage them to be involved in their own care are more motivated to adhere (O'Malley, Forrest, & Mandelblatt, 2002). Such agreement fosters a cohesive partnership and allows physicians and patients to work together toward a mutually agreed upon treatment plan (Jahng, Martin, Golin, & DiMatteo, 2005). Training physicians to be better communicators results in significant improvements in patient adherence. Research by Zolnierek and DiMatteo (2009) found that the odds of patient adherence were 1.62 times higher for physicians who were trained in communication skills compared with the physicians who did not receive communication training. Effective communication also gives patients the ability to build rapport and trust; clinicians who promote trust through collaborative partnerships and who express compassion and "bedside manner" for their patients are more likely to succeed in fostering adherence and cooperation for a variety of treatment regimens (Schillinger et al., 2003).

Improving Adherence Using the Information–Motivation–Strategy (IMS) Model

Current empirical research highlights the complexity of establishing adherence-enhancing interventions and suggests that interventions should be tailored to meet the specific needs of patients for the most optimal effectiveness (DiMatteo et al., 2012; Martin et al., 2005). Evaluating and targeting patients' specific needs can be a difficult task for clinicians and healthcare providers, however, especially given the limited time constraints of the medical visit itself.

A well-organized and simple model known as the Information–Motivation–Strategy Model(c) can be used by clinicians and healthcare teams during medical encounters to help guide and promote patients' adherence behaviors (DiMatteo et al., 2012). Utilizing these three elements, that is, providing patients with *information*, building *motivation*, and offering effective *strategies*, in the context of effective clinician–patient communication can result in substantial and significant improvements in adherence and overall health outcomes.

The *information* element of the IMS Model outlines the importance of empowering patients to become more knowledgeable about their disease or condition by means of effective clinician–patient communication. In a review assessing more than 300 studies, researchers found that patients often do not understand much of the information they receive from their healthcare provider (Kindig, Panzer, & Nielsen-Bohlman, 2004). Proper understanding can be achieved when clinicians communicate effectively with their patients, however (Zolnierek & DiMatteo, 2009). Empirical research suggests a 19% higher risk of nonadherence among patients whose physician communicated poorly than among patients whose physician communicated well (Zolnierek & DiMatteo, 2009). Thus, cohesive partnerships, in which clinicians work together with their patients, make it possible for clinicians to both effectively and thoroughly provide clear information and check the adequacy of their patients' understanding (DiMatteo et al., 2012). Patients who feel that their clinicians communicate well with them and encourage them to be involved in their own care tend to be more motivated to adhere (Martin et al., 2005).

A patients' level of trust in their physician is also an essential component of the physician–patient relationship and can greatly affect patient adherence. Patients must believe that their physician is someone who can understand their unique experience and who can provide them with reliable and honest advice. Martin et al. (2005) found that adherence rates were almost three times higher in primary care relationships consisting of higher levels of patient trust and physicians' knowledge of their patient as a person. In fact, patients' trust in their physician has been found to exceed many other variables in promoting both patient adherence and overall satisfaction with care (Martin et al., 2005).

The second element of the IMS Model, *motivation*, emphasizes the importance of shared decision making between patients and their physician in order to develop a treatment plan the patient believes in and one to which the patient can make a commitment (DiMatteo et al., 2012; Zolnierek & DiMatteo, 2009). Helping patients to believe in the potential efficacy of a recommended treatment and the establishment of informed collaborative choice can influence a patients' motivation to adhere (Zolnierek & DiMatteo, 2009). Some research suggests that when a patient believes in the importance of their recommended treatment, healthcare teams can use behavioral contracts to gain further commitment (Martin et al., 2005). Ultimately, patients are more adherent to treatment if they believe that the consequences of nonadherence are more detrimental to their health than if they take the consequences of nonadherence less seriously. Thus, it is extremely important for health professionals to discuss openly, with their patients, any beliefs and specific perceptions or expectations of treatment that may hinder adherence behaviors.

The final element of the IMS Model involves developing workable *strategies* or resources to help patients overcome any (real or perceived) barriers that may hinder adherence. Members of the healthcare team must be willing to direct patients to resources to overcome such barriers as the financial cost of medication, the disadvantages of complex treatment regimen, or the lack of transportation to scheduled appointments. Patients also need assistance and encouragement to access supportive resources from their social support group (such as spouse, family, or friends) and any other aid that might be available to them to support the regimen (e.g., community- or work-based interventions) (Miller & DiMatteo, 2013). Health professionals should routinely assess the levels of social support available to their patients, as research by DiMatteo (2004) has shown that the absence of social support is a significant barrier to adherence.

The IMS Model can be used as simple heuristic through which clinicians can target the specific needs of their patients in order to establish the most effective treatment. The IMS Model illustrates that knowledge, commitment, and ability are essential for improving patient adherence (DiMatteo et al., 2012).

Conclusion

Patient adherence is essential for the achievement of quality healthcare outcomes. Effective patient communication can increase patient satisfaction, improve overall quality of life, and ultimately reduce the risk of nonadherence. Current empirical research continues to try to understand, assess, and predict the many challenges that patients face in the management of their care. The elements of the *Information–Motivation–Strategy* (IMS) model can be used by clinicians and health professionals to assist patients in building effective long-term disease management strategies to improve overall health outcomes and ultimately maximize adherence to treatment.

Author Biographies

Tricia A. Miller, PhD, is the research scientist for Cottage Children's Medical Center. She received her doctorate from the University of California, Riverside, in social-personality psychology. Her research focuses on the social psychological process of health and medical care delivery including provider–patient communication and treatment adherence. Dr. Miller is a lead contributor to grant-funded projects examining Pediatric Care Coordination among medically complex children and improvements in clinical and social outcomes for very low birth weight infants and their families.

Summer L. Williams, PhD, received her doctorate in social-personality psychology from the University of California, Riverside. Her research expertise is in health communication and health outcomes research, where she has spent the last decade examining doctor–patient communication in diverse populations, patient adherence, and patient satisfaction. She is an associate professor at Westfield State University in Massachusetts, currently teaching courses in introductory psychology, health psychology, social psychology, psychology of illness, and health of vulnerable populations.

M. Robin DiMatteo, PhD, is a distinguished professor emeritus of psychology at the University of California, Riverside. She received her BS in mathematics and psychology from Tufts University, and her MA and PhD degrees from Harvard University. She has served as a resident consultant in health policy at the RAND Corporation. Dr. DiMatteo has been elected Fellow of the American Association for the Advancement of Science. Dr. DiMatteo received the Distinguished Teaching Award from the University of California, Riverside, and is a member of the UCR Academy of Distinguished Teachers.

Overview

The diagnosis of tobacco use disorder is a relatively new name for a long-standing health problem that was previously referred to as nicotine dependence (Britt, Cohen, Collins, & Cohen, 2001). Though the terms “nicotine” and “tobacco” are often synonymously used, “tobacco” technically refers to a plant, while “nicotine” refers to a primary addictive chemical in the tobacco plant. Although this classification was somewhat recently amended, the use of products containing tobacco has been around for centuries. In fact, the popularity of such products swelled in the years preceding the establishment of the United States, and since that time, the tobacco industry has worked tirelessly to increase their consumer base. More recently, tobacco companies have marketed electronic nicotine delivery systems (ENDS). The popularization of these and other tobacco products have contributed to tobacco’s role as the number one cause of preventable death in our society (World Health Organization [WHO], 2011).

It is alarming to consider that tobacco use is currently linked to 6 million deaths annually (WHO, 2016). To put this in perspective, during the twentieth century, tobacco use was linked to more deaths than both world wars combined (Chalabi, 2013). Further, one-quarter of all deaths among US women and men aged 35–69 are directly linked to a smoking-related illness (Jha et al., 2013). In addition to high mortality rates, tobacco use is associated with declines in health status, economic productivity, and environmental conditions (WHO, 2011).

History and Landmark Studies

Tobacco use has a long history, dating back to the pre-Columbian period where indigenous peoples chewed, smoked, and inhaled tobacco for medicinal and ritualistic purposes (Kohrman & Benson, 2011). This cash crop spread across Europe in the 1500s after Jean Nicot, a diplomat and scholar, first introduced tobacco to the French court. It was not until the beginning of the twentieth century, however, that researchers began warning the public about the harm caused by the use of tobacco. Specifically, in 1930, researchers in Germany noted a correlation between smoking and cancer. However, tobacco was not publically scrutinized until Reader's Digest published their 1952 article, *Cancer by the Carton*. As a result of this article, the public's attention was piqued and cigarette sales plummeted (CNN, 2000). Twelve years later, the surgeon general of the United States released a landmark report warning Americans of tobacco's adverse effects for the first time (U.S. Department of Health and Human Services [USDHHS], 1964). At that time, an estimated 42.4% of the US population were classified as current smokers (Wilson, 1967).

Since the release of the first surgeon general's report, tobacco companies and public health advocates have been at odds. Specifically, public health advocates have fought for harsher policies to protect the public, while big tobacco companies have worked to persuade the public that they have designed a "cleaner smoke." As consumers became more aware of the dangers associated with tobacco use, many attempted to quit. Others sued tobacco companies for failing to warn them of the deadly consequences of tobacco use. In 1996, the US Department of Health and Human Services appointed a panel of experts to create clinical practice guidelines. These guidelines were designed to assist in the delivery and support of evidence-based treatments for tobacco use and dependence (Abrams et al., 2003). Since that time, the guidelines have undergone several rounds of revisions utilizing an evidence base of over 8,700 research articles. Ten key recommendations, mostly focusing on brief and intensive treatments and system-wide changes, were put forth in the most recent update.

Despite an overall decrease in smoking rates and discovering more effective ways to help people quit, problems associated with the use of tobacco products remain. Although smoking rates declined by 10% between 1997 and 2015, 36.5 million Americans continued to smoke in 2015 despite awareness of the harmful consequences to themselves and others (Centers for Disease Control and Prevention [CDC], 2016). Additionally, since the release of the surgeon general's report, over 2.5 million *nonsmoking* Americans have died due to the dangerous effects of secondhand smoke (USDHHS, 2014).

Another more recent concern involves the misperception that alternative tobacco products (e.g., e-cigarettes and smokeless tobacco) are safe. In 2003, ENDS became globally available. Now a multibillion dollar industry, ENDS advertisers promise a "cleaner smoke," leading many to mistakenly assume that these products are less harmful or represent a viable, safe substitute for cigarettes that can be used to aid in cessation (USDHHS, 2016). The available data, however, suggest this is not the case. Specifically, e-cigarettes contain aerosol, while smokeless tobacco products contain known carcinogens and toxic chemicals (USDHHS, 2016). In addition to this misperception, tobacco companies appear to be targeting youth, adding various flavors that mimic familiar sweet tastes (e.g., cotton candy, gummy bears, and sweet tarts) to these products. Sadly, it appears to be working as e-cigarette use has increased by 900% among high school students between 2011 and 2015 (USDHHS, 2016). In addition to adolescent smokers, several populations are considered particularly vulnerable to developing tobacco use disorder. Broadly, those experiencing negative affect, women, blue-collar workers, low-income populations, ethnic minorities, and those without health insurance have a higher risk of adopting tobacco use patterns leading to disorder (Cohen, McCarthy, Brown, & Myers, 2002; Orleans et al., 1998).

Classification of Tobacco Use Disorder

Researchers and clinicians have historically grouped tobacco use with other substances of abuse. However, tobacco influences the human body in a distinct way as nicotine acts as both a stimulant and a depressant. Therefore, it causes the body to relax while simultaneously causing blood pressure to increase. Accordingly, several diagnostic manuals, namely, the APA's *Diagnostic and Statistical Manual of Mental Disorders* (DSM) and the *International Classification of Diseases* (ICD), began to address nicotine use disorders as distinct from other substance use disorders.

Exactly what symptoms constitute tobacco use disorder has changed over time. Most recently, the changes made in the current version of the DSM (5th Edition; DSM-5; American Psychiatric Association [APA], 2013a) includes increased clarity with regard to smoking patterns and severity of cravings (APA, 2013b). Additionally, the term "tobacco abuse" was added, a severity criterion was implemented (i.e., experiencing 2–3 criteria indicates "mild" severity, 4–5 indicates "moderate" severity, and 6 or more indicates "severe"), new specifiers "in a controlled environment" and "on maintenance therapy" were included, and the "physiological" subtype specifier was removed (APA, 2013a). Further, early remission is defined as "at least 3 but less than 12 months without meeting substance use disorder criteria (except craving)," and sustained remission is defined as "at least 12 months without meeting the criteria (except craving)" (APA, 2013a).

The DSM-5 (APA, 2013a) defines tobacco use disorder as "a problematic pattern of tobacco use leading to clinically significant impairment or distress" where a minimum of two of the following symptoms occur within a 12-month period:

1. Tobacco is used in larger amounts or for a longer period than intended.
2. There is a persistent desire to quit use or there are unsuccessful quit attempts.
3. A great deal of time is spent obtaining or using tobacco.
4. There are cravings or strong urges to use tobacco.
5. There is interference in daily activities that occurs as a result of tobacco use.
6. Use continues despite adverse consequences in personal or social situations.
7. Important activities (social, occupational, recreational) are given up due to tobacco use.
8. Tobacco use persists in situations where it is physically hazardous.
9. Despite having a physical or psychological tobacco-related problem, tobacco use persists.
10. Tolerance to tobacco is observed.
11. A well-defined withdrawal syndrome is experienced when use is discontinued (p. 571).

Tolerance and withdrawal are other constructs associated with tobacco use disorder. Tolerance is defined by either "a need for markedly increased amounts of tobacco to achieve the desired effect" or "a markedly diminished effect with continued use of the same amount of tobacco." Withdrawal is recognized by either "the characteristic withdrawal syndrome for tobacco" or use of tobacco "to relieve or avoid withdrawal symptoms." The withdrawal syndrome is characterized by an "abrupt cessation of tobacco use" or a "reduction in the amount of tobacco used." Further, four or more of the symptoms below are experienced within 24 hr of reduced use or cessation (p. 575):

1 Irritability, frustration, or anger
2 Anxiety
3 Difficulty concentrating
4 Increased appetite
5 Restlessness
6 Depressed mood
7 Insomnia

Initiation and Maintenance

A common question that has plagued researchers and clinicians alike is, "Why do individuals start smoking in the first place given that we have data to support that it is unhealthy?" While the answer to this question has not yet been identified, much has been learned about the process of initiation and maintenance. Generally, tobacco use begins before 18 years of age, and recent research indicates that a person can become addicted to nicotine after just one cigarette (University of Massachusetts Medical School, 2007). Since 20–30% of those who experiment with tobacco will meet lifetime criteria for tobacco use disorder over the course of their lifetime, it is not surprising that many teen smokers who experiment with tobacco several times as a means of fitting in socially will progress to more frequent use (Abrams et al., 2003; American Academy of Addiction Psychiatry [AAAP], 2015). Further, those who experiment with smoking commonly develop associations between smoking, daily life occurrences (e.g., socializing, drinking, waking up, finishing a meal), emotional states (e.g., anxiety, anger), and sensory aspects of tobacco use. These associations frequently contribute to the maintenance of tobacco use. Since nicotine is highly addictive and tobacco use becomes easily engrained in a person's daily life, quitting becomes difficult. Lastly, the interaction of nicotine and human physiology also helps to explain why people maintain this unhealthy behavior and find it difficult to quit. Tobacco companies have worked untiringly to design the perfect nicotine delivery system. After a person's first inhalation, nicotine takes only 8 s to reach the brain, where it targets areas associated with feelings of pleasure and reward.

Benefits to Tobacco Cessation

The detrimental health effects of using tobacco products have been well established. Regardless of the manner in which it is used, tobacco harms the human body. It increases heart rate and blood pressure while simultaneously decreasing the health of respiratory and circulatory systems. In addition, protracted use of tobacco changes cellular characteristics, which may support the development of cancer. This said, research has indicated that vast improvements in health can occur in the absence of tobacco use (CDC, 1990). Specifically, in 2013, Jha et al. used the US National Health Interview Survey to obtain smoking and smoking cessation information from 202,248 men and women between 1997 and 2004. This data set revealed that adults who quit smoking reduced their risk of mortality from smoking-related illnesses by close to 90%. Researchers have also discovered tremendous health improvements including reduced smoking-related symptoms such as coughing and shortness of breath and decreased risk of smoking-related illnesses (e.g., heart attack and diabetes), some of which occur within 20 min after a person stops smoking (American Cancer Society, 2016).

Evidence-Based Treatment

Now that it has been established that nicotine is a highly addictive substance, is delivered to the human brain in an optimal way, and becomes part of many aspects of individuals' lives, it should be clear that most individuals who wish to quit smoking find it difficult. In fact, 44% of smokers' quit attempts result in relapse within 14 days, and 60–98% of smoking quit attempts lead to relapse (Abrams et al., 2003). In addition to the more common challenges described thus far, people tend to present to treatment with an array of problems or "comorbidities" that may complicate the process of smoking cessation. Accordingly, clinicians should take an individual's unique barriers to smoking cessation into account when creating a treatment plan. Thankfully, a variety of options are available. Currently, the most effective treatment includes a combination of behavioral therapy and pharmacotherapy (i.e., nicotine replacement therapy [NRT]). Before delving into an overview of these broad treatment modalities (as well as other more specific ones), it is important to mention the importance of assessment, which is a common and important component throughout treatment.

Assessment

It is best practice to begin any cessation program with a comprehensive assessment. The goal of assessment is to equip the clinician with a better idea of how to work most effectively with a particular individual. Assessment should take different forms throughout treatment and can be useful in understanding an individual's barriers that may undermine a quit attempt. Generally, healthcare providers attend to five clinical areas when conducting smoking cessation assessments: (a) motivation, (b) nicotine dependence, (c) past quit attempts and smoking history, (d) substance abuse comorbidity, and (e) psychiatric comorbidity (Abrams et al., 2003). By attending to these five areas, clinicians can tailor smoking cessation treatment to specific clients to give them the best chance of success.

Additionally, assessment can inform which type of treatment may be best suited for a particular client given that different types of therapy have led to better treatment outcomes among certain populations (e.g., pregnant women, racial and ethnic minorities, low-income smokers; Vidrine, Cofta-Woerpel, Daza, Wright, & Wetter, 2006; Weinberger, Pittman, Mazure, & McKee, 2015). Lastly, given that a person's level of motivation and other relevant individual factors may change across time, it is important that assessment occur throughout treatment so that the clinician is quantitatively and qualitatively aware of how their clients are adjusting during the various stages of treatment.

Pharmacotherapy

Beginning with the development of nicotine gum, pharmacotherapy has been the principal treatment modality in most smoking cessation research studies. Since smoking is perpetuated by habitual behavior and the addictive nature of nicotine, it makes sense that the combination of nicotine replacement and behavioral therapies may be helpful for people attempting to quit. By using pharmacotherapy, smokers can focus more on the behavioral aspects of their habit, while at the same time, receiving help with respect to the severity of withdrawal symptoms that they may be experiencing. Currently there are five modalities of nicotine replacement therapy (NTR; i.e., gum, patches, lozenges, inhalers, and nasal spray) and two oral medications that do not contain nicotine [Chantix (varenicline tartrate) and Zyban (bupropion hydrochloride)]. Of these options, nicotine gum, patches, and lozenges are available over the counter, while the others require a prescription. It is important to note that while each option in this category may come with its own side effects, use of such products has evidenced higher rates of smoking cessation success when compared with behavioral therapy alone (Fiore et al., 2000). Still, for those who are unable or unwilling to use pharmacotherapy, other options such as nicotine fading are available. Finally, while use of Chantix and Zyban can be used before the quit date, the NTRs should not start until one has quit smoking.

Behavioral Therapy: Preparing to Quit

Whether a person decides to receive brief or more intensive behavioral treatment, the first phase of such treatment involves preparation. While behavioral treatment may differ somewhat based on individuals' specific needs, it is generally the case that the early stage of this approach focuses on preparing the individual to quit. This includes the use of psychoeducation (e.g., learning about the effects of nicotine), motivational enhancement techniques (e.g., eliciting reasons for wanting to quit), preparation for overcoming withdrawal symptoms (e.g., brand fading or gradual reduction in number of cigarettes), unlearning a behavior (e.g., reducing the number of places an individual smokes), practicing urge control strategies (e.g., delaying the next cigarette), letting others know that you are working on quitting, and ultimately, setting a definitive quit date (which is a critical step given that many have indefinite plans to quit).

During the preparation stage, individuals learn as much as they can about their smoking behavior (i.e., when they smoke, what "triggers" their smoking) by self-monitoring and recording data relevant to this behavior. This phase enables individuals to plan their quit attempt (with the use of data) so that their chance for success is optimized. During this phase, individuals may be advised to purchase cigarettes in smaller quantities than usual so that they do not have too many cigarettes readily available to them or too many left over once they get to their quit date. This strategy is both economical and creates an inconvenience to their normal routine. Individuals may also wish to slowly reduce the number of cigarettes they smoke per day (or gradually change their brand of cigarettes to a brand with less nicotine) in order to minimize withdrawal when they quit (especially if they prefer to not use one of the available pharmacotherapies). It is during this phase of treatment that healthcare providers can help patients identify what in their environments may lead to failure. For instance, evaluation of an individual's context may reveal that stress at work leads to smoking. Learning and mastering stress reduction techniques as well as planning for what they can do rather than take a "smoke break," before the quit date, will likely help that individual increase the chance of a successful quit attempt (Abrams et al., 2003). Additionally, clinicians and smokers should consider their time commitments and availability before beginning treatment. The amount of time a smoker can dedicate to treatment must be considered to avoid gaps. Finally, past quit attempts that ended in relapse should be reframed as learning opportunities prior to beginning anew. Utilizing previous quit attempts in a positive way will likely contribute to success in a new quit attempt.

Behavioral Therapy: Quit Day

As mentioned above, a quit date is generally set during the preparation phase of treatment. Hopefully by this day, the individual has learned a great deal about their smoking behaviors and is ready for any challenges they face. It is recommended that on this day, individuals change their regular routine. The reason for this is to lessen the occurrence of paired associations that will ultimately be too difficult to resist. For example, if a cigarette is paired with a cup of coffee at home in the morning, either drink tea or get the cup of coffee on the way to work and drink it in the car (where there are presumably no cigarettes available). It is also important on this day (and every day that follows) to be on guard for triggers and difficult situations.

Behavioral Therapy: Relapse Prevention

Being smoke-free will get easier and easier as time goes on; however, it is important for ex-smokers to not get overconfident and always be prepared to deal with the stressors or cravings they experience in ways other than smoking. It is important for individuals to utilize any urge control strategies they practiced during the preparation stage. Whereas in the preparation stage, a helpful urge control strategy was to delay the amount of time until the next cigarette, in this stage appropriate strategies include, escaping or avoiding situations that historically led to smoking, using distraction techniques such as staying busy, and substituting smoking with other, healthy behaviors, like eating carrots or chewing gum. It is also important to set up a reward structure for being successful (e.g., buying something with the money being saved from not smoking). Additionally, asking friends and family for support when things get rough may be helpful. Finally, if a cigarette is smoked, it is important to frame the occurrence as a “slip” rather than a failure or excuse to continue smoking regularly. If this is not possible, consider setting a new quit date and use all that has been learned from previous quit attempts.

Complementary and Alternative Treatments

Despite the advances in more traditional smoking cessation treatments, some people prefer to use methods that are less mainstream and not typically considered standard practice. While some of the treatments that fall into this category have been carefully evaluated, others have not. Complementary treatments are those that are used in conjunction with more traditional methods, whereas alternative treatments are those that are used instead of other options. Although a growing number of these types of treatment are available, a comprehensive discussion of all that are currently used falls outside the scope of this entry. Below are summaries for three such therapies including, hypnotherapy, acupuncture, and confectionery chewing gum. For a more thorough discussion, refer to the National Center for Complementary and Integrative Health’s Clinical Digest (2014), which can be found online at nccih.nih.gov/health/providers/digest/smoking.

Hypnotherapy

Hypnotherapy is a method that aims to decrease a person’s desire to smoke, strengthen the will to quit, and increase a person’s focus on quitting by acting on underlying impulses. Hypnotherapy treatments differ in regard to hypnotic induction, amount of sessions, duration of treatment, and use in combination with other therapeutic methods.

While research in this area is quite varied, hypnotherapy’s effectiveness has been studied alongside a number of other smoking cessation methods. For example, in 2010 Barnes and colleagues reviewed literature pertaining to the efficacy of hypnotherapy for smoking cessation and found 11 studies with data from 1,120 participants. Overall, Barnes et al. (2010) found conflicting results with regard to hypnotherapy's efficacy. In comparison to no intervention, hypnotherapy was not demonstrated to be more effective 6 months after the beginning of treatment. Additionally, these studies did not reveal a greater effect when compared with rapid smoking or psychological treatments such as counseling (Barnes et al., 2010). More recently, Hasan and coauthors conducted a randomized controlled trial (RCT) among individuals who were hospitalized for a variety of health concerns including cardiac and pulmonary illnesses. This study revealed that at 12 (43.9 vs. 28.2%; $p = 0.14$) and 26 weeks post-hospitalization (36.6 vs. 18.0%; $p = 0.06$), hypnotherapy patients were more likely than NRT patients to be nonsmokers. These findings indicate that hypnotherapy may aid in smoking cessation; however, more research is needed to determine the extent to which hypnotherapy is efficacious and with which populations it is most useful. For a more complete review of the use of hypnotherapy for the treatment of smoking cessation, refer to the Cochrane report at www.cochrane.org/CD001008/TOBACCO_does-hypnotherapy-help-people-who-are-trying-to-stop-smoking.

Acupuncture

Acupuncture, a traditional Chinese method that uses needles to stimulate energy points, has also been promoted as an aid for smoking cessation. The aim of acupuncture techniques for smoking cessation is to reduce nicotine withdrawal symptoms. Similar to current research on hypnotherapy, studies on the efficacy of acupuncture for smoking cessation are mixed. While some lines of research support the use of acupuncture techniques in the short term, it is likely that these results are attributed to a placebo effect. Overall, acupuncture research has not revealed clear evidence in support of its effectiveness above and beyond other treatments (White, Rampes, & Ernst, 2014). For a more complete review of the use of acupuncture for the treatment of smoking cessation, refer to the Cochrane report at www.cochrane.org/CD000009/TOBACCO_do-acupuncture-and-related-therapies-help-smokers-who-are-trying-to-quit.

Confectionery Chewing Gum

One healthy alternative to smoking that has received empirical attention is the use of confectionery chewing gum. Previous research has shown that confectionery gum appears to aid in the reduction of withdrawal symptoms, particularly those related to negative affect, among individuals dependent on nicotine. In a series of studies, Cohen, Britt, Collins, al'Absi, and McChargue (2001); Cohen, Britt, Collins, Stott, and Carter (1999); and Cohen, Collins, and Britt (1997) have evaluated the utility of confectionery chewing gum as an aid to help smokers when they are asked to abstain from smoking for brief periods of time in the laboratory. Results from two of these studies (1997 and 2001) revealed that the use of chewing gum reduces the severity of self-reported withdrawal symptoms following 3–4 hr of abstinence. Results from the other study show that the use of chewing gum is associated with changes in smoking behavior (Cohen et al., 1999). Specifically, participants showed significant decreases in the number of cigarette puffs that were taken as well as increased periods of abstinence. More recently, the use of chewing gum has been shown to be useful in reducing symptoms of withdrawal over 24 (Cortez-Garland, Cohen, VanderVeen, & Cook, 2010) and 48 (Cohen, Collins, VanderVeen, & Weaver, 2010) hr of abstinence.

In conclusion, confectionery chewing gum has demonstrated its utility as an aid for smokers during periods of abstinence ranging from 3 to 48 hr. Chewing gum may be a useful adjunct to existing smoking cessation treatments given that it is easily accessible, inexpensive, and simple to administer. Due to the well-documented risk of smoking and the difficulty individuals who smoke face during the cessation process, a behavioral substitute that can positively influence the symptoms of negative affect associated with nicotine withdrawal may improve upon treatment success.

Future Research Directions

Many important questions concerning tobacco use have been addressed over the past 50 years. Yet, better treatments for tobacco use disorder are needed as it is estimated that 1.1 billion people smoked tobacco in 2015 alone (WHO, 2017). Five key areas concerning tobacco use disorder treatment remain to be addressed.

First, since we know smoking initiation typically begins in adolescence and young adulthood, it may be helpful to understand more about underlying mechanisms unique to these age groups. By pinpointing smoking behavior, prevention and effective treatments should aim to reduce the number of people who attempt to begin smoking in the first place. High-risk and low-risk thinking patterns in adolescents can be identified and may aid in the development of critical prevention efforts for youth (Choi, Gilpin, Farkas, & Pierce, 2001). Since those who experiment with smoking are highly likely to become regular users, prevention efforts seem to be most effective during this developmental period. Second, more effective treatments are needed for adult smokers. Particularly, current research exploring the relationship of the neurobiology of nicotine addiction to behavioral, pharmacological, and combined treatments is needed. Third, more information about tailoring treatments to smokers with distinct profiles may be helpful. Continued research on how to most successfully match smoker profiles to treatment options may result in more efficacious smoking cessation outcomes. Fourth, although smoking and drinking alcohol seem to go hand in hand, we are still uncertain about how these two addictive behaviors are connected or why they tend to be seen regularly in conjunction with one another. More information about underlying smoking and drinking pathways could be helpful for understanding why people start smoking and drinking and how we can help them stop if they wish to do so. Finally, broad system-wide considerations must be taken into account to reduce the prevalence of tobacco use disorder. Strengthened collaborative efforts between researchers and practitioners will likely aid in this process. As researchers continue to pioneer new treatments and clinicians implement changes into practice, tobacco use disorder will hopefully become less of an issue in our society.

Conclusion

Based on recent data, 60–80% of Americans who currently report smoking cigarettes meet diagnostic criteria for tobacco use disorder (AAAP, 2015). A recent survey by the CDC indicates that while rates of cigarette smoking have been generally trending downward in the United States (CDC, 2016), there is a 900% increase in youth e-cigarette usage from 2011 to 2015. As such, more work in this area remains. Researchers have asserted that the initiation of tobacco use rates in a population predict future smoking patterns. However, little is currently known about adolescent and young adult smoking patterns. Future efforts must target youth tobacco prevention, more effective treatments, and improved system-wide cessation efforts. As public health advocates continue to be vigilant about this issue, a reduction or elimination of a widespread, long-standing problem will hopefully soon be seen.

Author Biographies

Victoria A. Torres, BA, is a doctoral candidate in the clinical psychology program at the University of Mississippi. Her current research focuses primarily on factors that contribute to tobacco use. Before Ms. Torres came to UM, she received her baccalaureate degree in psychology from Baylor University. After graduating from Baylor, she worked for 2 years as a research assistant at Baylor Scott & White as part of the Warriors Research Institute, where she contributed to several federally funded research projects.

Lee M. Cohen, PhD, is dean of the College of Liberal Arts and professor in the Department of Psychology at the University of Mississippi. Dean Cohen came to UM from Texas Tech University, where he served in a number of administrative roles including the director of the nationally accredited doctoral program in clinical psychology and the chair of the Department of Psychological Sciences. As a faculty member, he received several university-wide awards for his teaching and academic achievement. As a researcher, he received more than $1.5 million from funding agencies, including the US Department of Health and Human Services, the National Science Foundation, and the National Institutes of Health/National Institute on Drug Abuse. His research program examines the behavioral and physiological mechanisms that contribute to nicotine use, and he worked to develop optimal smoking cessation treatments.

He is a fellow of the American Psychological Association and received his PhD in clinical psychology from Oklahoma State University.

Suzy Bird Gulliver, PhD, is a licensed clinical psychologist and clinical researcher. Currently, she serves as director and chief of the Warriors Research Institute (WRI) and as a professor of psychiatry at Texas A&M Health Science Center. She earned her PhD in clinical psychology from the University of Vermont and went on to work as a National Institute of Alcohol Abuse and Alcoholism-funded postdoctoral fellow at Brown University. Dr. Gulliver later spent 18 years in a variety of roles within the VA in Boston, Massachusetts. Before founding the WRI within Baylor Scott & White Health in 2013, Dr. Gulliver served as the director of the VA VISN 17 Center of Excellence in Waco, Texas. Dr. Gulliver's team has been federally funded and has published 88 peer reviewed manuscripts, 2 book chapters, as well as hundreds of presentations to academic, medical, and emergency response audiences.

Psychological Assessment in Medical Settings: Overview and Practice Implications

Kelsey A. Maloney and Adam T. Schmidt

Department of Psychological Sciences, Texas Tech University, Lubbock, TX, USA

The field of health psychology is a rapidly changing and expanding area of clinical and research focus. Skills of psychologists are increasingly being utilized in medical settings, including primary care, rehabilitation, and specialty medical clinics including oncology, cardiology, and organ transplantation. Approximately 60 medical disorders frequently encountered in primary care settings can also cause or exacerbate mental health conditions (Kush, 2001). Many primary care physicians may not have sufficient time to routinely detect, diagnose, or provide treatment for common psychological problems in their patients; moreover, many referrals that are made are not followed-up on by patients because of constraints of access, insurance coverage, or unfamiliarity with mental health assessment and intervention. Because so many common medical disorders impact mental health and vice versa, many physicians are beginning to work collaboratively with psychologists as part of a multidisciplinary treatment team in order to provide holistic, integrated care to their patients. Through the formal assessment of psychological symptoms, psychologists can help turn the focus of treatment either to or away from primary psychological issues and help streamline treatment for patients (Kush, 2001).

Anxiety disorders, followed by depressive disorders, are the most common presenting problems for mental health professionals practicing across medical settings. Both the occurrence of anxiety and depression can complicate treatment of other health conditions either by interfering with reporting of symptoms, reducing compliance with medically recommended treatments, or by contributing to behaviors that complicate the course of the medical ailment (e.g., a patient smokes to reduce stress caused by anxiety thereby exacerbating their cardiovascular disease). Not only can primary medical concerns be complicated by secondary mental health disorders, but primary mental health concerns can also be complicated with secondary medical disorders. Psychologists can provide a more thorough description of a patient's

psychosocial milieu and a better understanding of mental health concerns that may exacerbate the course of the presenting medical issue or, at the very least, complicate the treatment of this condition. Efficient and thorough psychological assessment is a key portion of the role of psychology in a medical setting. In this chapter, our goal is to present a brief overview of the specific roles for psychologists and of psychological assessment in particular within different types of medical settings in which their expertise is routinely employed.

Primary Care Settings

"Primary Care Psychologists are experts in: (a) assessment & evaluation of common psychosocial symptoms…[seen in primary care setting]; (b) [able to distinguish between symptoms associated with a medical disease and a mental health condition]; (c) collaborate with primary care teams; (d) have the knowledge to triage appropriately; (e) have an understanding of biomedical conditions commonly seen in primary care and applicable pharmacological interventions (p. 8)" (Frank et al., 2004, in James, 2006). Primary care psychologists can be helpful in screening for common psychological conditions impacting certain age groups such as autism and attention deficit hyperactivity disorder (ADHD) in pediatric settings or mild cognitive impairment in older adults, common psychiatric symptoms including depression and anxiety (Kush, 2001; Thombus et al., 2012), and screening for psychoactive substance use (Kush, 2001).

Psychologists working with primary healthcare providers may be called on to facilitate screening for disorders common in specific age groups. For example, a psychologist working with a pediatrician may administer screening measures to assess for developmental disabilities such as autism spectrum disorders in toddlers or ADHD in school-aged children. These could be direct administration of screening measures by the psychologist or, more commonly, consultation and interpretation of instruments administered by the medical staff. A positive result on one of these measures may trigger consultation with a psychologist to either perform a more in-depth assessment or to provide additional guidelines or context for the findings. Similarly, physicians working with older adults may refer for additional assessment following a physical exam in which a patient appears confused or somewhat disoriented. This model of working with primary care providers can greatly facilitate the continuum of care and help to ensure that individuals who may not otherwise be evaluated for these, relatively common, disorders are able to be screened and, if necessary, assessed in a timely fashion.

Screening for depression can be another important role for psychologists working in primary care settings. Screening for depression includes "the use of questionnaires concerning the symptoms of depression or small sets of questions about depression to identify patients who may have depression but who have not sought treatment and whose depression has not already been recognized by health care providers" (Thombus et al., 2012). Using depression rating scales can help physicians identify depression, sometimes increasing their ability to do so by 2.5- to 25-fold (Kush, 2001). Certain medical illnesses have been associated with high risk for depression, including "seizure disorders, diabetes, hypothyroidism, hyperthyroidism, Huntington's disease, Parkinson's disease, and cancer" (Kush, 2001). Depression in these populations can complicate treatment and exacerbate the course of the medical disorders. More general patient stressors such as disability resulting from the medical condition and/or significant psychosocial stressors (e.g., the loss of a job, grief from the loss of a loved one, or stress resulting from rigorous treatment regimens) should also trigger evaluations for depressive symptoms. A common and quick depression questionnaire that can be used for screening in primary care settings is the Beck Depression Inventory, Second Edition (BDI-II) (Beck, Steer, & Brown, 1996). The BDI-II is a 21-item self-report measure that can be completed in 5–10 min, can be scored rapidly, and can be used from age 13 to adulthood. Mean BDI-II scores "have been established for Major Depression (single episode, 28.065, recurrent 29.45), Dysthymic Disorder 24.02, Bipolar-Depressed 20.59, and Adjustment Disorder with Depressed Mood 17.29" (Kush, 2001). The BDI for Primary Care (BDI-PC) (Steer, Cavalieri, Leonard, & Beck, 1999), an abridged version, is also an option in primary care settings (Kush, 2001).

Although advantages for screening for depression has potential value, "no trials have found that patients who undergo screening have better outcomes than patients who do not when the same treatments are available to both groups" (Thombus et al., 2012). Routine screening of all patients for depression is labor intensive and can lead to misidentification of depression in some individuals, resulting in treatment for depression in patients with subclinical or mild symptoms and resources allocated away from patients who truly have depression (Thombus et al., 2012). As an alternative to screening, the National Institute for Health and Clinical Excellence 2010 guidelines recommend physicians be alert to possible depressive disorders, especially when there is (a) a previous history of depression in the target patient, (b) when patients have a chronic physical condition, and (c) when the patient has a new or worsening physical impairment that causes functional limitations, and screen for depressive symptoms when there is a specific concern such as the recent loss or change in the individual's living situation, support network, or quality of life (Thombus et al., 2012).

Anxiety disorders have significant comorbidity with medical disorders including heart and lung diseases, fibromyalgia, and diabetes (Kush, 2001). Screening for anxiety disorders in primary care health settings is especially important in patients reporting somatic concerns including shortness of breath and chest pains. If undertaken in an efficient manner so as to not interfere with legitimate medical problems, screening can lead to reduced medical costs and improved outcomes by helping physicians make differential diagnoses and guide the selection of appropriate treatment (Kush, 2001). The Beck Anxiety Inventory (BAI) (Beck & Steer, 1993) is a 21-item self-report measure that can be completed and scored quickly. Fourteen items measure biological symptoms of anxiety, and seven items measure psychological anxiety symptoms; no items specifically measure phobias or obsessions and compulsions (Kush, 2001). Mean BAI norms have been established for "Panic Disorder with Agoraphobia (M = 27.27, Panic Disorder without Agoraphobia (M = 28.81), Social Phobia (M = 17.77), Obsessive-Compulsive Disorder (M = 21.69), and [Generalized Anxiety Disorder] (M = 18.83)" (Kush, 2001).

Another consideration for psychologists practicing in primary care settings where time and resources are commodities is the significant comorbidity between anxiety and depression. In settings where this is of concern, other measures that screen for both types of symptoms may be most appropriate. The Hamilton Rating Scale for Depression (HAM-D) (Hamilton, 1960) is clinician administered and is used to screen for depression; it also contains three anxiety items and can be used to assess a patient's overlap in anxiety and depression symptoms. Both the BDI-II and BAI have shown discrimination between depression and anxiety (Kush, 2001).

In addition to internalizing concerns, drug and alcohol abuse are aspects of concern when patients present to primary care settings. According to Kush (2001), approximately 10% of adults experience significant dysfunction from alcohol or drug use at any time, yet most of these adults can present to medical appointments without any outward presentation of their substance use. Substance use and complications arising from this use can complicate the course of chronic health conditions and can attenuate the effectiveness of medical interventions. As a result, psychologists need to incorporate screening measures of substance abuse in their standard assessment protocols for primary care patients. The Drug Abuse Screening Test (DAST-20) (Skinner, 1982) is a 20-item assessment for drug abuse over 12 months, including both prescription drug and illicit drug use, and it can be administered in approximately 5 min via self-report or interview (Kush, 2001). The Alcohol Dependence Scale (ADS) (Skinner & Horn, 1984) is a 28-item assessment for alcohol abuse over 12 months, and it can be administered in approximately 10 min via self-report or interview (Kush, 2001). In cases of suspected drug or alcohol abuse, it is important to establish a timeline of whether drug or alcohol use preceded medical problems or vice versa as this distinction may have implications for etiology, prognosis, and treatment.

Rehabilitation Settings

In addition to primary care settings, psychologists also frequently play a role in physical rehabilitation settings where patients present with a wide range of physical injuries/disabilities and co-occurring mental health concerns. Important components of psychological assessment in rehabilitation settings include the measurement of social problem solving that may impact treatment, functional impairments that may influence daily living, measures of disability status, and coping skills/behavioral adjustment (Dreer et al., 2009; Hall, 1999). Empirically supported measures of social problem solving include "the Means-End Problem Solving Procedure (MEPS; Platt & Spivack, 1975), the Problem Solving Inventory (PSI; Heppner, 1988), and the Social Problem Solving Inventory-Revised (SPSI-R; D'Zurilla, Nezu, & Maydeu-Olivares, 2002)" (in Dreer et al., 2009). These and similar tools are helpful adjuncts to treatment in rehabilitation because social problem skills can help those living with chronic health conditions or disabilities cope with psychological distress (Dreer et al., 2009).

Functional assessment measures assess disability across domains including "self-care, mobility, and, more variably, cognition, communication, and behavior" (Hall, 1999). Measures of functional disability include the Functional Independence Measure (FIM), which measures motor and cognitive functioning; the Functional Assessment Measure (FAM), which is an addition to the FIM (known together as the FIM + FAM) and adds 12 items on cognitive, behavioral, communication, and community function (Hall, 1999); and the Disability Rating Scale (DRS; Rappaport, Hall, Hopkins, Belleza, & Cope, 1982). Other measures of functional disability include length of inpatient stay, hospital or rehabilitation charges (excluding physician fees), and the intensity and type of treatment (i.e., service utilization; Hall, 1999). Finally, client satisfaction with services is an important target variable for ascertaining the quality of outcomes (Hall, 1999). These measures can help psychologists understand the limitations of their patients and provide a road map for cognitive behavioral interventions targeting specific areas of concern. Moreover, using these screening instruments can augment information gained from traditional psychological assessments by providing context as to the physical and cognitive limitations, patients may face upon returning home or during their stay at the facility.

Measures of disability status typically include analyses of community integration, service utilization, and independence. The Community Integration Questionnaire (CIQ) (Willer, Ottenbacher, & Coad, 1994) is a 15-item self-administered or interview-based questionnaire that assesses community integration for individuals with TBI across three dimensions: home integration, social integration, and productivity (Hall, 1999). The Craig Handicap Assessment and Reporting Technique (CHART) (Whiteneck, Charlifue, Gerhart, Overholser, &

Richardson, 1992) assesses five domains of "physical independence, mobility, occupation, social integration, and economic self-sufficiency" in individuals with spinal cord injury (Hall, 1999). Other measures of handicap status include employment, which can be measured by the CIQ, CHART, FIM + FAM, DRS, or a monthly employment ratio; living arrangements, which provides an estimation of an individual's "level of dependence…and cost to society"; and service utilization (Hall, 1999). Measures of handicap status are useful additions to assessments of functional limitations as they illustrate a patient's level of independence in the community and the extent to which their functional impairments impact their occupational and social functioning all of which may interact with mental health conditions and personality characteristics.

It is also important to assess psychosocial and behavioral adjustment in patients in rehabilitative settings (Hall, 1999). The Neurobehavioral Rating Scale (NRS) (Levin et al., 1987) is a 27-item assessment of cognitive and emotional disturbances and has been "the scale of choice for assessing behavioral changes following TBI in neurosurgical trials," although it requires substantial training, judgment, and "familiarity with the patient" to administer (Hall, 1999). Additionally, quality of life should be assessed as it is "arguably an ultimate aim of rehabilitation"; quality of life can be assessed using the Satisfaction with Life Scale (Diener, Emmons, Larsen, & Griffin, 1985) or the Quality of Life Scale (Chubon, 1987, in Hall, 1999).

Specialty Settings

Cardiology

Anxiety and depression are the most prevalent classes of psychiatric disorders, and coronary heart disease (CHD) is a highly prevalent cardiovascular issue in the general population. Anxiety is an independent predictor of later CHD events and cardiac mortality, and depression is associated with elevated risk of later cardiac episodes (Compare, Germani, Proietti, & Janeway, 2011). "In 2008, the American Heart Association recommended [and the American Psychiatric Association endorsed] that 'screening tests for depressive symptoms should be applied to identify cardiology patients who may require further assessment and treatment' if appropriate referral for further depression assessment and treatment is available" (Compare et al., 2011). As patients who have anxiety or depression are at increased risk for cardiovascular complications, it is important to assess patients with cardiovascular disease, in particular, for emotional conditions that may compound their risk for adverse cardiovascular events (Compare et al., 2011).

Although general measures of anxiety and depression mentioned previously (BDI, BAI, Hamilton Anxiety Scale) can be used to assess these symptoms, there are several assessment measures for anxiety and depression that were developed for specific use in cardiovascular patient populations. The Diagnostic Interview with Structures Hamilton (DISH) (Freedland et al., 2002) is used with patients with acute coronary syndrome as a measure conducive to brief hospital visits, whereas the Maastricht Questionnaire (Appels, 1989) specifically assesses exhaustion (Compare et al., 2011). If assessment identifies patients with moderate to severe symptoms of anxiety or depression who have also either failed several trials of psychotropic medication, who have a history of previous psychiatric diagnosis, and/or who possess any one of a variety of risk factors (e.g., history of physical abuse or sexual victimization), the recommendation would be for these individuals to receive a more thorough assessment (Compare et al., 2011).

Organ Transplantation

Patients on the wait list for or who have received a donor organ are vulnerable to a variety of psychological issues. Adaptive and mental health challenges can occur at each stage of illness and treatment, including "organ failure/chronic illness, pretransplant evaluation, waiting for a donor, surgery, recovery, rehabilitation, [and] permanent maintenance (Olbrisch, Benedict, Ashe, & Levenson, 2002)." The selection process to receive a donor organ includes a process for determining a patient's fitness to receive a donor organ such as psychological functioning and determination of any contraindications to transplantation (Maldonado et al., 2012).

As the gap between organ donation and patients awaiting transplant increases, it is becoming more important to identify potential risk factors (i.e., "substance abuse, compliance issues, serious psychopathology") that could result in greater risk of postoperative noncompliance through the utilization of pretransplant psychological evaluations (Olbrisch et al., 2002). Psychological evaluations also help "[promote] fairness and equal access to care, [provide] a description of the patient's neuropsychiatric and cognitive functioning, [serve] as a guide for the clinical management of the patient and [address] the psychological needs of the transplant team with regard to patient care" (Olbrisch et al., 2002). A typical pretransplant psychological evaluation consists of a clinical interview on the patient's background and functioning, the possible use of standardized instruments, possible brief screenings for cognitive deficits such as mental status evaluations or neuropsychological measures of memory and executive functioning, collateral information (especially in patients with substance abuse history), and assessing for the quality of the patient's support system (Olbrisch et al., 2002).

Standardized measures that can be used to assess patients as candidates for organ transplant include the Psychosocial Assessment of Candidates for Transplantation (PACT) (Olbrisch, Levenson, & Hamer, 1989), the Stanford Integrated Psychosocial Assessment for Transplantation (SIPAT) (Maldonado et al., 2012), and the Readiness for Transition Questionnaire (RTQ) (Gilleland, Amaral, Mee, & Blount, 2012) (Maldonado et al., 2012; Marchak, Reed-Knight, Amaral, Mee, & Blount, 2015; Olbrisch et al., 2002). The PACT consists of eight items on a five-point Likert scale and includes the rater's impressions. The SIPAT consists of 18 items across 4 domains: "Patient's Readiness Level & Illness Management, Social Support System Level of Readiness, Psychosocial Stability and Psychopathology, and Lifestyle and Effect of Substance Use" (Maldonado et al., 2012). The RTQ consists of three parallel versions—the RTQ-Provider, RTQ-Teen, and RTQ-Parent—all designed to be completed by healthcare providers (Marchak et al., 2015).

Oncology

Cancer is a significant physical health ailment in modern society with approximately 14.5 million people currently diagnosed with cancer in the United States (Stanton, Rowland, & Ganz, 2015). Diagnosis and treatment of cancer can cause significant psychological distress in patients, including elevated symptoms of depression and anxiety that can affect more than one in four patients with cancer (Stanton et al., 2015; Thalen-Lindstrom, Larsson, Glimelius, & Johansson, 2013). Stanton et al. (2015) proposed three periods during the survivorship phase—reentry (completion of treatment to up to 1 year), early survivorship (approximately 5 years post-diagnosis), and long-term survivorship (beyond 5 years post-diagnosis)—and proposed that psychological distress may be more pronounced in certain periods than in others. As a result, different assessment questions may predominate depending upon the stage of treatment a patient is in.

For cancer patients, anxiety can center on a fear of cancer recurrence. Fear of recurrence is common in long-term survivors and can be triggered by "follow-up medical visits, symptoms that mimic illness (e.g., pain that may be attributed to disease spread), death of a public figure from cancer, or a family member's illness" (Stanton et al., 2015). Depression is also present in cancer survivors, and there is a higher risk for depressive symptoms in those with advanced cancer, receiving chemotherapy, and with more physical symptoms. However, it should be noted that at 7 years after diagnosis, cancer survivors' rates of depression are not significantly different from healthy controls. Nonetheless, cancer treatments themselves can also result in a number of cognitive effects including impairments in attention, working memory, concentration, and executive functioning (Stanton et al., 2015).

Similar to organ transplant assessment, assessment in oncology settings can help maximize limited resources and identify patients in the most distress (Vodermaier, Linden, & Siu, 2009). Brief, self-report measures can be used to screen for oncology patients who are most in need of psychological services, and systematic screening helps promote equal access to resources better than physician- or patient-initiated referrals, which can fail to identify emotionally distressed patients (Vodermaier et al., 2009). For a detailed review of ultrashort, short, and long assessment measures that can be used as screeners for emotional distress in cancer patients, see Vodermaier et al. (2009).

The Hospital Anxiety and Depression Scale (HADS) (Zigmond & Snaith, 1983) is a 14-item self-report measure for anxiety and depression, with scores greater than 10 signifying clinical cases of anxiety and depression. The HADS has been used as a screener for oncology patients in clinical settings and does increase referral rates; those referred using the HADS, however, had no difference in improvement from those in standard care (Thalen-Lindstrom et al., 2013).

Beyond anxiety and depression, cancer survivors are also likely to experience fatigue, cognitive impairment, pain, and sexual and urinary/bowel problems, as well as difficulty with more global issues such as finding benefits in their cancer experience and returning to work (Stanton et al., 2015). Anxiety and depression symptoms can be risk factors for fatigue; other risk factors for fatigue include elevated body mass, catastrophic thinking, loneliness, and early life adversity (Stanton et al., 2015). Cancer survivors often endorse problems in memory, attention, concentration, and executive function abilities; these problems can be exacerbated by risk factors such as older age, lower education, or lower IQ (Stanton et al., 2015). Therefore, in addition to psychosocial stressors and mental health symptoms, evaluations involving oncology patients should also include screening measures for cognitive functioning in order to determine if additional referrals for a comprehensive neuropsychological assessment is appropriate.

Quality of life is also an important outcome to consider for cancer survivors. Quality of life measures can include indicators of strength of interpersonal relationships and support systems, life appreciation, personal regard, and attention to health behaviors (Stanton et al., 2015; Thalen-Lindstrom et al., 2013). Although quality of life measurement is not typically included in standard psychological assessments, it is understandable how these may facilitate treatment of cancer survivors or those patients dealing with continued cancer treatment. An example measure for evaluating quality of life in oncology patients is the European Organization for Research and Treatment of Cancer (EORTC) quality of life questionnaire (QLQ-C30) (Aaronson et al., 1993) that includes five functional scales (higher scores reflect better functioning), nine symptom scales (higher scores reflect more severe problems), and a global quality-of-life (QOL) scale (higher scores reflect better functioning; Thalen-Lindstrom et al., 2013).

Conclusions

Having psychologists in medical care settings can provide useful insight into issues that arise when there is comorbidity between medical and psychological disorders in medical health settings. Psychological assessments can be used to screen for common psychological syndromes, such as depression and anxiety, autism spectrum disorders, ADHD, and dementia, and to evaluate conditions that may directly impact medical interventions such as substance abuse. The role of psychology in specialty care settings is less focused on direct diagnosis of psychological disorders (although that may continue to be a focus of screening) but rather on issues that are important for treatment and rehabilitation planning such as psychological distress, contraindications of treatment, functional impairment, behavioral/social adjustment, and coping skills. Psychological evaluations have already demonstrated usefulness in a variety of medical settings, and their use and utility will likely increase as we continue to appreciate the role of mental health in the etiology and maintenance of physical disease and the impact of positive psychological adjustment on long-term physical health and well-being.

Author Biographies

Kelsey A. Maloney is a doctoral student in clinical psychology at Texas Tech University. She received her MA from Sam Houston State University in 2016 and BS from Mississippi State University in 2014. Her research interests include the intersection of health and forensic psychology, such as improving health outcomes in juvenile justice populations.

Adam T. Schmidt is an assistant professor of clinical psychology at Texas Tech University. He received his PhD in psychology from the University of Minnesota. His research interests are in the areas of psychological and neuropsychological assessment with at risk populations and in using psychological assessment data to improve treatment outcomes.

Complementary, Alternative, and Integrative Interventions in Health Psychology

Jeffrey E. Barnett

College of Arts and Sciences, Loyola University Maryland, Baltimore, MD, USA

Complementary and alternative treatments and interventions (widely known as CAM or complementary and alternative medicine) are composed of a wide range of healthcare practices, interventions, systems, and products that are not considered to be a part of conventional medicine and healthcare practices (e.g., National Center for Complementary and Integrative Health [NCCIH], 2015d). Complementary practices are those used along with conventional healthcare practices, and alternative practices are those used instead of conventional healthcare practices. In contrast, integrative practices involve utilizing conventional and complementary healthcare practices in a coordinated manner (NCCIH, 2015a).

While CAM interventions have received greater scientific scrutiny in recent years, many forms of CAM have been practiced for thousands of years and have rich histories of use in many cultures. Examples include Traditional Chinese medicine (TCM), which dates back to 800 BCE and Ayurveda, a whole medical system with roots in Hinduism over 10,000 years ago (Duke Center for Integrative Medicine [DCIM], 2006). At present, over 100 different interventions, products, systems, and modalities are included in widely accepted definitions of CAM (Cochrane Reviews, 2015).

Despite the historical acceptance and use of some forms of CAM, the level of support for each form of CAM varies, so a careful review of available research is needed before recommending or utilizing any CAM modalities with patients. In addition to searching for recent studies on the efficacy of various CAM modalities for the treatment of specific health conditions as well as for health promotion, a careful reading of relevant meta-analytic studies available through Cochrane Reviews is recommended (Cochrane Reviews, 2015). Additionally, the NCCIH, an institute of the National Institutes of Health, provides up-to-date information on the efficacy of various CAM modalities to include defining "through rigorous scientific

First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

investigation, the usefulness and safety of complementary and integrative health interventions and their roles in improving health and healthcare" (NCCIH, 2015b, para. 2).

Various CAM modalities may be used to promote health as well as to treat disease. While traditional explanations for the efficacy of many CAM modalities have been questioned by the scientific community, recent research has demonstrated the effectiveness of a range of CAM interventions for a wide variety of disorders. This research has also shed light on the underlying mechanisms of many CAM modalities, helping to explain scientifically what many individuals have accepted based on religious and cultural beliefs and many years of anecdotal support.

CAM has a significant presence in the United States. Nahin, Barnes, Stussman, and Bloom (2009) found that there were over 354 million visits to CAM practitioners in 2007 with over 42 billion dollars spent on these services that year. Additionally, it is estimated that 38.3% of adults and 12% of children in the United States use at least one CAM modality each year (Barnes, Bloom, & Nahin, 2008; NCCIH, 2015a). Further, as research demonstrates the efficacy of various CAM modalities and as individuals embrace lifestyles consistent with the practice of CAM, the number individuals utilizing CAM has steadily increased.

In the most recent extensive surveyq of CAM practices in the United States, the National Health Interview Survey (National Institutes of Health [NIH], 2012) found that CAM practices are used to promote health, to help treat chronic conditions, and to alleviate the side effects of medications and other conventional treatments with these interventions largely being used along with conventional healthcare and not in place of it. Dietary supplements have consistently been found to be the most widely used form of CAM with 17.7% of all US adults found to be using them (NIH, 2012). While differences exist within and between groups, overall, CAM is used by individuals across the age span from a wide range of cultural backgrounds, socioeconomic levels, and educational levels.

For children and adolescents ages 4–17, the most widely used CAM approaches in order of frequency are dietary supplements and natural products; chiropractic or osteopathic manipulation; yoga, tai chi, or qi gong; deep breathing; homeopathy; meditation; special diets; massage; guided imagery; and movement therapy. These are used to promote health and wellness as well as to treat conditions (in order of frequency) such as back or neck pain, other musculoskeletal symptoms, head or chest cold, anxiety or stress, ADHD, and insomnia (NCCIH, 2015c).

In general, psychologists tend to hold positive views of CAM, both for their personal use and for their patients' use. Additionally, many are actively integrating various CAM modalities into their treatment of patients and/or referring patients to CAM practitioners in addition to the psychological treatment they are providing (Barnett & Shale, 2012). Members of the general public also tend to hold positive views of CAM and are open to its use in their lives. Increases in the use of CAM by members of the public in recent years are attributed to factors such as dissatisfaction with conventional medicine to include its increasingly technological focus, a focus on more holistic health promotion and healthcare, and a desire to take a more active role in, and have increased control over, their health and healthcare (Stapleton et al., 2015).

The NCCIH (2015b) views CAM as being made up of five domains. These are the following:

- Whole medical systems. These include homeopathy, naturopathy, TCM, and Ayurveda.
- Mind–body medicine. These include meditation, biofeedback, hypnosis, spirituality and prayer, art therapy, music therapy, dance movement therapy (DMT), and yoga.

- Biologically based practices. These include dietary supplements, herbal supplements, and aromatherapy.
- Manipulative and body-based practices. These include massage therapy and spinal manipulation such as chiropractic and osteopathic.
- Energy therapies. These include qigong, reiki, therapeutic touch, and electromagnetic therapy.

While a wide range of CAM modalities exist, not all are commonly used, and not all receive equal support and acceptance in our nation today. Information will be shared on the 14 most widely used CAM modalities in the United States as reported by Barnes et al. (2008) and NCCIH (2015c). These are, in order of the frequency of their use from greatest to least, dietary supplements; meditation; chiropractic; aromatherapy; massage therapy; yoga; progressive muscle relaxation (PMR); spirituality, religion, and prayer; DMT; acupuncture; reiki; biofeedback; hypnosis; and music therapy. For additional information on each of these CAM modalities to include their origins, uses, relevant research, and limitations, readers are referred to the website of NCCIH at www.nccih.nih.gov.

Dietary Supplements

Dietary supplements include a wide range of typically orally ingested substances that are used to enhance general health and well-being or to help treat a wide range of ailments and health concerns. Dietary supplements include one or more of many "dietary ingredients (including vitamins; minerals; herbs or other botanicals; Amino Acids; and other substances) or their constituents" (Office of Dietary Supplements [ODS], 2011 para. 3).

While dietary supplements are regulated by the US Food and Drug Administration (FDA), they are regulated quite differently than prescription and over-the-counter medicines and vitamins. In fact, as Barnett and Shale (2012) emphasize, "the FDA does not review the safety and/or effectiveness of any supplements prior to them being sold" (p. 577). Additionally, for many supplements, there can be significant differences between brands and even between batches within brands for the potency, purity, type, and quantity of the active ingredients and other substances included in them. Additionally, while many dietary supplements are marketed as "natural products," the use of some of them, both alone and in combination with other products, can result in harmful effects and side effects. Yet, 17.7% of adults use herbal products, and when including vitamins and minerals, 52% of adults are using dietary supplements (Radimer et al., 2004).

Psychologists should not make recommendations to patients about the use of dietary supplements and should not integrate their use into psychological treatment. Yet, it is recommended that psychologists ask all patients about their use of dietary supplements (as well as their use of prescription and over-the-counter medications). While many of these substances may be quite helpful, there are numerous significant health risks associated with their use and misuse. Additionally, when certain herbal supplements are taken along with widely prescribed medications, serious side effects are common. Therefore, it is recommended that psychologists keep informed about the literature on the use of dietary supplements and educate patients about their possible use and attendant risks. All patients currently using, considering using, or who in the psychologist's view may benefit from the use of dietary supplements (as well as prescription and over-the-counter medications) should be referred to their primary care physician to oversee and/or recommend their use to help ensure optimal outcomes are achieved.

Meditation

Meditation is a mind–body practice that has long been integrated into a wide range of religious and spiritual practices. The most widely used and studied forms of meditation at present are mindfulness meditation and concentrative meditation. Mindfulness meditation involves paying attention in a nonjudgmental way in the present moment (Kabat-Zinn, 1994). It has formed the basis of integrative treatments such as mindfulness-based stress reduction (MBSR) and mindfulness-based cognitive therapy (MBCT) and is a component of acceptance and commitment therapy (ACT) and dialectical behavior therapy (DBT). Concentrative meditation involves focusing on a specific word or phrase to alter one's conscious state and to achieve a deep state of relaxation. In the most commonly used and studied form of concentrative meditation, Transcendental Meditation, it "allows the mind to simply, naturally and effortlessly transcend thinking and to experience a deep state of restfully alert consciousness" (e.g., Nagendra, Maruthai, & Kutty, 2012).

With appropriate training and competence, meditation practices may be integrated into the treatment of patients with a wide range of presenting problems. Patients may be referred to various commercially available meditation programs to augment the work they are doing in psychotherapy, meditation practices may be integrated into ongoing psychotherapy, and meditation-based treatments such as MBSR and MBCT may be offered.

Numerous studies have demonstrated the usefulness of meditation practices for the treatment of conditions such as high blood pressure, irritable bowel syndrome, ulcerative colitis, anxiety, depression, insomnia, and acute respiratory illnesses, and initial findings indicate some promise for pain management and for smoking cessation (NCCIH, 2015e). For example, in a randomized controlled study, Barnhofer et al. (2015) demonstrated the effectiveness of mindfulness approaches in reducing depressive and suicidal cognitions. While no significant contraindications or side effects are reported with the use of meditation practices, as with all healthcare interventions, consultation with each patient's primary care physician before recommending or integrating meditation into psychological treatment is recommended.

Chiropractic

Chiropractic is a system of spinal adjustments or manipulations that are performed to realign the spine in a manner that is believed to relieve pain and to promote health and wellness. Chiropractic is most widely used to treat back pain, neck pain, pain in the joints of the arms and legs, and headaches (American Chiropractic Association [ACA], 2015). Chiropractic has a long history dating back to 2700 BCE in ancient China and Greece (ACA, 2015). There exists a range of techniques used by in chiropractic treatment, but their primary aim is to realign the spine to reduce or correct spinal nerve impingement and to improve joint mobility. Chiropractic manipulation may be provided as a stand-alone treatment or in conjunction with conventional healthcare interventions.

Research has been conducted on the use of chiropractic for acute low back pain, chronic low back pain, and headaches with moderate to significant effectiveness being found, depending on the studies reviewed. It has also been studied for the treatment of phobias, ADHD, and nocturnal enuresis, with questionable effectiveness being found (Barnett, Shale, Elkins, & Fisher, 2014).

Chiropractic is a profession that is regulated by state law. Only licensed doctors of chiropractic may offer these treatments in the United States. Thus, if chiropractic care is to be considered for patients, referral to a licensed doctor of chiropractic is essential. But these professionals may use a wide range of techniques, with some offering nutritional counseling and other services, so being clear on their training, areas of competence, and techniques used is essential. Additionally, due to the very forceful physical nature of chiropractic spine manipulations, side effects such as muscular soreness are common (Ernst, 2007).

Aromatherapy

Aromatherapy is the use of essential oils from herbs, flowers, and trees to promote physical, emotional, and spiritual health and wellness. Proponents of aromatherapy believe that the inhalation of various essential oils from plants positively influences "mood, behavior, and spiritual well-being by stimulation of the olfactory or somatic senses" (Barnett et al., 2014, p. 181). While aromatherapy has a long history of use dating back to ancient Egypt, China, and India as parts of whole medical systems such as TCM and Ayurveda, its use and effectiveness have only recently begun to be studied.

Aromatherapy may be used to treat specific symptoms and disorders such as stress, anxiety, insomnia, and pain (Chalifour & Champagne, 2008). It has also been used holistically to promote overall wellness and for esthetic purposes such as to promote relaxation and to create a pleasing and peaceful home environment. Reviews of controlled studies do not yield significant findings for the treatment of any disorders, yet many individuals report that smelling the aroma of a range of plant extracts helps them to feel more relaxed and peaceful.

Aromatherapy should be used with caution as there are serious side effects that may result from applying essential oils in an incorrect manner or with incorrect doses. Additionally, some essential oils are toxic and should be avoided completely. Further, some essential oils are contraindicated with pregnant women and children. Thus, the possible use of aromatherapy should be given careful consideration that includes a review of the relevant literature and appropriate oversight for any aromatherapy use.

Massage Therapy

Massage therapy is a manipulative and body-based practice that involves "pressing, rubbing, and moving muscles and other soft tissues of the body, primarily by using the hands and fingers" (Barnett et al., 2014, p. 210). It is primarily used as a means of reducing stress and promoting relaxation and to reduce muscular tightness and strain. It has also been used in the rehabilitation of sport-related injuries and to improve mood and reduce anxiety and depression as well as to promote overall wellness. Research findings indicate strong support for the use of massage therapy in the treatment of anxiety, depression, and stress, with moderate effectiveness in the treatment of low back pain and neck pain. Massage therapy has also been shown to positively impact immune functioning for individuals with breast cancer, HIV, and leukemia (Field, 2006).

There are numerous massage therapy techniques that are commonly used. Additionally, there are four main forms of massage presently being practiced in the United States. These are Swedish, deep tissue, sports, and trigger point massage. Massage therapy is regulated in the

United States, and referrals for massage therapy should only be to those who are licensed or certified. Care should be taken to ensure that when massage is included in patients' overall treatment, it is done so with appropriate oversight. While few side effects or contraindications are reported in the literature, it is recommended that massage therapy only be used after clearance is received from the patient's primary care physician. Some patients with musculoskeletal difficulties or injuries should not participate in massage therapy.

Yoga

Yoga is a form of CAM with ancient roots that has become increasingly popular in recent years. There are a large number of yoga "schools" with each emphasizing different techniques and goals, with different styles existing within each school. But, overall, yoga involves physical postures, meditation, breathing exercises, and sustained concentration to promote wellness, relaxation, strength, and flexibility. The most widely practiced form of yoga in the United States is Hatha yoga with some of its popular styles including Bikram, Ashtanga, Iyengar, and Kundalini yoga.

Yoga is practiced by more than 13 million adults in the United States; 58% practice it to promote overall health and well-being, 16% to treat specific medical conditions such as low back pain, and 11% to seek relief from musculoskeletal conditions. Yet, only 22% reported that their physician recommended the use of yoga (NCCIH, 2015e). Thus, it is likely that many individuals are seeking out the practice of yoga on their own initiative.

Psychologists may recommend yoga for a wide range of health concerns. Strongest support has been found for yoga's use in the treatment of pain and to promote coping skills, with weak evidence for its use in treating depression, anxiety, and eating disorders. Yet, it is widely used to enhance wellness and quality of life overall, with many individuals reporting significant benefits from its use.

While few risks are associated with the use of yoga, not all forms of yoga are suitable for all individuals. Each patient's needs should be assessed, the different forms of yoga researched, and then an individual decision made. Before engaging in some of the more strenuous forms of yoga, clearance by the patient's physician is recommended.

Progressive Muscle Relaxation

PMR is a widely used CAM modality that is now so widely accepted for use in psychological treatment that it soon may not be considered complementary or alternative. PMR is a technique in which the patient learns to progressively relax different muscle groups throughout the body. Its use may also incorporate guided imagery and deep breathing exercises. Psychologists may easily integrate PMR into ongoing psychological treatment, and its use is quite frequently taught in graduate training for psychologists. No additional licensure or certification is needed to teach patients PMR. Scripts and recordings of PMR instructions are widely available online and may be utilized by psychologists and patients alike.

Research indicates that PMR can be used quite effectively to treat anxiety, muscular tension, and other stress-related symptoms to include tension headaches, neck ache, and back pain. PMR is useful for promoting general relaxation and as a component of the treatment of a wide range of stress-related disorders. PMR may be utilized in conjunction with other forms of CAM such as meditation, yoga, massage therapy, and biofeedback in the treatment of stress-related disorders.

Spirituality, Religion, and Prayer

While many mental health professionals may not consider religion, spirituality, and prayer as relevant to the provision of psychological services, for many individuals who seek out psychological treatment, these are important parts of their lives. In fact, many patients' suffering and distress may be related to religious or spiritual issues or concerns. For others, religion, spirituality, and prayer may be important sources of strength and support that can be tapped into to assist them in treatment.

Spirituality, religion, and prayer are commonly incorporated into the treatment of addictions, trauma, and depression, but they may be utilized in a wide range of treatments to assist patients to achieve their goals. They may also be useful for helping patients find meaning in their suffering, for enhancing coping ability and resilience, and to promote general well-being. Research support is found for the use of prayer as a coping mechanism for patients with cancer or other terminal illnesses, to treat pain, and for stress reduction (Barnett et al., 2014).

Psychologists should be cautious about imposing personal religious beliefs on patients or not valuing and respecting patients' beliefs and preferences. Further, for those psychologists who will integrate prayer and other religious or spiritual interventions into psychological treatment, care must be exercised not to take on the role of the clergy. When concerns exist, consultation with, and referrals to, members of the clergy are recommended.

Dance Movement Therapy

DMT is a mind–body practice that incorporates dance and movement and that views motion and emotion interconnected, using expressive movement to assist patients to address unresolved emotional conflicts. The dance movement therapist analyzes the patient's movements to better understand the patient's underlying emotional drives and conflicts and, with this deeper understanding, assists the patient to work through and resolve them.

DMT has been used to treat anxiety, distorted body image, depression, and fatigue and to promote psychological adjustment and quality of life. Well-designed studies are uncommon in the literature, and support for DMT is predominantly anecdotal (Barnett et al., 2014). Available research on the effectiveness of DMT indicates some support for its use in the treatment of the abovementioned issues, but due to methodological issues, caution should be exercised in recommending its use.

Acupuncture

Acupuncture is a component of TCM that has been in use for thousands of years. In TCM it is believed that each individual's life energy, or qi (pronounced *chi*), flows through 16 pathways throughout the body called *meridians*. Acupuncturists place needles in combinations of some of the 360 specific *acupoints* along these meridians and stimulate them either by manually manipulating the needles or with electrical stimulation, with the goal of rebalancing the life energy and thus ameliorating the symptoms being experienced (DCIM, 2006).

In recent years acupuncture has been studied extensively with well-designed studies and has been found to be moderately effective for the treatment of chronic low back pain, cancer-related pain, anxiety, migraines and headaches, and insomnia. While it has also been used for the treatment of depression and schizophrenia, support for these uses is quite limited (Barnett et al., 2014). While some may question traditional beliefs about acupuncture's underlying mechanisms, recent research provides support for the stimulation of nerve endings that result in changes in the brain's pain centers (White & Ernst, 2004).

Acupuncture is found to generally to be safe with minimal side effects when provided by a trained and competent practitioner, and it has fewer side effects than many conventional treatments for chronic low back pain (Thomas et al., 2005). Acupuncture should only be provided by a trained and credentialed acupuncture professional. In many states licensure and/or certification is required to provide acupuncture, and each practitioner's credentials should be assessed before making referrals.

Reiki

Reiki is a form of energy therapy in which the practitioner transfers energy, or life force, into the patient by placing her or his hands slightly above or lightly on the patient's body. By passing this energy to the patient at a series of known hand positions, it is believed that this energy transfer promotes healing in the participant by allowing her or his own life force to flow more freely (Barnett et al., 2014). While limited research has been conducted on the use and effectiveness of reiki, evidence exists that demonstrates some benefit in the treatment of depression and anxiety and for relieving stress and promoting general wellness. It has also been shown to reduce pain, fatigue, and insomnia in cancer patients.

No known side effects or risks are associated with the use of reiki, but due to the limited research support for it at present, caution should be taken when recommending it, and reiki should only be used as a complementary treatment and not a replacement for well-researched treatments. Reiki practitioners must be certified, yet at present there are numerous certification agencies with no single standard for training and for demonstrating competence. Thus, the competence of reiki practitioners should be carefully assessed when considering making referrals.

Biofeedback

Biofeedback is another CAM modality that has been extensively studied and that has been widely integrated into psychological practice. As such, many practitioners are now considering biofeedback to be a component of conventional psychological practice. Biofeedback involves utilizing one of several possible monitoring devices to provide feedback to the patient on underlying physiologic processes such as respiration, heart rate, muscle tension, skin temperature, and brain wave activity. By use of the ongoing feedback, patients learn to impact and control these underlying physiologic processes to reduce or ameliorate symptoms associated with them.

Extensive research has demonstrated biofeedback's effectiveness in treating tension headaches, migraines, Raynaud's disease, anxiety, and ADHD. Some support is also found for its use in treating fibromyalgia, phantom limb pain, and depression (Barnett et al., 2014). There are no known side effects of biofeedback, and its practitioners provide it within the scope of their professional license when appropriately trained. Optional board certification is available through the Biofeedback Certification International Alliance (see www.bcia.org) that also maintains a list of board certified professionals for use when making referrals. Biofeedback is widely used and regularly integrated into treatment provided by appropriately trained psychologists.

Hypnosis

Hypnosis is a mind–body therapy that also has been extensively studied and widely integrated into conventional healthcare by appropriately trained practitioners. Hypnosis, also known as hypnotherapy, involves a hypnotic induction that places the patient into an altered stated of consciousness during which the patient is receptive to suggestions that assist the patient to achieve desired goals and symptom reduction. While some individuals are more hypnotizable than others, most individuals are able to benefit from its use. Hypnosis has been utilized as a stand-alone treatment as well as integrated with other healthcare practices. There is strong research support for the use of hypnosis to treat acute and chronic pain and as an analgesic during medical and surgical procedures. It has also been shown effective in the treatment of irritable bowel syndrome and in the reduction of the side effects of chemotherapy. While it has been used for smoking cessation and other types of habit control, the evidence for these uses is more limited (Barnett et al., 2014).

When offered by competent professionals, side effects from the use of hypnosis are quite rare. Most professionals who utilize hypnosis do so within the scope of their licenses as health professionals. Yet, board certification is available through the American Society of Clinical Hypnosis (www.asch.net), and this should be considered when making referrals. Appropriately trained psychologists may easily integrate the appropriate use of hypnosis into their patients' treatment.

Music Therapy

Music therapy involves the use of music appreciation, creation, and performance for emotional expression. As a mind–body intervention, music therapy may assist patients to explore and express their thoughts and feelings through music, with the goal of this process being improved health.

Music therapy has been used in the treatment of depression, anxiety, chronic pain, PTSD, chemotherapy side effects, dementia, and schizophrenia. While mixed results have been seen thus far, music therapy does appear to be at least somewhat helpful in the treatment of depression and anxiety, and for promoting general relaxation in response to various stressors. Thus, it may be a useful when integrated with other treatments. Music therapy practitioners should be certified by the American Music Therapy Association (www.musictherapy.org).

Conclusion

A wide range of CAM modalities exist that have received strong scientific support for the treatment of a wide range of conditions and disorders either alone or in conjunction with other treatments. Yet, not all CAM modalities are helpful to all patients, and some modalities may prove harmful if not applied appropriately. One must possess the education and training necessary to be knowledgeable about CAM to make the best possible treatment decisions for patients. Some CAM modalities may effectively be integrated into conventional treatments by psychologists, and for others, referrals to competent and appropriately credentialed CAM practitioners should be made. With so many individuals utilizing CAM on their own and with so many patients open to, or even requesting, the use of CAM in their psychological treatment, it is important that psychologists educate themselves about the use, benefits, limitations, and contraindications of CAM in psychological practice.

Author Biography

Jeffrey E. Barnett, PsyD, ABPP, is a licensed psychologist as well as associate dean and professor of psychology at Loyola University Maryland. He is board certified by the American Board of Professional Psychology in clinical psychology and in Clinical Child and Adolescent Psychology, and he is a distinguished practitioner in psychology of the National Academies of Practice.

From Mesmer's early ventures in using suggestion to alleviate physical and psychological distress in the eighteenth century to the use of hypnosis to facilitate surgery prior to effective anesthetics, and extending to the present, hypnosis has played an increasingly prominent role in treating medical conditions and in ameliorating pain and suffering (e.g., Flammer & Bongartz, 2003). As hypnosis has moved into the mainstream of psychological science and clinical practice, there is increasing recognition that hypnosis can be used as a stand-alone intervention and, more commonly, as an adjunct intervention in the field of health psychology. This review will feature qualitative reviews, meta-analyses, and randomized controlled trials (RCTs) that have documented the promise of hypnosis in treating many health-related conditions, ranging from acute and chronic pain and obesity to irritable bowel syndrome.

Applications of hypnosis to the field of health psychology have been spurred by research that has debunked many popular myths about hypnosis and has, instead, documented that hypnosis is not a special trance or sleep-like state in which participants respond in robot-like fashion to suggestions delivered by a powerful hypnotist, lose awareness of their surroundings, and spontaneously forget what transpired during hypnosis. Rather, participants who experience hypnotic suggestions retain their ability to resist or oppose suggestions; are aware of what occurs before, during, and after hypnosis; and achieve therapeutic gains not because of a trance but because merely defining the context as hypnosis can catalyze motivation to experience suggestions fully and bolster positive treatment expectances relevant to successful clinical outcomes.

An Introduction to Clinical Hypnosis

Hypnosis—defined as any set of suggestions that are either administered to participants in a context that is presented as "hypnosis" or participants understand to be "hypnosis"—provides

The Wiley Encyclopedia of Health Psychology: Volume 3: Clinical Health Psychology and Behavioral Medicine,
First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

health psychologists with tremendous leverage in crafting suggestions that are individually tailored or can be administered in manualized interventions. Hypnosis traditionally involves a so-called induction that can be virtually any array of verbal (e.g., suggestions for relaxation) and nonverbal communications (e.g., suggestions delivered in a calm, soothing manner) presented by the person in the role of the hypnotist that define or establish the proceedings as "hypnosis." Inductions can range from highly ritualized methods (e.g., the proverbial "swinging watch" popularized in the media) to more naturalistic conversations to experience an increasingly deep hypnotic state. Hypnotic inductions typically contain imaginative suggestions for relaxation, focusing on suggested events, and deepening experiential involvement in suggestions. The attention individuals receive from the hypnotist, accompanied by the soothing, calming way hypnotists often converse with participants, can promote a close therapeutic alliance, bolster motivation to respond, and diminish anxiety. After the induction, suggestions often hone in on the participant's problem or condition and can be tailored to address specific patient needs.

Given the prevalent views that hypnosis can produce positive outcomes, the very idea of undergoing hypnosis can engender positive expectancies for treatment gains. The context of hypnosis lends itself well to adaptation to a health psychology setting because participants can detach themselves from everyday concerns and attend to therapeutic suggestions and helpers can talk to patients in deeply personal ways and exhort participants to modify deeply ingrained cognitive behavioral patterns and to comply with medical recommendations and treatment regimens.

The experience of hypnosis depends much more on the motivation and willingness of participants to think and imagine along with suggestions, and the nature of the suggestions themselves, rather than on any special skills of the hypnotist. Accordingly, hypnosis can justifiably be presented to individuals as self-hypnosis, and participants can learn to "self-administer" suggestions apart from the hypnotist, which can increase the "portability" of hypnosis and generalize treatment gains to everyday life. Additionally, so-called posthypnotic suggestions for comfort and pain relief, for example, can extend the benefits of hypnosis well beyond the consulting room. Such suggestions may be reinforced with tapes or DVDs that contain therapeutic suggestions that the patient can use to revivify and reinstate key points and elements of the hypnotic proceedings.

Hypnotic Suggestibility

In many health-related interventions, hypnotic suggestibility does not play a prominent role. Although about 15% of people are low or non-suggestible and pass no or few suggestions, and a comparable percentage of people are highly suggestible and pass most suggestions, the majority of individuals (approximately 70%) can respond to a variety of suggestions. Many of the suggestions (e.g., relaxation, focused attention) delivered in the context of medical interventions do not require a high level of suggestibility. Even people who score relatively low on standardized scales of hypnotic suggestibility can benefit from hypnotic suggestions. In the case of hypnotic treatment of clinical pain, for example, there is only a weak association of hypnotic suggestibility and pain relief.

Although a formal hypnotic induction increases suggestibility by approximately 10–20%, compared with identical waking suggestions administered in a nonhypnotic context, the addition of hypnosis can provide incremental benefits beyond nonhypnotic interventions. Kirsch, Montgomery, and Sapirstein's (1995) meta-analysis documented the ability of hypnosis to enhance treatment gains of psychotherapeutic approaches that span psychodynamic and cognitive behavioral psychotherapies. Another meta-analysis provided preliminary evidence for the use of hypnosis in treating numerous psychosomatic disorders (e.g., conversion disorder, gastrointestinal problems, enuresis, asthma; Flammer & Alladin, 2007).

Applications of Hypnosis in Health Psychology

Pain Relief

Hypnosis exerts its effects largely via altering subjective experience and therefore impacts perceptions of pain. The effects of hypnotic analgesia are reflected in brain and spinal cord functioning and vary as a function of the suggestions administered (Jensen & Patterson, 2014). In addition to suggestions for relaxing and imagining a "favorite place" of comfort, calmness, and soothing, for example, suggestions for easing pain can involve reinterpreting pain sensations (e.g., as pressure), distraction (e.g., watching absorbing scenes on a mental television or movie or reliving positive past events), and transforming sensations and perceptions (e.g., imagining pain as a color and suggesting the patient transform the color).

Meta-analyses (Montgomery, DuHamel, & Redd, 2000) have found that (a) hypnosis produces moderate-to-large effects in relieving both clinical pain (e.g., coronary disease, cancer, headache, burns) and experimental pain (e.g., pressure, ischemic pain, cold pressure) and that hypnosis produced salutary effects for 75% of the population and (b) hypnosis is associated with greater pain reductions and better recovery outcomes in adults undergoing surgical or medical procedures compared with standard care alone and attention control interventions (Tefikow et al., 2013). Montgomery, David, Winkel, Silverstein, and Bovbjerg (2002) documented that surgical patients undergoing hypnosis treatment experienced better clinical outcomes (e.g., reduced emotional distress, pain medication, recovery time) than 89% of patients in comparison groups. Moreover, hypnosis has proved useful in reducing pain associated with needle procedures (Birnie et al., 2014) and in treating fibromyalgia, compared with control interventions (e.g., relaxation, pharmacological treatment, usual care, wait list; Bernardy, Klose, Busch, Choy, & Häuser, 2012). In a RCT of a 15-min hypnosis intervention administered preoperatively to women undergoing excisional breast biopsy or lumpectomy, hypnosis was superior to attention control, as reflected in decreased medication use; reports of pain, nausea, fatigue and discomfort; emotional upset at discharge time in surgery; and institutional cost savings ($772.71, on average, per patient). Importantly, hypnosis appears to reduce anxiety associated with medical conditions, as a meta-analysis has revealed in cancer patients (Chen, Liu, & Chen, 2017).

Qualitative reviews (e.g., see Elkins, 2016; Elkins, Jensen, & Patterson, 2007; Jensen & Patterson, 2014) confirm that hypnosis (a) is associated with decreases in chronic pain conditions (e.g., arthritis, sickle cell disease, cancer, low back pain, headaches) and (b) produces salutary effects in reducing nausea and vomiting associated with cancer and (c) that hypnosis is generally more efficacious in reducing chronic pain compared with attention control, physical therapy, and psychoeducation. Moreover, hypnosis can be combined with virtual reality to relieve pain across the age spectrum and that hypnosis outperforms attention placebo in reducing pain in burn wound debridement (see Elkins, 2016). Hypnosis for pain control and modulation is the best established of all applications of hypnosis in the field of behavioral health psychology.

Irritable Bowel Syndrome (IBS)

Meta-analyses, RCTs, and narrative reviews document the promise of hypnosis in treating IBS, even among medically treated refractory patients, and that the benefits of hypnosis are not limited to short-term success. Gonsalkorale, Miller, Afzal, and Whorwell (2003) followed over 200 patients consecutively treated with hypnosis for IBS and reported that 71% of patients responded positively to treatment and that over 80% of these patients maintained their treatment gains over 5 years. Nevertheless, a Cochrane Review (Webb, Kukuruzovic, Catto-Smith, & Sawyer, 2007) tempered these positive conclusions in indicating that the evidence base, while promising, requires additional rigorous studies to permit more definitive conclusions regarding the effectiveness of hypnosis in treating IBS.

Obesity and Weight Loss

Hypnosis produces weight loss when combined with cognitive behavioral interventions. Milling, Gover, and Moriarity (2018) reported two meta-analyses, which revealed that hypnosis is a highly promising treatment for obesity, especially when incorporated into cognitive behavioral therapy for weight loss. The average participant reported greater weight reductions than about 94% of participants in control conditions at the conclusion of treatment and 81% of control participants at follow-up. The average individual who received CBT combined with hypnosis lost more weight than 60% of participants that received CBT alone at the end of treatment and 79% of individuals that received only CBT at follow-up. The reviewers suggested that studies of long-term effects of hypnosis on weight loss are needed, on the order of 1–5 years, to determine the persistence of treatment effects over more lengthy time intervals.

Smoking Cessation

Hypnosis shows promise in treating smoking. Meta-analyses indicate that hypnotic interventions are associated with quit rates on average of 31% for men and 23% for women (Green, Lynn, & Montgomery, 2008). Nevertheless, a 2010 Cochrane Review (Barnes et al., 2010) reported considerable heterogeneity of findings and that the claims regarding hypnosis for smoking cessation based on case studies extended beyond evidence secured from relatively few RCTs reported in the literature. Clearly, more RCTs that include biochemical measures to verify self-reports of smoking cessation are warranted.

Other Applications

More preliminary yet promising findings indicate that hypnosis can be effective in treating a variety of other medical conditions, such as skin disorders, asthma, insomnia, hot flashes, and hypertension, and be useful in palliative care and in assisting women in labor, as summarized in Elkins (2016). Hypnosis awaits further evaluation before more confident conclusions can be drawn.

Conclusions

The evidence for hypnosis for treating pain-related and medical conditions is promising, although findings across studies are mixed. Additionally, firm conclusions are limited by the lack of adequate follow-up periods and assessments and the difficulty of disentangling hypnosis-specific effects from nonspecific treatment variables, including placebo/expectancy effects, a positive therapeutic alliance, and participating in a symptom-relief endeavor. It is important to distinguish the effects of "hypnosis" from adjunctive cognitive behavioral strategies and to control for placebo/expectancy effects, naturally occurring changes in symptoms, and relaxation and visualization. Further, the effects of hypnosis remain to be disambiguated from the effects of suggestion alone. Additionally, as the response to hypnosis is variable, researchers would do well to evaluate hypnotic suggestibility and to also ensure that studies use naïve raters of treatment effects and that participants are adequately randomized to conditions in research with samples adequate to discern clinically meaningful treatment outcomes. Finally, the mechanisms by which suggestion exerts salutary effects have yet to be well established.

In conclusion, hypnosis is a brief, cost-effective, and popular intervention that can be easily learned to administer by a medical or mental health professional. A steadily accumulating literature, marked by studies of increasing rigor and sophistication, indicates that hypnosis can be employed as a vehicle to administer "direct suggestions" in the context of pain or as an adjunctive intervention to augment the effects of cognitive behavioral and other interventions for diverse medical conditions. Again, the positive effects of hypnosis in a health or medical setting are neither the product of a trance nor unique to hypnosis, but are associated with variables that likely mediate the effectiveness of many nonhypnotic interventions, including positive treatment-relevant expectations, attitudes, and beliefs; a viable therapeutic alliance; goal-directed motivation; and suggestions that target processes (e.g., relaxation for stress management) that are directly or secondarily related to medical symptoms and conditions.

Author Biographies

Steven Jay Lynn is Distinguished Professor of Psychology (SUNY) at Binghamton University. He received his bachelor's degree in psychology from the University of Michigan and his PhD in psychology (clinical) from Indiana University. He is the editor of *Psychology of Consciousness: Theory, Research, and Practice*, and he is on the editorial board of 10 other journals, including the *Journal of Abnormal Psychology*. Dr. Lynn has authored or edited 25 books, and he has published more than 360 articles and chapters on the topics of hypnosis, dissociation, trauma, fantasy, psychotherapy, and scientific thinking in psychology. He is the recipient of the Chancellor's Award from the State University of New York and numerous awards bestowed by the American Psychological Association and other professional societies. His research has been supported by the National Institute of Mental Health and has garnered substantial media attention.

Craig P. Polizzi is a clinical psychology doctoral student at Binghamton University. He has collaborated on randomized controlled trials investigating integrative and complementary interventions for veterans with posttraumatic stress disorder (PTSD). He has also participated in trials examining educational interventions promoting self-regulation in children. His current research focuses on clarifying the relations among acceptance, mindfulness, emotion regulation, and resilience and on elucidating how each functions as a self-regulation strategy. Recently, he has served as principal investigator on a longitudinal study examining novel ways to facilitate the salutary effects of mindfulness meditation.

Joseph P. Green is a professor of psychology at The Ohio State University and works at one of OSUs regional campuses in Lima, Ohio. He has published 70 journal articles and book chapters primarily in the area of hypnosis, imagination, and suggestion-based approaches to psychotherapy. He has authored or edited two volumes on applying clinical hypnosis for health care and tobacco addiction. Dr. Green served two terms as president of the American Psychological Association, Division 30 (Society of Psychological Hypnosis). His work has been recognized with numerous awards, including *Early Career, Distinguished Contributions to Scientific Hypnosis* and *Distinguished Contributions to Professional Hypnosis* (APA D30), *Clark Hull Award for Scientific Excellence in Writing on Experimental Hypnosis* (American Journal of Clinical Hypnosis), *Arthur Shapiro Best Book Award* (Society for Clinical and Experimental Hypnosis), and the *Distinguished Teaching Award* (OSU Alumni Association.

Damla E. Aksen is a clinical psychology doctoral student at Binghamton University. She has worked in interdisciplinary psychology laboratories that studied perception, development, and evolutionary perspectives. She is interested in studying impulsivity, mindfulness, and emotion dysregulation.

Ashwin Gautam is a clinical psychology doctoral candidate at Binghamton University. He has coordinated studies investigating the effect of mindfulness inductions on experimental fear conditioning, inhibition, and extinction. He is currently serving as a principal investigator on a study exploring the association between mindfulness and procrastination. His current research interests involve the application of acceptance and mindfulness-based therapies for treatment of posttraumatic stress and anxiety related disorders.

James Evans is a clinical psychology doctoral candidate at Binghamton University, where he is a research associate in the Laboratory of Consciousness and Cognition. His primary research interests are in mindfulness and states of consciousness, including those reported in hypnosis, mystical, and other unusual experiences. His clinical interests are in disorders of personality and emotion regulation.

Motivational Interviewing

Thad R. Leffingwell

Department of Psychology, Oklahoma State University, Stillwater, OK, USA

MI's technical and theoretical roots trace to the client-centered counseling strategies popularized by Carl Rogers and classic social psychological theories of cognitive consistency (Festinger, 1962) and psychological reactance (Brehm, 1966). The first clinical application of the method that would come to be known as MI appeared in the research literature in 1988 in the form of the *Drinker's Check-up*, which utilized nonjudgmental client-centered listening skills while reviewing assessment feedback (Miller, Sovereign, & Krege, 1988). William Miller continued to develop the method, and, after developing a collaborative partnership with Stephen Rollnick, the first book fully describing the MI approach was published in 1991 (Miller & Rollnick, 1991).

For the first few decades of the development, investigation, and dissemination of MI, applications of the method were focused almost exclusively upon intervening with misuse of and addiction to psychoactive substances, including alcoholism and drug addiction. Indeed, the subtitle of the first book was *Preparing People to Change Addictive Behaviors* (Miller & Rollnick, 1991). MI targets ambivalence in the behavior change process, which often manifests as resistance to change and is common among people struggling with addictions. After the initial empirical success and accelerating dissemination of MI among substance use professionals, others began applying and investigating MI in other contexts with other target behaviors and populations including primary healthcare (Rollnick, Miller, & Butler, 2008), health promotion (Resnicow & Rollnick, 2011), and mental health (Arkowitz & Westra, 2004), with both adults and adolescents (Cushing, Jensen, Miller, & Leffingwell, 2014; Jensen et al., 2011). The growing recognition of the wider applicability of the MI approach was reflected in the second book, subtitled *Preparing People for Change* (Miller & Rollnick, 2002). Today MI is recognized as a broadly useful tool for helping me make a broad range of behavior changes, especially when ambivalence or resistance to change is present.

The Wiley Encyclopedia of Health Psychology: Volume 3: Clinical Health Psychology and Behavioral Medicine,
First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

The Problem of Resistance to Change

It is a well-known problem that habits are difficult to change even when the status quo is maladaptive or unhealthy and that people often resist professional attempts to assist with change. According to the transtheoretical model, people may be in the pre-action stages of precontemplation (not even thinking about change) or contemplation (acknowledging need or desire to change, but not now or soon) for months or years (Prochaska, DiClemente, & Norcross, 1992). The contemplation stage is characterized by ambivalence about change—a part of the person sees the need or wants the change, but another part prefers and defends the status quo. The preference for the status quo can be driven by many factors including, for example, lacking confidence about the likely success of change attempts, valuing other priorities more highly right now, or favoring immediate benefits more than long-term payoffs that are subject to delay or probability discounting (Bickel, Johnson, Koffarnus, MacKillop, & Murphy, 2014). From the MI perspective, these individuals are viewed as *stuck* in ambivalence, and the goal of the MI conversation is to help patients get *unstuck* and move toward attempting and sustaining necessary behavior changes.

Patient Language About Change

In conversations about a behavior change, patient language basically takes one of two forms—*change talk* or *sustain talk* (referred to as "*resistance*" in earlier versions of MI). Change talk is defined as any expressions that favor or encourage change, including concerns about the status quo, fears about the future if the behavior does not change, ideas about how change might be accomplished, or intentions to change. Sustain talk, on the other hand, is defined as any expressions from the patient that argue for or defend the status quo, including descriptions of advantages or benefits of the status quo, denigration or barriers to change, or hopelessness about change.

The MI approach takes several important positions about patient language in conversations about behavior change. First, the MI model posits that the patient's language is much more influential on subsequent behavior than the provider's language. As a result, MI de-emphasizes motivational strategies that are more provider centered such as education, warning of dangers, direct persuasion, or professional advice. Second, the MI model suggests patients are better persuaded by their own language and that the more they hear themselves expressing *change talk* in the conversation (and, as a result, less *sustain talk*), the more subsequent attempts at change are to occur. Miller and Rose (2009) proposed a *theory of MI* that proposes that when *change talk* grows and *sustain talk* falls away during an MI conversation, the patient is more likely to experience and/or express a sense of commitment to change that is supported by a sense of intrinsic motivation, and it is this inner psychological experience that sets the stage for subsequent behavior change. As a result, the primary goal during an MI conversation is to increase the frequency and/or intensity of *change talk* and decrease the frequency and/or intensity of *sustain talk* as a way of building intrinsic motivation and evoking commitment to change.

Style and Spirit of MI

MI has been described as have both a "*style and spirit*" as well as a set of proscribed conversational strategies and recommended techniques. The style and spirit can be thought of as the attitude, worldview, or stance of the MI provider. Rather than being about what the

MI provider is to "do," the MI style and spirit is about how the MI provider should "be" during the conversation. The style and spirit have been described as the music or melody of MI, giving it pace and feeling, when used with the "lyrics" of the skills and strategies.

In the original formulations of MI (Miller & Rollnick, 1991, 2002), the spirit of MI was described as consisting of three main characteristics. First, MI should have a spirit of *collaboration*. The interaction between provider and patient should have a sharing of power, as opposed to a "one up, one down" character. The provider is to avoid taking on a role as expert or authority and instead try to develop a sense of equal partnership in exploring the topic of behavior change. Second, MI should be *evocative*. In MI, the most valued words in the conversation at the patient's own. If change is to happen, it is mostly likely to be as a result of the patient being persuaded by his or her own words, rather than succumbing to the arguments or persuasion of the provider. For this reason, it is important for the MI provider to act in ways that encourage and evoke the patient's side of the conversation. Finally, MI should be *autonomy supportive*. Ideally, in an MI conversation, the patient would experience an expansion of their sense of personal choice and autonomy, rather than experiencing attempts to control or limit choices (e.g., "you must…"). This aspect of MI reduces the influence of psychological reactance and improves the chances that the patient may overcome ambivalence and reactance and choose to make necessary changes.

The latest description of the MI technique (Miller & Rollnick, 2013) expanded a bit upon these basic aspects of the spirit of MI. The aspects of collaborative partnership and evocation remain, but autonomy support has been subsumed under a broader concept of *acceptance*. Autonomy support is viewed as one facet of acceptance, but the concept also includes a fundamental belief in the *absolute worth* of the individual, accurate *empathy*, and *affirmation*, or actively seeking out and elevate an individual's strengths. Finally, the third edition also adds *compassion* as an important aspect of the essential spirit of MI. *Compassion* refers to the intentional application of MI in the service of what is best for the patient, not the provider.

Skills and Strategies of MI

MI also includes a number of proscribed or recommended strategies for the competent practice of MI. These strategies represent the "microskills" by which the spirit of MI is translated into practice and are in service of enacting the spirit. The skills can be reliably coded, and more consistent use of the strategies in the context of MI conversations has been found to lead to more favorable outcomes (Magill et al., 2014; Moyers, Martin, Manuel, Hendrickson, & Miller, 2005).

The most fundamental skills of the MI conversation involve the strategic use of active listening skills. In MI, the provider is expected to utilize evocative strategies such as open-ended questions, accurate reflections, and frequent summaries. MI de-emphasizes the value of provider-centered language of advice, education, or persuasion. The goal of the MI provider is to strategically and intentionally apply the skills of active listening to evoke and grow *change talk* and quiet *sustain talk* from the patient.

One highly effective MI strategy is the use scaled questions, or what are sometimes referred to as *readiness rulers* (Rollnick et al., 2008). MI providers may wish to assess readiness to change, confidence in change, or the important of change using a 0–10 scale. For example, "How ready would you estimate you are to quit smoking today, from zero to ten, with zero being 'no interest at all' and ten being 'totally committed?'" The answers provided to such questions provide a very useful and quick assessment of the constructs of interest, but they are especially valuable if follow-up questions are asked. For example, if patient were to respond to the example question with “four,” a useful follow-up question might be something like “Why did you choose four, and not zero?” The answers to that question would almost certainly take the form of change talk. This strategy reliably evokes valuable change talk into the conversation. Scaled questions are often recommended in brief and specialized adaptations of MI like the “5 A’s” and Screening, Brief Intervention, and Referral to Treatment (SBIRT) models, discussed below.

Two other broad MI strategies are essential to the competent practice of MI—*rolling with resistance* and *developing discrepancies.* Argumentation and confrontation in response to patient resistance are seen as counterproductive, largely because they tend to *increase* frequency and intensity of *sustain talk.* Rolling with resistance is an alternative strategy for responding that is intended to quiet *sustain talk* or, ideally, evoke the “other side of the coin” of *change talk.* MI includes many specific strategies rolling with resistance including the use of reflective listening strategies but also reframing or emphasizing choice and autonomy, among others.

Developing discrepancy is based upon theories of cognitive consistency and dissonance that posit that people strive for consistency between attitudes and actions (Festinger, 1962). When individuals are confronted with inconsistency, they experience a sense of dissonance that is uncomfortable, and they are thus motivated to act in such a way to reduce the discrepancy. When one’s behavior is experienced as inconsistent with an attitude or belief that is highly valued, that individual may be expected to change their behavior to better fit, or “square,” with the attitude or belief. For this reason, the MI practitioner is constantly listening for ways that the status quo may be inconsistent with a value, goal, or aspect of self-image of the patient. If such discrepancies are found and made salient, they may help move the patient in the direction of change. For example, an MI provider working with a smoker may at some point in the conversation say something to the patient like “you strike me as the kind of person who really values your independence, but at the same time you find yourself quite dependent on those cigarettes. In a sense, you don’t choose them – they choose you.”

Four Processes

In the latest iteration of MI (Miller & Rollnick, 2013), a new concept was introduced of the *four processes* of MI. The four processes essentially define the beginning, middle, and end of an MI encounter, though they do not necessarily always proceed in a linear fashion. The four processes are *engaging*, *focusing*, *evoking*, and *planning*. Engaging is the first step into an MI conversation and involves establishing a rapport and relationship as a foundation for proceeding. Focusing is a process of narrowing the agenda for the conversation onto one, or a few, important target behaviors for the conversation. Evoking is the process that most providers may recognize as the “meat” of the MI conversation. It involves an intentional conversation about the target behavior, with a focus of evoking and growing change talk and minimizing resistance. The final process of planning involves the transition from *whether* change should or will occur (the primary focus of MI) into *how* a change may occur. This process might involve plans to simply revisit the issue if now is not the right time to change, or might involve a detailed plan for change including the use of professional assistance.

Evidence Base for Motivational Interviewing

MI has emerged and developed in the age of evidence-based practice. As a result, MI has been rigorously studied from its very outset, and today there have been hundreds of randomized clinical trials and several meta-analyses evaluating the efficacy of MI for a broad range of outcomes and populations. In general, the data overwhelmingly support the conclusion that MI does have a reliable effect on a broad range of target behaviors including alcohol misuse (Burke, Arkowitz, & Menchola, 2003), tobacco dependence (Heckman, Egleston, & Hoffmann, 2010), obesity (Armstrong et al., 2011), and gambling (Yakovenko, Quigley, Hemmelgarn, Hodgins, & Ronksley, 2015) and as an adjunct for treatment of psychological disorders (Arkowitz, Miller, & Rollnick, 2015), among both adults and adolescents (Cushing et al., 2014; Jensen et al., 2011). The effect sizes for MI interventions are typically small to moderate, but that may not be surprising given that the durations of the interventions studied are often quite brief, typically ranging from only a few minutes to two brief sessions. As a result, the cost-effectiveness of MI interventions is quite strong.

Training in MI

MI is a complicated clinical intervention approach for which training is necessary. The available evidence suggests that a broad array of health professionals, including both medical providers and social service providers, can be trained to effectively implement MI competently (Madson, Loignon, & Lane, 2009). However, in order for improvements toward the competent practice of MI to be maintained, a single training or workshop is unlikely to be sufficient. Sustained competent practice of MI typically requires intensive training with performance feedback followed by several months of ongoing coaching and supervision (Schwalbe, Oh, & Zweben, 2014).

Applications and Adaptations of Motivational Interviewing

MI proper is a principle-driven approach that relies upon the expertise of the provider to identify appropriate targets for MI and to weave MI interventions together with other strategies that suit the needs of the particular client or problem at the moment. However, due to the demands of clinical trials to have replicable interventions and the demands of real-world settings to have more easily disseminable models for specific target behaviors (e.g., tobacco use) or settings (e.g., hospital emergency rooms), there have been a number of efforts to develop specific MI-based treatment and intervention models.

One example of an MI-based treatment is motivational enhancement therapy (MET), a treatment designed and tested initially as part of Project MATCH, a large multisite clinical trial of interventions for alcohol abuse and dependence (Miller, Zweben, DiClemente, & Rychtarik, 1992). MET was a brief intervention consisting of four treatment sessions and utilized the basic principles of MI at the time. Like the original Drinker's Check-up (Miller et al., 1988) and many early trials of MI, the MI conversation occurred in the context of reviewing the results of a comprehensive clinical assessment, especially in the first two sessions. In the last two sessions, spaced weeks apart, the therapist would use MI principles to encourage motivation and progress.

Other adaptations of MI have attempted to create simplified, targeted intervention models that could be more easily disseminated to a variety of providers. For example, the Surgeon General's influential document *treating tobacco dependence* promoted a "5 A's" model of brief intervention designed to be implemented by a variety of healthcare providers at every encounter with patients who use tobacco (Tobacco Use and Dependence Guideline Panel, 2008).

The five A's are as follows: (a) assess every patient for tobacco use and for those who are current users proceed to (b) advise quitting with brief, personalized advice; (c) assess for readiness to make a quit attempt and motivate those who are not currently ready; (d) assist with a quit attempt by offering guidance, prescriptions, or referrals; and (e) arrange for follow-up at subsequent visits. The recommendations for assessing readiness and motivated unmotivated patients essentially describe the practice of MI. A similar brief intervention model that incorporates MI is SBIRT (Babor et al., 2007). SBIRT is a model for brief intervention designed initially for use in busy hospital emergency departments to address patients for who alcohol or drug misuse may have contributed to their illness or injury. The brief intervention component of SBIRT is essentially MI.

Conclusions

MI is a broadly applicable and essential evidence-based approach to working with patients to overcome resistance and move toward healthy behavior changes. The approach can be learned and applied by many different types of providers and is applicable to many clinical problems and populations.

Author Biography

Thad R. Leffingwell is a clinical health psychologist and is currently a professor and head of the Department of Psychology in the College of Arts and Sciences at Oklahoma State University. His research has explored how people change health risk behaviors and how providers can interact with patients to encourage behavior change more effectively. He is a member of the Motivational Interviewing Network of Trainers and has providing training in MI to thousands of providers over the last 20 years.

Rehabilitation psychologists "enhance the lives of people with disabilities and chronic illness" (American Psychological Association Division 22 Rehabilitation Psychology and the Rehabilitation Psychology Synarchy, 2015, p. 6) as noted in the petition for recognition of rehabilitation psychology as a specialty approved by the American Psychological Association's (APA) Council of Representatives in August 2015 (e.g., Dunn & Elliott, 2008). Rehabilitation psychologists recognize the wounds and resilience of the people with whom they work. Since World War II, rehabilitation psychologists have partnered with physicians treating patients with a variety of injuries and/or chronic illness, including amputations, spinal cord injuries, and head injuries (Cox, Hess, Hibbard, Layman, & Stewart, 2010). As the field of rehabilitation psychology matured, the specialty expanded to include working with children with disabilities and their families related to the establishment of the National Society of Crippled Children and Adults, working with government vocational rehabilitation organizations funded by state-federal partnerships, and, more recently, advocating for people with disabilities through the passage of the Americans with Disabilities Act (ADA) in 1990.

Rehabilitation psychologists may specialize in working with particular medical diagnoses, such as head injury, stroke, spinal cord injury, amputation, or other neurological illness/injury, or they may work with a more broadly varied group of patients whom they encounter in inpatient or outpatient settings, similar to health psychologists. For example, rehabilitation psychologists may work with people who have become debilitated due to treatments for metastatic cancer, patients who are being considered for or have undergone solid organ transplant, and people who have sustained burn or electrical injuries. While the focus of psychological evaluation and intervention may be similar among both rehabilitation and health psychologists,

The Wiley Encyclopedia of Health Psychology: Volume 3: Clinical Health Psychology and Behavioral Medicine, First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

the petition for recognition of rehabilitation psychology as a specialty noted that "Rehabilitation Psychology works with individuals who have acquired a disability or chronic health condition. Clinical Health Psychology uses similar assessment and intervention techniques to identify and enact health behavior change, while Rehabilitation Psychology has a 'specific focus on adaptation to illness or injury' (Klonoff et al., 2011), and the interactions between the individual, family, and physical, social, and policy environments in order to enhance social role participation" (APA Division 22 Rehabilitation Psychology and the Rehabilitation Psychology Synarchy, 2015, p. 32).

In 1952, rehabilitation psychology was introduced as a new subspecialty within the APA. Rehabilitation psychologists were identified as practitioners, educators, researchers, and advocates for people with disabilities working with interdisciplinary teams. Since that time, the field of rehabilitation psychology has expanded to include expertise as policy makers, healthcare administrators, and program developers. The importance of the role of rehabilitation psychology in the team has also been recognized by regulatory agencies, such as CARF (formerly known as the Commission for Accreditation of Rehabilitation Facilities) that includes psychology in their guidelines for staff inclusion on rehabilitation teams.

The purpose of this chapter is to introduce rehabilitation psychology as a subspecialty particularly with regard to practice areas of assessment, intervention, and interdisciplinary team functioning. Although some assessment instruments and interventions are similar to clinical health psychology, readers will understand how rehabilitation psychology contrasts with health psychology in its roles and focus. The role of rehabilitation psychology in research, advocacy, and training is also explained. For further information on rehabilitation psychologists performing as program developers, policy makers, and healthcare administrators, readers are encouraged to review Cheak-Zamora, Reid-Arndt, Hagglund, and Frank (2012).

Practice of Rehabilitation Psychology: Assessment

In rehabilitation psychology, the assessment process is used to develop a multidisciplinary or interdisciplinary treatment plan that addresses the impact of a disability or other chronic health condition. In addition, adjustment and accommodation to the disability along with the necessary social and community supports to optimize functioning are also evaluated. Reasons for referral are many: individuals may be referred for assessment of physical, cognitive, emotional, and/or social adaptation to injury, illness, and disability in the patient and family; cognitive, emotional, and behavioral dysfunction; neuropsychological evaluation to determine ability to function at home, school, and/or work with or without accommodations; evaluation of self-care and independent living skills; evaluation of psychosexual functioning, with an emphasis on education regarding disability-related changes and use of adaptive technology; evaluation of social and recreational participation; assessment of health self-management and prevention of secondary complications; and assessment of caregiver status and functioning, including caregiver knowledge and skills, social support, and self-care. Assessment of each of these domains requires knowledge of a broad range of quantitative and qualitative assessment instruments and techniques.

Along with instruments for mood, pain, coping, adjustment to disability, and cognitive and physical functioning in health populations, assessment instruments have also been created to be used with diverse rehabilitation populations to address capacity for self-care, work, and independent living. Instruments specific to rehabilitation populations, for example, may include instruments that assess the psychological assimilation of traumatic events, monitor progress throughout inpatient rehabilitation, and assess how people with disabilities function as active members of their communities (Heinemann & Mallison, 2010). Given the high prevalence of brain injury in traumatic physical injuries, cognitive screening measures are vital to determine the presence and extent of potential cognitive processing issues that can negatively impact treatment and recovery (Novack, Sherer, & Penna, 2010). Assessments of specific environmental or behavioral features relevant to intervention, such as stimulus control or contingency management, often focus on factors to aid integrative assessment for the development of a rationale for a particular intervention, to develop a working relationship with the patient and/or significant others, to address emotional reactions, and to develop expectations and attributions that support the intervention.

The importance of assessing and providing psychological services that best meet the individual and diverse needs of people with disabilities while maximizing their health and welfare, independence and choice, functional abilities, and social participation was highlighted in the *Guidelines for Assessment of and Intervention with Persons with Disabilities* (APA, 2012). Multiple issues relevant to diversity must be considered (e.g., age, gender, sexual orientation, socioeconomic status, religion, race, ethnicity) along with disability identity. An individual's military or veteran status may be an important part of their identity and may differentially affect their adaptation to disability or approach to assessment. Individuals with disabilities need to be included in all aspects of decision making to the best extent possible to ensure that their preferences and values are integrated into the conceptualization of assessment results.

As part of the comprehensive evaluative process, a rehabilitation psychologist may consult with other professionals, such as attorneys, government agencies, educational institutions, the Department of Vocational Rehabilitation, insurance companies, and case managers to optimize an individual's community functioning. Such consultations may include evaluation of acquired cognitive deficits with educational or vocational implications, development of reasonable accommodations for return to school or work, quantification of accident-related "loss" for forensic purposes, recommendations related to hospital discharge plans, or recommendations concerning resumption of premorbid activities such as driving.

Practice of Rehabilitation Psychology: Intervention

Psychotherapeutic interventions are an important part of the rehabilitation plan for individuals with disabilities to improve emotional distress often produced by changes in physical, task, and social functioning; to address the disruption of prior personal, family, and community roles; and to aid motivation, adherence, or participation in rehabilitation efforts. Interventions in rehabilitation psychology focus on applying the findings of assessment and diagnosis to facilitate functional task performance and social role participation in order to maximize the productive engagement of the individual in *all* environments. As disability is seen as a problem of exclusion from ordinary life through a "person-first" perspective (Wright, 1983), interventions are aimed at facilitating adaptation and accommodation to illness or injury while seeking to minimize the attendant limitations. Evidence-based interventions are modified to address the specific challenges an individual, couple, or family face that limit activities and restrict social role participation. Therapeutic interventions can involve emotional, cognitive, and/or behavioral domains. They can help shift the focus of the individual with a disability from premorbid sources of self-esteem, such as physical prowess, to less impaired areas, such as cognitive and personality strengths (Keany & Glueckauf, 1993). At the family and community level, such emotional, cognitive, and behavioral shifts in emphasis can also significantly reduce disability by helping develop accommodations in the physical and social environments.

Hart and Ehde (2015) developed a theory-driven framework for specifying rehabilitation interventions according to its targets, its active ingredients, and the mechanisms of action that connect them. They suggest that rather than describing rehabilitation treatments by the discipline(s) providing them (e.g., physical therapy, vocational retraining program), or by the problems they are intended to solve (e.g., attention training), treatments must specify the desired changes to narrow choices about specifically what one can do to effect change. Hart and Ehde call for a common system of nomenclature for characterizing and quantifying the treatment targets and ingredients used in clinical interventions and research to advance theory development and improve the quality of intervention research.

In rehabilitation, the team includes not only direct service providers but also the patient, family and significant others, and available community, school, and work relationships. Family members who provide care for persons with disability are themselves at risk for associated physical, mental, emotional, social, and financial problems and therefore may benefit from caregiver-oriented interventions (Chwalisz & Dollinger, 2010). Caring for the caregiver improves and sustains the care provided to the person experiencing chronic illness or disability resulting in improvements in outcomes. Rehabilitation psychologists not only help caregivers understand their loved ones' difficulties but also help to manage problem behaviors, obtain and utilize social supports, and provide interventions to maintain caregiver health and well-being. In caring for others, caregivers must take care of themselves in order to avoid burnout and the disintegration of a previously workable care plan.

Rehabilitation psychologists also intervene to assist with reducing the morbidity and cost of work injuries. Delivering health and rehabilitation services to injured workers in the work environment, instead of in community care settings, has been demonstrated to significantly reduce days away from work and worker's compensation costs (Wegener & Stiers, 2010). Negative experiences, including stereotyping and marginalization, discrimination, and disempowerment in the workplace, may also need to be addressed for individuals with disabilities, as with any individuals of minority status.

Practice of Rehabilitation Psychology: Interdisciplinary Team Functioning

Rehabilitation includes many disciplines working collectively to serve patients with a wide variety of disabilities and chronic conditions. Rehabilitation psychologists contribute across the full spectrum of care from prevention, diagnosis, consultation, treatment, rehabilitation, and/or end-of-life and palliative care. As rehabilitation psychologists practice in these diverse healthcare delivery systems, they have a long tradition of working within multidisciplinary and interdisciplinary teams (Butt & Caplan, 2010). Interdisciplinary typically implies a team that is not only composed of different disciplines working toward a shared set of treatment goals but also have some fluidity of professional boundaries as team members collaborate to best assist the patient to achieve their goals. Functioning within teams requires expertise in communication, behavioral issues and management, patient decision making, and human interaction in systems with attention to the environment, culture, and context in which care is delivered. Rehabilitation psychologists must understand the roles, skills, and contributions of each discipline involved on the team as they educate other disciplines about the potential contributions of psychologists to the team. Awareness of areas of overlap in team member's contributions is aided by clear communication and respect for each team member's identified role that can change across patients or an individual's rehabilitation program. Barriers to effective team functioning can include hierarchical attitudes, unhealthy stress reactions, the lack of understanding of the advantages of coordinated team care, fear of change, risk aversion, and the challenge of developing an entrepreneurial spirit. Rehabilitation psychologists operate within rehabilitation teams, systems, and programs and provide expertise in the measurement and understanding of rehabilitation team functioning, rehabilitation outcomes, and facilitation of interdisciplinary rehabilitation team functioning (Butt & Caplan, 2010). Participation in interdisciplinary team meetings, case consultations, and rounds allow for the psychologist to aid the integration of problem definition, goals, observations, and services of different providers. As disability results from person–task–environment interactions, a focus on effective and efficient team functioning is necessary to optimize outcomes.

Research in Rehabilitation Psychology

Health and rehabilitation psychology research has grown significantly in the past several decades. Although pioneers in the field of rehabilitation psychology provided an early framework for conceptualizing the work of rehabilitation psychology (i.e., Meyerson, 1948; Wright, 1983), rehabilitation psychology has generally been more focused on empirical evidence and clinical application than theory development (Dunn & Elliott, 2008). This is due in part to the challenge of applying psychological theories in multidisciplinary settings as well as the focus of rehabilitation on the individual and family, whose circumstances are unique and limit generalization as demanded in science. As scientist-practitioners, practitioners often rely on single-subject designs to apply the rigorous methods of science to their daily practice in an effort to determine whether interventions work and to improve patient outcomes. For general and geriatric rehabilitation populations, common areas of rehabilitation research typically focus on the natural history of disability, functional assessment and performance evaluations, intervention issues and outcomes, and rehabilitation service delivery systems.

Rehabilitation has been called a black box as its precise ingredients, their mechanisms of action, and their efficacy and effectiveness remain largely unknown. This lack of a systematic way to characterize interventions in rehabilitation has prevented advances in the field of rehabilitation in several ways (Dijkers, Hart, Tsaousides, Whyte, & Zanca, 2014). Rehabilitation research has been disadvantaged by interventions that cannot be readily replicated, tested against one another, or analyzed to try to match specific components to different kinds of patients. Lack of clear evidence about effective treatments and the lack of guidance by which to choose specific therapies for individual patients have hampered progress in clinical applications in rehabilitation. Communication and collaboration across the rehabilitation team, as well as communication with patients and third-party payers, has been impeded by the lack of a common system for naming and describing treatments. Rehabilitation research needs to apply a systematic approach to treatment definition. When we can clearly define the active ingredients and targets of a treatment, then we can reliably study its effects; assess the fidelity of its implementation; replicate it in the correct doses in further studies, both experimental and observational; specify the changes and refinements that might be made to improve it; and disseminate it to the clinic setting (Hart & Ehde, 2015).

Healthcare in the United States suffers from high and rising costs and poor and uneven quality and safety, factors that increase the vulnerability of individuals with disabilities. The increasing prevalence of disability and chronic health conditions across the general population is largely driven by behavioral and lifestyle factors that are the primary contributors to premature morbidity and mortality and the foundation of the work of rehabilitation psychologists. Theories of health behavior change applied to people with chronic illness and disability help to explain the cognitive mechanisms of behavior change and adherence to treatment in the rehabilitation setting.

Research in positive psychology and posttraumatic growth, which focuses on resilience and promotes the concept that individuals can grow positively in response to challenge, stress, and trauma, has been applied to a variety of medical populations. The integration of positive psychology and rehabilitation psychology research has only more recently been applied to rehabilitation populations. Peter, Geyh, Ehde, Müller, and Jensen (2015) identified three commonalities between the two areas of study: positive principles, focus on individual strengths and resources, and well-being, social participation, and growth as key outcomes.

Within a population health context, MacLachlan and Mannan (2014) identified areas of potential research that rehabilitation psychology could contribute to in an effort to address many of the challenges identified in the *World Report on Disability*. Specific targeted contributions include addressing the human resources needed for health crises in rehabilitation, developing prosocial and community-based interventions and programs, helping to identify and overcome difficulties to accessing healthcare, refining the measurement and classification of disability, and strengthening research, policy, and advocacy for and with people with disabilities.

Research in interdisciplinary team science has also grown significantly within the past decade. Interdisciplinary research in rehabilitation is performed by individuals or teams that integrate information, data, technique, tools, perspectives, concepts, and/or theories from two or more disciplines or bodies of specialized knowledge to advance fundamental understanding or to solve problems whose solutions are beyond the scope of a single discipline or field of research (Committee on Science, Engineering and Public Policy [COSEPUP], 2004). Elements necessary to facilitate interdisciplinary team science include mutual respect among scientists; regular interactions focused on science; common language, constructs, and cultural norms; and institutional leadership and funding that supports transdisciplinary research. For rehabilitation psychologists practicing in the field, interdisciplinary science must address pragmatic concerns that impact how the psychologists can be an effective partner on the team. Concerns may include how the team's mission is determined; how the team and its mission is tied to the larger organization and the climate for the team's functioning; how leadership is determined, if it is shared, and whether and how it may change over time; what are the team's communication patterns; and how does the team make decisions and review and evaluate its progress and decisions. Each of these aspects of effective interdisciplinary team functioning is crucial to understand within our changing healthcare environment and shift toward integrated care in order to optimize patient outcomes within person–task–environment models of care.

Rehabilitation Psychologists as Advocates

The essence of advocacy in rehabilitation psychology is captured in Guideline 21 of the *Guidelines for Assessment of and Intervention With Persons With Disabilities* (APA, 2012), which states that "When working with systems that support, treat, or educate people with disabilities, psychologists strive to keep the clients' perspectives paramount and advocate for client self-determination, integration, choice, and least restrictive alternatives" (p. 26). Rehabilitation psychologists advocate on treatment teams, within their family structure and social network, and in the community for their patients with regard to their physical and emotional needs. They advocate for needed environmental changes, such as accessibility to/from health provider offices (e.g., ramps, curb cuts), for additional time to complete tasks or other accommodations (e.g., at work or at school), or for therapeutic assistance (e.g., obtaining a therapy dog to assist with physical or sensory needs).

Rehabilitation psychologists also advocate at local, state, and national levels for legislation to assist people with disabilities, including ensuring access to affordable healthcare, social service, and rehabilitative therapy resources, and inclusion in social roles through the ADA (1990) (Cheak-Zamora et al., 2012). They do this because they are "mindful of the fact that limitations of functioning may not only be inherent in the disability itself, but are often attributable, in whole or part, to environmental and institutional barriers, and to negative social attitudes" (APA Division 22 Rehabilitation Psychology and the Rehabilitation Psychology Synarchy, 2015, p. 6).

Training in Rehabilitation Psychology

Graduate students in clinical and counseling psychology programs may first be introduced to physical rehabilitation in practicum experiences in inpatient and/or outpatient medical rehabilitation settings tied to clinical health psychology programs. For example, at the University of Kansas and the University of Kansas Medical Center, where the first author is located, graduate students in clinical psychology (health track) participate in required health practicum medical center experiences, including a neurorehabilitation psychology rotation (the first author is the supervisor) that allows them to participate in interviews, evaluations, and treatment of patients with new onset or chronic physical and medical issues. Externs also have the opportunity to participate in interdisciplinary team meetings, patient/family education, support/education groups, and community outings. The foundation of clinical psychology, learned within the first 2 years of their graduate program, provides a basis from which the students apply their skills in the new setting of inpatient or outpatient physical rehabilitation. Training may also occur during predoctoral internship or in postdoctoral experiences.

According to postdoctoral training guidelines first published in 1995 by Patterson and Hanson, training at the postdoctoral level is expected to occur for a minimum of 1 year with a minimum of two supervisors and include supervised practice, seminars, and coursework, a minimum of 2 hr of weekly didactics, a minimum of 2 hr of weekly supervision, and the patient populations and didactics are to be related to disabilities and chronic health conditions (Patterson & Hanson, 1995). In addition, trainees should be funded, written objectives for the training program are to be provided, formal trainee evaluations are to occur at least twice a year, and program evaluations are to occur annually.

The petition for rehabilitation psychology as a specialty notes that "Training in Rehabilitation Psychology is based upon a disability-specific body of theory and research (Cox, Cox, & Caplan, 2013; Dunn & Elliott, 2005) which focuses on the physical, psychological, social, environmental, and policy aspects of disability and rehabilitation, and includes individual, psychosocial, and cultural aspects of disability. Knowledge acquisition concentrates on the application of psychology principles to understanding the needs of diverse people with disabilities in rehabilitation settings and their families. Content focuses on understanding the impact of physical, cognitive, and/or mental health disabilities on diverse individuals and their relevance in providing rehabilitation services such as assessment, intervention, vocational rehabilitation, case management, and advocacy. Such training can occur in formal experiences, such as didactics, seminars, and journal clubs, in interdisciplinary forums, such as interdisciplinary team-patient care meetings, case conferences and grand rounds, and in supervision, both individual and group" (APA Division 22 Rehabilitation Psychology and the Rehabilitation Psychology Synarchy, 2015, p. 21).

The American Board of Rehabilitation Psychology has also determined specialty competencies for practice in rehabilitation psychology that guide training in progress toward an individual's attainment of board certification in the specialty (Cox et al., 2013). Such competencies include, but are not limited to, the ability to provide assessment and treatment related to adjustment to disability, cognitive functioning, family/couples functioning, pain, substance abuse, and educational, vocational, and recreational functioning; the ability to participate in interprofessional collaboration and consultation; knowledge of ethical, legal, and professional issues including laws related to persons with disability; knowledge of research and treatment and program evaluation methods as well as the ability to apply research findings to patients; and knowledge of and attention to diversity and cultural issues (Stiers & Nicholson Perry, 2012).

Summary

In this chapter, we have introduced rehabilitation psychology as a specialty within psychology, simultaneously recognizing its similarities with and differences from clinical health psychology. We have discussed practice aspects including assessment, intervention, and interdisciplinary team functioning that together allow rehabilitation psychologists to assist the team in treating the whole person. Research in rehabilitation psychology was reviewed, and the need for more theory-driven research was described. Advocacy and training in rehabilitation psychology, both vital engagement areas, were also described. While rehabilitation psychologists are involved to varying degrees in research, practice, advocacy, and training, the Division of Rehabilitation Psychology within the American Psychological Association provides a home for those interested in this discipline of psychology. The approval of rehabilitation psychology by the APA Council of Representatives in August 2015 as a recognized specialty within psychology demonstrates the importance of this distinct field, thereby recognizing the ability of rehabilitation psychology to treat the wounds that expose the "best and beautiful" aspects of our patients.

Author Biographies

Monica F. Kurylo, PhD, ABPP(Rp), is an associate professor and director of neurorehabilitation psychology in the Departments of Psychiatry and Rehabilitation Medicine at the Kansas University Medical Center. She received her doctorate in clinical psychology (health/rehabilitation emphases) and has internship and postdoctoral experience in rehabilitation psychology and neuropsychology. She is active in practice, training, advocacy, and research and has served on several local, state, and national professional psychology, rehabilitation psychology, and interdisciplinary groups (http://www.kumc.edu/school-of-medicine/psychiatry-and-behavioral-sciences/faculty/clinical-psychologists/monica-kurylo-phd-abpp.html).

Kathleen S. Brown, PhD, is a rehabilitation psychologist involved in consulting, leadership training, and supervision in her independent practice in Fort Myers, Florida. Dr. Brown's clinical and research interests include pain management, interdisciplinary team development, leadership training in healthcare, and adjustment/coping responses to medical illness.

Administrative Issues in Primary Care Psychology

Esther N. Schwartz and David R. M. Trotter

Department of Family and Community Medicine, Texas Tech University
Health Sciences Center, Lubbock, TX, USA

Introduction

Psychologists and other behavioral health providers (BHPs) have become increasingly integrated into primary care in the United States (Bray, 2016; McDaniel et al. 2014; Miller, Petterson, Burke, Philips, & Green, 2014). The types of administrative issues encountered by BHPs working in primary care will vary by proximity of BHP and medical services locations and the level of integration between medical and behavioral health services. BHPs face administrative challenges that are distinct from providers in traditional mental health settings. In this article, the practicalities of BHPs' daily function such as their appointment structure, coding and billing for services, documentation, availability of administrative support, and position in the organizational hierarchy are discussed. Additionally, BHPs' navigation and resolution of ethical quandaries specific to psychological practice in a medical setting are also explored.

A Brief Context: Behavioral Health Providers in Primary Care Settings

Primary medical care (PC) is defined as "the provision of integrated accessible health care services by clinicians who are accountable for addressing a large majority of personal health care needs, developing a sustained partnership with patients, and practicing in the context of family and community" (Institute of Medicine, 1994, p. 1). PC clinics, including family medicine, general internal medicine, and general pediatrics practices, are the primary entry point for medical and mental healthcare for most Americans. Specifically, more than half (54.6%) of all healthcare visits occur with a primary care physician (PCP) (Centers for Disease Control [CDC], 2012). Integration of BHPs into PC is important as psychosocial and behavioral

First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

factors such as diet, activity level, and substance use critically affect morbidity and mortality in the United States. Additionally, psychological symptoms and disorders are frequently comorbid with medical illnesses (Petterson et al., 2008). Finally, approximately 50–70% of Americans who receive treatment for mental and behavioral health and substance use problems do so from PC (McDaniel & deGruy, 2014). There is mounting evidence supporting that the integration of PC and behavioral health improves health at individual and population levels (Blount et al., 2007). However, primary care behavioral health integration is still not yet widespread.

Administrative Issues as a Function of Level of Integration

The types of administrative issues encountered by BHPs working in PC will vary at least partially as a function of the level of integration between medical and behavioral health services. In general, integration of services requires a team-based collaboration between all providers using a biopsychosocial framework (Bray, 2016; Engel, 1977). There are three broad levels of integration: coordinated, colocated, and fully integrated care (Bray, 2016). In coordinated care, the BHP retains a separate practice (i.e., separate physical spaces, electronic health record [EHR] systems, scheduling and billing staff) and collaborates via referrals from the PCP. In a colocated arrangement, the psychologist and PCP are located within the same office space but maintain separate practices (e.g., scheduling and billing staff, EHR) and financial arrangements (e.g., billing and reimbursement structures). In this arrangement the BHP accepts referrals from PCP and provides consultation (written and face to face). In a fully integrated model, the psychologist is embedded within the primary care system and is an integral part of care delivery and treatment. They share the same space, systems (e.g., EHR), and resources (e.g., scheduling and billing staff). In these settings, psychologists may provide immediate consults to patients during their doctor's visits as requested by the PCP, as well as see patients for brief interventions. For a full discussion of levels of integration, the reader should see Bray (2016). Deft negotiation of administrative issues requires an awareness of the administrative processes operating in each clinical setting and the level of behavioral health service integration.

Basic Practice Management Considerations for BHP Integration

General Practice Organization

BHPs working in colocated or fully integrated primary care settings typically work in a medical facility. Familiarity with the organizational hierarchy and the numerous players in the medical system is helpful for ensuring coordinated care. Key players in these facilities often include a medical director (a physician who makes decisions on standing orders, supervises "mid-levels," and may provide general oversight of medical services), medical staff (e.g., physicians and mid-level providers like nurse practitioners and physicians assistants), clinic manager (a staff administrator who oversees the day-to-day operations of the clinic and provides general supervision of the staff), various department managers (e.g., nurse manager, billing manager, medical records manager, scheduler/call center manager, lab manager; typically report to the clinic manager), care coordinators (may coordinate referrals and/or manage patient care plans), and various departmental staff (e.g., nurses, billers/coders, call center staff). It is critical that a BHP understands where they fit into this hierarchy, including who they report to, who provides practice oversight, how they interact with the other key players, and what services and support they will receive from the various clinic departments (e.g., scheduling assistance, billing/coding). For example, will the BHP report to the medical director and be granted privileges in accordance to their license/certification and in a manner similar to the other providers, or will they report to the clinic manager, be considered general staff, and be afforded fewer privileges? Discussions regarding how a BHP will fit into the administrative clinic structure is critical prior to integration.

General Clinic Supports

As stated above, BHPs should consider and negotiate how they will interact with, and what services they will receive, from the various clinic departments. For example, who will take charge of the day-to-day management of the BHPs schedule? Is the BHP responsible for scheduling of patients, taking their phone calls, and contacting them if they have not showed up, or does the scheduling department complete these tasks as they do for the medical providers? In full integration, the BHP's appointments are often marked on the same standardized weekly clinic grids utilized by all other providers. With these grids in place, the BHP's current appointments and total available slots in the future are visible to the entire clinic, increasing transparency and availability for same day access (Kearney, Smith, & Pomerantz, 2015). An additional question is, who does the BHP's billing and coding? Does this responsibility fall under the purview of the BHP's responsibilities, or is this handled by the billing/coding department in accordance with the other providers? It is advisable (when possible) for patients to have a generally equivalent experience (e.g., with scheduling, billing) with the clinic regardless of the type of services (i.e., medical or behavioral health) they are receiving.

Office/Clinic Space

Space in PC settings is often at a premium, and clinics are typically not designed with behavioral health practice in mind. Often, the only available space to see patients is an exam room, and BHPs may be expected to meet with patients in exam rooms. Additionally, it is the norm for many PC practices that providers do not have a private office space for charting and completing other administrative activities (e.g., letter writing, responding to patient messages) and may instead do these activities in a more central provider pod or work hub. While this may take some adjustment on the BHP's part, these centralized work spaces encourage communication between providers in ways that enhance coordination, builds camaraderie, and conveys accessibility. Even if a psychologist is designated a private office space to see patients, simply leaving the door open and being visible conveys accessibility (Robinson & Reiter, 2016). It is advisable that BHPs advocate for space that is roughly equivalent to that or their medical colleagues, use space judiciously, and be flexible.

Appointment Structure

Physician visits are typically scheduled in 15-min increments (high volume), while traditional mental health visits are typically scheduled for 50 min (comparatively low volume). When BHCs work in a coordinated model, they often retain this 50-min structure. However, when working in colocated or fully integrated settings, many move to using a 25-min session structure (a higher volume 16 total appointment slots in a day). When choosing an appointment structure (i.e., either 50 or 25 min), a number of administrative issues should be considered. First, what are the clinical volume expectations in the clinic? Do the other providers expect you to have a volume more similar to theirs, or is there no expectation of this? If a BHC works in a clinic with many other providers, a 25-min structure is generally preferable as it allows the professional to be available for more of the PCP patients. Second, what level of staffing is available for patient scheduling and check-in/check-out? Are there enough scheduling staff to accommodate an additional 16 patients a day plus the calls they will generate? Finally, will the BHP utilize nursing staff to room patients? While this is not common, some clinical settings will provide nursing support for their BHP to room patients, allowing them to move faster through their clinic without having to make trips to the waiting room or ensure that patients have completed the appropriate paperwork. For a more comprehensive discussion and justification for the use of 25-min appointment structure, the reader may consult Robinson and Reiter (2016).

Documentation

Psychologists' documentation of patient encounters is an important administrative skill, but the style and processes of documentation differ based on level of BHC integration. In a coordinated model, BHP documentation will look similar to other mental health settings, with the addition of workflows and processes to ensure that the referring PCP is provided some level of feedback on the referral (e.g., that the patient was seen, that progress is being made). BHPs working in colocated models often document in a manner similar to traditional mental health providers (i.e., in a separate system, using traditional mental health note structures), while some document more like a BHP in a fully integrated setting. BHPs in fully integrated settings typically document in the same chart used by the PCP. This kind of communication requires that notes are written in a way that is useful to other healthcare team members. Typically, this means that the notes use a structure similar to other providers (e.g., SOAP style), are concise, do not contain psychological jargon, clearly convey the assessment of the patient including risk factors, include a follow-up plan, and provide recommendations for other providers (when necessary). When using this style of documentation, BHPs need to discuss the strengths and limitations of a shared health record during the informed consent discussion with the patient. The psychologist should also clarify with the patient what session information will be shared in the chart.

When using a shared chart, BHPs need to also consider who should have access to their notes. A PCP's notes are typically available to all staff and other providers, including other physicians and mid-levels, nursing staff, scheduling/call center staff, billers/coders, and other general administrative staff. A BHP using a shared EHR should carefully consider which of these groups will have a legitimate need to access to their portion record. For example, it would be important for the BHP to grant access to all referring providers in the clinic, as they will be collaborating on patients. Additionally, it may be important for some of the nursing staff to have access to these notes, as the nursing staff are often in charge of triaging patients who contact the clinic. However, it may not be necessary for scheduling staff and general administrative staff to have access to the notes. The BHP should give careful consideration to this issues and inform patients as to who will have access to their record.

Referral Management

In a coordinated practice, a BHP will receive referrals from a PCP's office, as well as from other sources. However, in colocated and fully integrated clinics, PCPs may be a BHP's sole source of referrals. Ensuring that the referral process is easy, smooth, and rapid is critical in promoting PCPs' actual placement of the referral and will increase the likelihood that a patient will follow through with the initial appointment. BHPs should consider the process of placing written and in-person referrals. PCPs will be most familiar with creating written referrals, as they refer patients to a host of services (e.g., preventive care screenings, specialist referrals). As most PC practices use an EHR, BHPs should work closely with their IT departments to ensure that their electronic referral process closely matches those that PCPs use for other services. Additionally, BHPs should ensure that common referral barriers (e.g., requirement of prior authorization for service, delays, wait lists) are removed or managed. While PCPs will be most familiar with written referral processes, in-person referrals are one of the BHPs most effective tools for achieving coordinated care. The most effective in-person referral is the "warm hand-off." A warm hand-off is when a PCP consults the BHP in person and then asks the BHP to meet a patient during the patient's regularly schedule PCP visit. Warm hand-offs by the PCPs to BHPs may be completed in just a few minutes and demonstrably increase the likelihood a patient will initiate therapy. In-person referrals may also occur during a "curbside consultation." A curbside consult is a brief discussion between a BHP and a PCP about a clinical issue that occurs spontaneously. These can occur in an exam room, PCP common work space, or hallway (being mindful of confidentiality issues). Curbside consults are good opportunities to provide accurate, specific, and actionable information on a behavioral problem and support the providers to be more effective in their interactions with patients. Over time, repeated consultations may provide physicians with a good sense of the biopsychosocial model in action and the range of services a psychologist provides. No less important, collaboration communicates to the PCP that they have a potential ally in caring for their patients (Gunn & Blount, 2009). Regardless of how a referral is placed, once a BHP has completed the initial referral visit, he or she should provide the referring PCP with feedback about what the patient is targeting in treatment and how treatment is progressing as a way to close the referral loop.

Billing and Reimbursement

BHPs working in either coordinated or colocated systems typically bill and are reimbursed in ways similar to that of traditional mental health settings. However, billing issues continue to be a serious hurdle in integrated primary care practices (Robinson & Reiter, 2016). Clinic administrators may hire a BHP with no plans for that provider to bring in direct revenue. In this model, the BHP is typically salaried hourly and paid as a member of the team. This system can work well in capitated payment structures, like those found in accountable care organizations (ACO). A capitated payment structure is a reimbursement model in which a health system receives a yearly flat fee from an insurance carrier to provide all services for a patient. Further, insurers may offer additional monetary incentives if the system can reduce overall healthcare costs for its patients by improving quality of care delivered (e.g., decreasing ER visits and hospital stays, reducing redundancy and waste). In fact, there is some evidence to suggest BHPs can reduce healthcare costs at a system level, making their inclusion in these systems attractive. See Blount et al. (2007) for a review of increased cost-effectiveness when behavioral health services are integrated into primary care.

Most BHPs still work in traditional fee-for-services models. BHPs working in these environments are typically either employees of the system who receive payment based on their billing or are contractors who provide services for a contracted fee. In fee-for-services systems, BHPs bill using current procedural terminology codes (CPT) to bill for services. There are two categories of CPT codes available to BHPs: psychotherapy CPT codes (e.g., 90791) and health and behavior CPT codes (i.e., 96150–96155). The psychotherapy codes are used for billing when a BHP is seeing a patient for a mental health issue (e.g., depressive disorder, anxiety disorder). Available psychotherapy CPT codes include those used for testing and assessment and counseling (based on time; 30, 45, 60 min). The CPT codes are used by those working in traditional mental health settings as well as all levels of PCBH integration. Health and behavior codes allow BHPs to bill for services that address social and behavioral aspects of physical health problems as diagnosed by a medical professional (Robinson & Reiter, 2016). Therefore, a BHP can bill for services to improve the course or outcome of medical issues like obesity, chronic pain, and diabetes. It is important to note that billing for both health and behavior codes and mental health codes in the same encounter is not allowed.

Managing Confidentiality

Protecting patient confidentiality and privacy in the primary care setting is an important administrative issue but can be challenging. Physicians and BHPs have different laws, rules, and ethics codes that govern provider–patient confidentiality. For example, medical care is organized around referrals and informal consultation with others in which protected health information is exchanged. This is permissible under the Health Insurance Portability and Accountability Act (HIPAA), which allows HIPAA-covered healthcare providers to disclose protective health information with another healthcare provider without the patients written consent, if the exchange of information pertains to that provider's treatment of the patient (see Federal Regulation 45 CFR 164.506). As such, PCPs expect team members to be able to discuss all patient care issues as deemed necessary. However, BHPs may be limited in their ability collaborate in this way as they are not covered under HIPAA and are subject to other privacy and ethical considerations. For example, the American Psychological Association Ethical Standard 4.06 clearly states that when consulting with colleagues, psychologists "do not disclose confidential information that reasonably could lead to the identification of a client/patient." Therefore, a curbside consult between a PCP and a psychologist BHP in which a patient is referred to by name and medical problem may be permissible under HIPAA, but in violation of APA standards on confidentiality. However, in the primary care culture of openly sharing patient information as a way to coordinate care, a psychologist's reticence to collaborate may be counterproductive (Gunn & Blount, 2009). BHPs must learn to navigate the complex rules, regulations, and work expectations regarding confidentiality. One of the simplest administrative solutions to this issue is to notify patients in writing during the informed consent process that the BHP may collaborate with other providers in the service of their care. Further, during informed consent, patients can be informed about how their written record will be handled (see above).

Managing Multiple Relationships

Medical providers and BHPs may possess different perspectives on the issue of multiple relationships. For example, consider the example of a provider providing and/or receiving clinical services to/from another colleague or trainee. The APA Ethical Code states: "A psychologist refrains from entering into a multiple relationship if the multiple relationship could reasonably be expected to impair the psychologist's objectivity, competence or effectiveness in performing his or her functions as a psychologist, or otherwise risks exploitation or harm to the person with whom the professional relationship exists" (see Standard 3.05 in the "Ethical Principles of Psychologists and Code of Conduct"; American Psychological Association [APA], 2017). While APA's code does not explicitly forbid treating colleagues or professionals in training under this code, the onus would fall on the psychologist to prove that entering into such a relationship would be reasonable, which would be difficult to do. On the other hand, the American Medical Association's (AMA) Code of Ethics stipulates that while one should exercise caution (for issues similar to those raised by the APA), "car[ing] for a fellow physician is a privilege" and that "physicians-in-training should not be required to provide medical care to fellow trainees, faculty members, or attending physicians if they are reluctant to do so." Taking these guidelines in combination in a real-world setting, BHPs and PCPs may have very different opinions about the appropriateness of working with a patient with whom both providers have multiple relationship (e.g., colleagues, family members, relatives of current patients). Managing multiple relationships as a BHP is an important administrative consideration, as it will influence the referrals (and associated referral process) that a BHP will or will not accept. Here we will discuss the two types of multiple relationships BHPs will most often encounter and potential administrative solutions.

Working with Colleagues

Psychologists are trained communicators with expertise in emotions, relationships, and behavior. They are in an apt position to promote team development and a healthy culture in the workplace (McDaniel & Fogarty, 2009). In primary care, the psychologist may be called on to help staff deal with difficult and divisive patients, identify staff burnout, and improve workflows (McDaniel & deGruy, 2014). In some situations, clinic staff may ask the psychologist for help with a personal problem. In such scenarios, a BHP must adopt a policy(s) that will help them navigate these requests. These policies are likely to fall on a spectrum, ranging from a refusal to see any colleagues as patients to a policy in which the BHP will see anyone for an initial appointment. If a BHP adopts a policy refusing to see colleagues as patients, this is best communicated in the beginning when negotiating the terms of a practice. It is always easier to adopt this policy from the beginning, rather than attempt to implement it later on. This policy should then be clearly communicated to providers and staff. If a BHP adopts a policy on the other end of the spectrum, prior to intervening, it is recommended that the psychologist consider his or her working relationship with the staff member, the severity and sensitivity of the problem, and the likelihood the consultation will negatively impact the working relationship between staff member and BHP and the team (Reiter & Runyan, 2013). Again, if a BHP choses such a policy, this should be communicated to providers and staff in a clear format. Regardless of the policies guiding a BHP's practice, in the event of crises or problems with elevated risk to the staff member, the BHP may advise follow-up care such as counseling or hospitalization. Additionally, all services rendered to colleagues should be documented in their chart in a fashion similar to documenting other patients' information.

Non-Colleague Patients

Issues of multiple relationships are also common when working with non-colleague patients. In primary care, it is not uncommon for members of the same family to receive care in the same clinic and even from the same provider ("whole family care"). PCPs may be skilled at navigating the challenges inherent in these multiple relationships, but such scenarios are far less common in specialty mental health settings and may present ethical and administrative challenges to psychologists (Reiter & Runyan, 2013). Consider the plausible example of an elderly man referred to a BHP to address suicidal ideation and his adult daughter who is referred to the same BHP for a distinct but related issue, stress-induced gastritis. In this scenario, if the BHP were to follow the APA Standard 10.02 Therapy Involving Couples of Families stating "When psychologists agree to provide services to several persons who have a relationship (such as spouses, significant others, or parents and children), they take reasonable steps to clarify at the outset (1) which of the individuals are clients/patients and (2) relationship the psychologist will have with each person," then the BHP would risk violating APA Standard 4.01 Maintaining Confidentiality, which instructs psychologists to "take precautions to protect confidential information." "Whole family care" presents an ethical dilemma for the BHP as it is impossible to abide by one of these guidelines without violating the other (Reiter & Runyan, 2013). In this case, the BHP may not even be aware that father and daughter are related when they are referred. In the event that the BHP is made aware of this existing relationship, several different administrative actions can be taken. First, if other BHPs are available at the clinic, it would be advisable to refer one of the family members to see another BHP. If there is only one BHP, then they should assess the extent to which the father's presenting issue and the daughter's presenting issue are reasonably discrete and can each be conceptualized and treated without undue consideration of the other. Based on this assessment, the BHP will have to prioritize which standard will take precedence and be prepared to provide a rationale for this decision.

Thus, even when embedded within the primary care team, psychologists' administrative challenges are unique from medical providers. Moreover, primary care psychologists' practice management, reimbursement process, and understanding of confidentiality and multiple relationships differ from their colleagues working in traditional mental health settings.

Author Biographies

Esther N. Schwartz, PhD is a postdoctoral fellow in primary care psychology in the Department of Family and Community Medicine at the Texas Tech University Health Sciences Center. Dr. Schwartz received her PhD in counseling psychology from the Department of Psychological Sciences at Texas Tech University and completed an APA-accredited predoctoral internship in psychology at the Dallas VA Medical Center.

David R. M. Trotter, PhD is assistant professor and director of behavioral sciences in the Departments of Family and Community Medicine and Medical Education at the Texas Tech University Health Sciences Center. Dr. Trotter earned his PhD in clinical psychology at Texas Tech University and received postdoctoral training in primary care psychology at the UMass Medical School, Center for Integrated Primary Care (Department of Family Medicine). His areas of expertise include behavioral medicine, primary care behavioral health integration, and medical education.

Affective forecasting, the process of predicting future emotional states, often drives decision making. Individuals routinely make decisions based on what they believe will optimize their happiness or general emotional well-being, such as whether to undergo or avoid a medical procedure that may cause some degree of distress. Unfortunately, affective forecasts are prone to a number of errors that may bias decision making. For example, in general people tend to overestimate the intensity and duration of future emotional states. Applied to healthcare behaviors, overestimating future negative emotionality surrounding proactive health behaviors may lead individuals to avoid medical treatments that may actually serve to improve their health and well-being. This entry reviews basic research on affective forecasting and discusses a number of important implications for health.

Affective forecasting research grew out of investigations of the disability paradox, or the tendency for individuals to overestimate the negative emotional impact of illness and disability (Albrecht & Devlieger, 1999). Although healthy individuals tend to predict catastrophic reductions in quality of life in response to disability, those actually living with disability often adapt to illness in a manner that affords a meaningful life. This work stemmed in part from late twentieth-century researchers such as Levine and Antonovsky who were interested in how quality of life could be obtained in the face of adversity. Around this time other researchers such as Albrecht and Higgins observed discrepancies between patient-rated well-being and their physical status. In the intervening years, numerous studies documented that healthy individuals overestimate the emotional impact of life-threatening illness such as cancer and noted a reasonable degree of well-being is possible at the end of life. The disability paradox

First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

may arise from several social psychological processes including a tendency disregard the impact of coping and adaptation while maintaining a hyper-focus on isolated symptoms and subsequent impairment.

The interesting and curious findings from the disability paradox yielded further and more rigorously controlled studies. A number of social and cognitive psychologists attempted to better understand how and why people overpredict the intensity of future emotional states by utilizing basic research methods to build upon the important but sometimes anecdotal evidence for the disability paradox. Understanding affective forecasting errors is an important topic of study for these fields as predictions about how the future will unfold are directly relevant to decision making. That is, the degree to which people base immediate choices and actions on predictions about how they believe they will feel highlights the intersection of emotional forecasts and decision making. Further, if an individual's decision making is driven by current beliefs about future emotional states, these decisions may be based on inaccurate information. Not surprisingly, greater inaccuracy in future expectation leads to biased decision making across a range of day-to-day decisions, from how to spend free time to consequential decisions such as who to choose as a romantic partner or whether to pursue a particular medical treatment. For example, if an individual predicts that undergoing a particular medical procedure will lead to increased pain or prolonged stress, he or she is not likely to pursue that option, even if it might be better for their longer-term well-being or longevity.

In order to systematically study the influence of affective forecasts on decision making, researchers measure at least two major components of experience: predicted and experienced affect. First, participants make predictions about how they expect to feel in response to a future event, whether it be their favored sports team winning or losing a game, an important career event (e.g., a professor earning or being denied tenure), or a major health event (e.g., being diagnosed with HIV). These expectations are assessed in advance of the event, and then researchers measure experienced affect during the event or shortly afterward. The predicted and experienced affect ratings are then compared in order to quantify the relative accuracy of the forecasts. Additional correlates of accuracy such as personality traits are often measured, or situational variables may be modified to intentionally influence accuracy.

In general, people tend to overestimate the duration and intensity of future emotional states, regardless of whether the events are positive or negative in valence, a phenomenon called the impact bias. The impact bias is especially prevalent when individuals make forecasts about future negative life events. When experiencing negative events, individuals utilize numerous coping mechanisms (e.g., motivated reasoning, rationalization, self-justification, and other aspects of the "psychological immune system") that combat negative emotional reactions in order to help restore a sense of well-being. As people tend to disregard this active healing process when they are making predictions about their responses to a negative future event, they overestimate the effect of that event on their future emotions, a phenomenon called immune neglect (Gilbert, Pinel, Wilson, Blumberg, & Wheatley, 1998). For example, a study looked at voters' affective forecasts if their favored candidate lost an election, as well as their evaluations of the winning candidate before and after the election. Not only were voters' predictions about how they would feel if their candidate lost the election more extreme than how they felt when that event actually occurred, but they also evaluated the winning candidate more favorably after the election than they had before the election. Furthermore, the voters were unaware of this change in their views regarding the winning candidate from before the negative event to after it, which may have served as a coping mechanism to reduce their experience of negative emotions. These findings are especially important to consider when making choices regarding future potentially uncomfortable or stressful events, such as difficult medical decisions. Although individuals have a tendency to fear the worst, many are later surprised that an unpleasant outcome was less intense or long lived as anticipated.

Additionally, when making an affective forecast, people tend to focus solely on the primary event in question, a common affective forecasting bias termed focalism (Wilson, Wheatley, Meyers, Gilbert, & Axsom, 2000). By doing so, individuals fail to acknowledge other simultaneously occurring events that may serve to diminish the impact of any single event on their emotions. For example, when predicting how they would feel if their school's football team lost or won a game, college students may not consider other day-to-day occurrences that could affect their emotional well-being during the same time span and therefore overestimate their emotional reactions to the outcome of that football game. However, if individuals are asked to list activities they engage in during a typical day (e.g., going to class, eating meals, studying, socializing with friends) prior to making a forecast about the outcome of the game, the prediction tends to be less extreme. Simply stopping and thinking about life events other than the focal event mitigates the influence of focalism and leads people to make more accurate affective forecasts.

Researchers have identified additional errors in affective forecasts beyond immune neglect and focalism. For example, affective forecasts are based on one's present understanding of an event in question. Therefore, inaccurate conceptions of an event that one has never before experienced (misconstrual) or an inaccurate memory of emotional responses to an event that one has experienced before (inaccurate theories) may lead people to make errors in their affective forecasts.

A number of individual difference variables can also influence affective forecasts (Hoerger, Quirk, Lucas, & Carr, 2009). Researchers determined that factors such as personality traits, attachment style, or mood at the time of the forecast are important predictors of the intensity of forecasts and/or accuracy. For example, neuroticism, or the relatively enduring tendency to experience negative emotional states across situations, is typically associated with greater predicted and experienced negative affect. Similar findings have been found for those scoring higher in introversion. Recent research has suggested that personality factors may explain about 30% of the correspondence between predicted and experienced affect. Other traits, such as scoring higher in emotional intelligence, particularly in the domain of emotional management, is associated with making more realistic predictions about future emotional states. In addition, affective forecasting accuracy can be influenced by one's mood state. People who experience negative affect during the time of affective forecasting have been shown to overpredict the extent of their negative reactions to future events (dysphoric forecasting bias).

Although there is a large body of research on affective forecasting and impact bias in the general population, researchers know less about how affective forecasting relates to health-specific circumstances. However, understanding how these phenomena manifest in medical settings may be key to understanding how patients make important healthcare decisions that have serious consequences for their health and quality of life. For example, a large portion of the adult population may avoid colorectal cancer screenings, putting themselves at greater risk of developing colorectal cancer, because they overpredict the extent of embarrassment and pain they will experience during the procedure. They may not imagine the event accurately (misconstrual) compared to actual patient reports of the procedure. Additionally, men with prostate cancer may choose an unnecessary aggressive or surgical treatment instead of watchful waiting (a more conservative option appropriate in many cases) because they focus too much on, and thus overpredict, the negative effect of "living with cancer" on their emotional well-being and fail to consider the consequences these treatments may have on their day-to-day functioning (focalism), such as incontinence and impotence. In both of these examples, patients' inaccurate affective forecasts may lead them to make less satisfying healthcare decisions. This is one reason why affective forecasting research needs to expand beyond the social cognitive perspective, which has historically focused on samples of White, healthy college students, and draw upon the health psychology perspective in order to understand and improve healthcare decision making.

Affective forecasting biases, such as focalism and immune neglect, play a significant role in many patients' health decision-making processes. Many health decisions can be understood as preference sensitive, meaning that the available options have comparable outcomes, unknown differences in outcomes, or outcomes that vary considerably across individuals. In absence of compelling evidence favoring one option over another, these decisions are often driven by affective forecasting. Next, we will discuss examples of preference-sensitive decision making across the health continuum, including decisions about health behaviors, illness screening, treatment, disease management, and end-of-life care.

One example of preference-sensitive decisions involves the decision to engage in health-related behaviors, such as exercise, alcohol consumption, or vaccinations. Using vaccination as an example, preference-sensitive decision making often influences people's decisions to get non-required vaccines, such as flu or HPV vaccines. Affective forecasting errors, such as expectation biases, can lead people to believe that post-vaccination pain will be greater or more bothersome than what it is in reality. Additionally, anticipating future worry or regret can lead patients to get vaccinations, especially if contracting the flu or HPV is forecasted to be of greater emotional impact. Furthermore, patients focusing on the anticipated regret of increasing their risk of cervical cancer may seek the HPV vaccination to avoid that future regret. Deciding against vaccinations based on forecasting errors can negatively influence a patient's health.

Other health-related examples include screening children for adult-onset illnesses and early screening for colorectal cancer. Regarding screening children for adult-onset illnesses, parents may prefer to delay screening due to immune neglect in which parents think that the child would not be able to cope with screening results. In regard to the age at which regular colorectal cancer screening should begin, patients may prefer to begin screening earlier than recommended due to forecasting errors in which they believe that the emotional impact of an abnormal screen will be greater than in reality. Conversely, patients might avoid colorectal cancer screenings altogether if overestimating the distress evoked by the screening process. Screening is an important aspect of preventative healthcare that can be significantly influenced by affective forecasting.

Affective forecasting also plays a role in preference-sensitive prevention and treatment decisions, such as starting preventative breast cancer medications and treating low-risk prostate cancer. Preventative breast cancer medications, such as tamoxifen, may reduce patient's risk of developing breast cancer, but patients often choose against these medications if they believe it will increase their health-related stress. Additionally, options for treating low-risk prostate cancer include (a) watchful waiting, in which patients and physicians monitor the cancer's progression; (b) surgery, after which urinary incontinence may occur; or (c) chemotherapy, in which debilitating side effects may occur. Some patients may choose watchful waiting because of difficulties recognizing their ability to cope with side effects or an overestimation of the intensity and duration of surgery or chemotherapy side effects. Other patients may choose surgery or chemotherapy because of difficulties recognizing their ability to adapt to a watchful waiting lifestyle and the potential anxiety of knowing cancer is present. In both of these scenarios, the pivotal factor is that challenges anticipating coping skills under varying circumstances can lead people to make decisions they later regret. Clearly, more research is needed to determine how to help patients to make forecasts more accurately.

In chronic disease management, preference-sensitive decisions can also be influenced by affective forecasting errors. For example, patients with kidney problems may need to choose between dialysis and an organ transplant. One patient may choose dialysis due to an underestimation of their ability to adjust to stress and post-transplant protocols, such as taking immunosuppressant medications, but another patient may choose a kidney transplant because he or she overestimated the extent of future improvements to their health after a transplant. Forecasting errors in disease management can influence which decisions a patient believes are preferable, but very little is known about the relative accuracy of affective forecasts in disease contexts, let alone individual differences or situational factors that may augment accuracy.

Affective forecasting also influences preference-sensitive decisions at the end of life. Patients may decide against palliative care if they overestimate the distress of palliative care consultations that are frequently viewed as “giving up,” rather than empathic conversations aimed at improving quality of life. Conversely, some patients may decide against disease-directed therapy if they overestimate the emotional toll of aggressive end-of-life treatments. In either situation, patients may be underestimating their ability to cope with side effects and/or overestimating the extent to which they will have to adjust to palliative or disease-directed care. More attention and investigation is needed to help patients and their families understand and make these difficult decisions.

Notably, patients are not the only individuals whose decisions are influenced by affective forecasting errors. Focalism and immune neglect may also influence families of patients and physicians in ways that affect the patient’s decision making. For example, family members may underestimate a patient’s ability to adjust and overestimate the emotional duration of a side effect. In these situations, family members’ difficulties in affective forecasting could sway patients’ healthcare decisions.

In the context of medical decision making, individuals often heavily weigh the perceived emotional consequences as they consider between alternative treatment plans. To the extent to which individuals are biased toward overestimating negative emotional consequences, they may be less inclined to follow through with a potentially beneficial treatment. Therefore, basic and applied researchers have explored interventions to help mitigate decisional biased resulting from the disability paradox and affective forecasting errors. For instance, Ubel and colleagues have demonstrated that prompting individuals to reflect on adaptation may lead to increased estimates of quality of life with paraplegia. However, it is unclear how these processes may generalize to medical decision-making situations where patients must choose between various treatment options.

Emotional well-being plays a pivotal role in motivating health behavior. The perceived enjoyment of health behaviors tends to be more important predictors of future behavior compared with rational assessments of risk and benefit (e.g., continuing to smoke for enjoyment despite recognizing the risks of lung disease; Loewenstein, Weber, Hsee, & Welch, 2001). Women at high risk for breast cancer who perceive limited emotional benefit from chemoprevention are less inclined to opt for those therapies. Because emotional outcomes to novel events can be hard to predict, it is possible that patients may benefit from more explicit information on how they may feel following various treatment options. Basic research by Gilbert, Killingsworth, Eyre, and Wilson (1999) found that prediction of response to anticipated events could be enhanced by gathering information from others who had already experienced those events. Similar applied research by Dillard and colleagues suggests that forecasting errors regarding colorectal cancer screening can be reduced by providing individuals with patient narratives about their experience with the screening process. The impact of these narratives on participants' attitudes toward screening was significantly more favorable compared with participants who did not receive the narratives.

Although anecdotal information and patient narratives may hold some influence over medical decision making, additional research is needed to determine how information could be derived and delivered. Consistent with the goals of the Patient-Centered Outcomes Research Institute (PCORI), clinical trials are needed to assess the differential impact of medical treatments on emotional outcomes so that this information can be shared with prospective patients and reduce uncertainty about emotional well-being. There is also a need to further explore how this information would be shared with patients in clinical settings. For instance, routine distress screening is now standard care, but healthcare professionals vary widely in their willingness and competence in addressing patient concerns. If comparative efficacy data on emotional well-being can be routinely tracked and providers can be coached to deliver this information with compassion and competence, patients may be guided to make better informed decisions.

While much of this discussion has focused on affective forecasts about specific life events, it is also important to emphasize that relatively generalized affective forecasts about the future—that life is getting better or worse—can have important implications for decision making, perhaps regardless of the accuracy of these expectations. Affective forecasting studies have often focused on predictions about the relatively immediate emotional consequences of events that are highly discrete, and often controllable, with the assumption that if people could forecast more accurately, they might make different and more satisfying life decisions. In the health arena, some events are relatively discrete (e.g., screening tests, influenza vaccinations, surgery). Other health events are significantly more complex such as the development and treatment of many chronic health conditions, which unfold gradually over time, are multidetermined by factors that vary in controllability, and are potentially influenced by decades of decisions. Thus, while people have specific affective forecasts relevant to relatively discrete events, they also have more generalized affect forecasts about the emotional consequences of aging, changing health trajectories, or the future, more globally. Along these lines, fuzzy trace theory (Reyna, 2008), for example, emphasizes the importance of people's relatively intuitive, gist-level understanding of life events (e.g., "the future is terrifying," "I can't handle cancer and a divorce," or "I'm lucky they caught it early") for decision making. These generalized affective forecasts refer to the more nebulous and long-term expected trajectories in emotional well-being, rather than the relatively short-lived affective reactions often studied under the social cognitive paradigm. When people experience a generalized expectation of improved emotional well-being, this has often been called "hope," which contrasts with the generalized negative expectancy, or "dread." Regardless of accuracy, the valence of these generalized expectations—relative hope or dread about the future—could have serious implications for decision making.

The importance of generalized affective forecasts about the future—the experience of hope or dread—has known importance to health and is potentially a fruitful path for further investigation. As summarized by crisis decision theory, which has organized several useful frameworks for understanding emotion and health decision making, people routinely manage negative anticipatory emotions by mentally and behaviorally disengaging. Thus, when people feel more hopeful about the future, they may be more inclined to engage in proactive health behaviors, but when experiencing dread, worry, or hopelessness, people may be more inclined to avoid proactive health behaviors. Several studies have shown, for example, that people who are more hopeful are more likely to have better medication adherence, seek cancer screenings, engage in exercise, and maintain healthy diets. Patients who are more hopeful may also be more likely to engage in "shared decision making," a collaborative process by which patients actively participate in preference-sensitive decisions. These sorts of affective forecasts may also have important implications for suicide and other escape–avoidance behaviors. Whereas suicidal ideation and suicide attempts in young adults often receive considerable attention, older adults are at the greatest risk of completed suicide, with the highest rates among older White males, especially those recently diagnosed with a serious health condition and when in the context of other life stressors, such as divorce and unemployment. The experience of hopelessness is a leading predictor of completed suicide in older adults, suggesting the importance of generalized affective forecasts about changing health circumstances in accounting for suicidal behavior.

These findings help to illustrate an important unanswered question in affective forecasting research: what constitutes a "good" affective forecast? The social cognitive paradigm has traditionally focused on accuracy, but as emphasized in Funder's (1995) realistic accuracy model of human judgment, there are other possibilities. One might define the relative goodness of an affective forecast not based on accuracy, but some other criterion, such as whether it is hopeful, benefits current emotional well-being, fosters particular decisions about health and healthcare, or has a beneficial impact on longevity. The impact bias suggests that in light of declining health circumstances, people may be inaccurately negative in their perceptions of the future; thus, helping patients to forecast more accurately is essentially synonymous with helping them to be more positive and hopeful. In contrast, near the end of life, conversations about prognosis are often extremely overly optimistic, and this increased positivity could represent a departure from accuracy with potentially serious implications. For example, while overoptimism may have immediate emotional benefits, it has been hypothesized to be an important driver of overtreatment, lower quality of death, poorer family bereavement, and medical bankruptcies. Therefore, in the context of end-of-life care, there is an important debate over the relative importance of realistic versus optimistic communication, the relative benefits of accuracy versus positivity, and even the meaning of the construct "hope" itself. Many have advocated for approaches that, while difficult, seek to increase accurate perceptions of the future while simultaneously fostering a sense of hope and controllability (variously described as "realistic hope," "deep hope," and "blues-inflicted hope"). Ultimately, there are many important open questions about the ways in which affective forecasting drives decision making and health.

In conclusion, this section demonstrates the importance of basic research on affective forecasting for understanding decision making across the healthcare continuum. More research is needed to quantify the significance of affective forecasting in medical populations and examine interventions for improving affective forecasting, decision making, and healthcare outcomes.

Background

Rotator cuff injuries are one of the most common joint ailments plaguing older adults today (e.g., Raymond, Sluka, McGowan, & American Academy of Orthopaedic Surgeons, 2011). This chapter describes the clinical epidemiology of shoulder impairment in older adults, standard approach to management, and the current ambiguity of the literature on the effectiveness of interventions for optimizing long-term outcomes. Preliminary data is presented grounded within a theoretical model, supporting the hypothesis that patients use "out-of-date" self-prototypes to establish expectations for outcomes, which has significant implications for long-term self-management behaviors and may explain lack of adherence to therapy. Finally, the authors describe feasibility work on theory-based interventions that have the potential to address and inform unrealistic patient expectations.

Epidemiology of Shoulder Impairment in Older Adults

The prevalence of symptomatic rotator cuff tendinopathy in the general population ranges from 2.8 to 7.6% (Milgrom, Schaffler, Gilbert, & van Holsbeeck, 1995; Reilly, Macleod, Macfarlane, Windley, & Emery, 2006; Senbursa, Baltaci, & Atay, 2011; Silverstein et al., 2006), while asymptomatic rotator cuff tendinopathy is found in 10–20% (Milgrom et al., 1995). Rotator cuff tears are even more common, with reported prevalence ranging from 20% in the general population (Yamamoto et al., 2010), 30% in cadaveric studies (Reilly et al., 2006; Silverstein et al., 2006), to 40% in adults over the age of 50 (Worland, Lee, Orozco,

The Wiley Encyclopedia of Health Psychology: Volume 3: Clinical Health Psychology and Behavioral Medicine,
First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

SozaRex, & Keenan, 2003). Self-reported prevalence of shoulder pain among all adults is estimated to be between 16 and 26% and is the third most common cause of musculoskeletal consultation in primary care (Luime et al., 2004; Urwin et al., 1998). Symptomatic pathology is increasingly common with age, occurring in up to 80% of adults over the age of 80 (Milgrom et al., 1995). The resultant pain and reduced range of motion (ROM) can significantly impair functional status and independence and negatively affect quality of life (Chambers, Shea, & Carey, 2011; Cigolle, Langa, Kabeto, Tian, & Blaum, 2007; Leveille, Zhang, McMullen, Kelly-Hayes, & Felson, 2005; Sha et al., 2005). In a prior survey of older adults, the authors found a 31% prevalence of chronic, severe shoulder pain (pain lasting more than 3 months in the past year) and 48% prevalence of impaired ROM. Of those with pain and reduced ROM, 36% had impaired basic activities of upper body function (e.g., grooming) (Burner et al., 2014).

Approach to Management of Shoulder Impairment

The first-line management for shoulder impairment and pain typically includes referral to physical therapy (PT) and home exercise programs (HEP) (Hawkins & Dunlop, 1995; Lombardi, Magri, Fleury, Da Silva, & Natour, 2008; Ludewig & Borstad, 2003). Conservative management may also include injections, pain medications, and other modalities (e.g., heat, topical analgesia). There is little evidence on which to base optimum management, with clinical guidelines being based on mostly inconclusive evidence and expert consensus (Pedowitz, Hunter, Tracy, & Brennan, 2012; Rechardt et al., 2010; Rookmoneea et al., 2010). Once patients undergo surgical repair, they are also referred to PT and instructed in HEP to maximize postoperative recovery.

There has been an increase in surgical treatment of rotator cuff trauma by 141% over the 10-year period from 1996 to 2006. When adjusting for population growth, this translates into a 115% increase in rotator cuff repairs over this 10-year period (Colvin, Egorova, Harrison, Moskowitz, & Flatow, 2012). The best operative results are seen when repairing smaller tears that are not associated with significant muscle atrophy. It remains standard practice to refer patients to PT after surgical repair to optimize recovery of ROM.

Efficacy of Management

Conservative treatments such as PT and HEP have been shown to contribute to significant improvement in function in small trials, though it may take many months or even years to reach full impact (Chambers et al., 2011; Fritz, Childs, Wainner, & Flynn, 2012). In usual clinical practice, many older adults have limited contact with PT for their shoulder impairment, and it is unknown how long they continue to maintain HEP. The average number of PT visits per patient for shoulder problems has been reported at about 9 over a period of 4 weeks (Fritz et al., 2012). In a longitudinal assessment of shoulder pain in general practice, 41% of patients with reported shoulder pain showed persistent symptoms after 12 months following conservative therapy (Luime et al., 2004). For those experiencing improvement in pain and function with PT, the degree of improvement, and how long improvements are sustained, is generally not specified (Chambers et al., 2011; Fritz et al., 2012). Surgery may lead to significant improvement in function, but pain and limited mobility are unlikely to resolve completely, and re-tearing is a common long-term complication (Van der Windt et al., 1996).

Several factors play into the paucity of high-quality literature on conservative management for rotator cuff impairment. Quantifying improvement remains a challenge, as no standardized treatment protocols or gold standard outcome measurements exist. Methodologic issues are prevalent, and published studies frequently are uncontrolled, and lack consistency in the outcome scales used to measure pain, ROM, and function (Chambers et al., 2011; Rookmoneea et al., 2010). Despite these limitations, there does seem to be improvement in rotator cuff symptoms without a full-thickness tear with PT (Bennell et al., 2010; Lombardi et al., 2008) or HEP (Ludewig & Borstad, 2003) and no difference comparing PT with HEP (Walther, Werner, Stahlschmidt, Woelfel, & Gohlke, 2004; Werner, Walther, Ilg, Stahlschmidt, & Gohlke, 2002). Adjunct therapies such as scapular stabilization (Baskurt, Başkurt, Gelecek, & Özkan, 2011) and manual therapy (Bang & Deyle, 2000; Senbursa et al., 2011) may provide additive benefit to PT. The improvements in pain range from 2 to 4 cm on the Visual Analogue Scale maintained at 8–10 weeks' follow-up (20–40% decrease in symptoms) (Bang & Deyle, 2000; Lombardi et al., 2008; Ludewig & Borstad, 2003). Improvements in pain, ROM, and function in these studies are maintained at 6–22 weeks of follow-up, though the magnitude of gain is vague (Baskurt et al., 2011; Bennell et al., 2010; Lombardi et al., 2008; Silverstein et al., 2006; Walther et al., 2004; Werner et al., 2002). Less evidence exists for the efficacy of PT and HEP for full rotator cuff thickness tears, consisting mainly of uncontrolled case series. Supervised PT (Ainsworth, 2006; Baydar et al., 2009; Hawkins & Dunlop, 1995) and HEP improved patients' function, with improvement maintained at 3 months to 3.8 years of follow-up (Bennell et al., 2010; Lombardi et al., 2008).

Thus, patients with rotator cuff issues are typically referred for PT, both with and without surgery and other treatment modalities. With any approach to treatment, it often takes months to years for full recovery, and though extended PT and HEP (self-management) may help to attain optimum outcomes, full recovery may never be achieved. If patients have the expectation that treatment should result in complete resolution of all symptoms and restoration of full function, especially in a short amount of time, they have a disincentive to maintain longer-term treatment. Because patients often focus on somatic symptoms (e.g., pain) and restricted movement as indicators of ineffectiveness of treatment, this may be particularly likely to happen with shoulder dysfunction and result in less than optimal self-management.

The Commonsense Model of Self-Regulation (CSM) as a Framework for Examining Management of Shoulder Impairment

CSM is based upon the patient's representations or mental models of the illness (e.g., rotator cuff injury), the procedures for treatment (e.g., surgery, PT), an action plan for implementing treatment, and timeline and expectations for outcomes against which they assess efficacy of a treatment. "Normal" ROM and strength is the underlying "self-prototype," which may be conscious and or automatic (e.g., "normal shoulder function will feel like it did when I was 25"). The creation of representations begins with the awareness, either implicit (minimally conscious) or explicit, of deviations from the normal, "healthy" self: pains (e.g., shoulder pain) and functional changes (trouble reaching, carrying). The location and properties of an experienced deviation (sharp pain when overextending the shoulder), its time frames (rapidity of onset, duration), perceived causes (a fall), and response to self or medical treatment (heat eased the pain, rate of "improvement") are concrete perceptual factors that "define" the deviations as a shoulder injury. The impact of the disorder on thought, physical activity, social exchanges, and work defines its perceived and anticipated consequences.

The five content areas of an "active" mental model are *identity* (symptoms and location), *timelines*, *cause*, *control*, *and consequences.* These areas are generated by the match of the deviations from the self-prototype to a belief structure or prototype of a specific illness. An active mental representation suggests a range of actions for ameliorating the perceived discrepancies that will be experienced as coherent with the illness/injury representation and repeated as needed. If benefits are temporary (timeline violated) or absent (no alleviation), or insufficient to permit important life activities (consequences), the individual is highly likely to talk to family and/or friends and eventually seek medical care (Cameron, Leventhal, & Leventhal, 1993).

Differences in the "changeability" of these processes are unfortunately little understood. Active mental models, that is, representations of an illness, a treatment, and their coherence (the treatment fits the problem, i.e., how it works), are potentially highly flexible, while the underlying prototypes are less so. The two least flexible prototypes are (a) the usual/healthy self (Self as Anchor) and (b) expected outcomes of action, that is, the fundamental "Expectancy that Actions Produce Immediate Outcomes" (EAPIO). The self is a powerful, underlying anchor, as the self is experienced implicitly and sometimes explicitly, every moment of the 24 hr in a day, every day of every year of life. Deviations and outcomes of actions (benefits) are perceived and measured against this anchor, and it shapes life expectancies (Mora, DiBonaventura, Idler, Leventhal, & Leventhal, 2008). The EAPIO is an anchor for action; the acquisition begins at birth, as the infant perceives environmental changes in response to action (the mobile moves when legs are shaken; grasping the object seen brings it to the mouth). When action fails to produce an immediate outcome and mom does not come in response to the cry, the cry morphs into distress, rage, and loss of hope. Violations of EAPIO are experienced daily, for example, when the effort needed to lift an apparently light or heavy object is discrepant with experience (small object is extremely heavy, large object unexpectedly light).

The Self as Anchor and EAPIO are critical factors for examining the rehabilitation process. The contrast between Self as Anchor and current function (e.g., rotator cuff injury) creates the representation of injury and the target and/or "hope" for treatment outcome. The model suggests that the representation of injury (perceived difference between pre- and post-injured self) often exceeds reality. The "psycho-logic" for this is simple; the sense of normal Self as Anchor is overlearned, and the "how I am now" versus "how I am (normally) supposed to be" is magnified. The best-case scenario for therapy is when the results are perceptible and match or exceed expectations. The worst case is that pain and distress following PT (negative feedback) overwhelms actual improved motion. Such immediate effects need to be seen and understood in terms of an extended time frame or pathway to reach recovery; otherwise maintenance of treatment is unlikely.

Self-Prototypes: The Case in Shoulder Impairment

Individual psychosocial factors such as passive coping style, fear of movement, and general psychological distress may impact the chronicity of symptoms. Patients also have explicit expectations for diagnosis, recovery, and self-management of their condition. Such "common-sense" perceptions may not accurately reflect the underlying biophysical and medical factors at play. There is often a difference between objective clinical and radiological evidence of musculoskeletal disease activity and a patient's experience of pain and functional ability (Hanusch, Goodchild, Finn, & Rangan, 2009). If actions are taken, and expected results are not seen within the anticipated time frame then further assessment and intervention may be justified (e.g., "I've gone to PT for my shoulder for 6 weeks and it doesn't feel like it's back to normal, so PT is obviously not working"). For patients, the greatest impact of their disease lies in the effect it has on their ability to continue with "normal" life. All the physician authors have had such perceptions communicated by their patients during the course of routine practice (SG, EB, AR).

A series of studies were conducted to explore patients' underlying self-prototypes and expectations for outcomes of PT in relationship to impaired shoulder function. In tandem, feasibility data was gathered on a system that will provide patients with clear, objective feedback on changes in ROM of an injured rotator cuff, allowing them to see that PT and HEP do improve shoulder function. We utilized a prototype software application and Kinect^{TM} system to generate and record a stick-figure image, or skeletal avatar, that may be stored and replayed to visualize progress in ROM over time. The feedback is designed to overcome the lack of awareness of the very gradual, slow changes generated by PT and HEP and maintain motivation for long-term adherence.

Semi-structured interviews were conducted with patients entering PT for shoulder pain for the first time ($N = 15$) and patients planning to undergo surgical rotator cuff repair ($N = 10$) to gather preliminary data on underlying self-prototypes (i.e., self "baseline" against which patients were comparing outcomes of treatment), expectations for outcomes of treatment, and anticipated timelines to reach successful outcomes. Mean age of the PT group was 65.7 ± 5.9 years, with an average of 6.3 chronic medical conditions (range 0–16). The presurgical group had an average age of 47.8 ± 11.2 years and a mean of 5.7 chronic conditions (range 1–21). About 90% of the entire group of patients reported shoulder pain lasting at least 3 months out of the last year, a decreased ability to complete basic activities of daily living (e.g., grooming, dressing), and that their sleep had been adversely affected by shoulder pain.

Self-Prototypes, Expectations, and Timelines for Outcomes

All patients were asked to give their age when their shoulders last felt "normal," that is, without any pain or symptoms of impairment. PT patients who had never gone for PT before ("PT-naive") all gave ages at least 15 years younger as their self-anchor (range 15–40 years). Those who had previously been to PT for other problems, expected their shoulder to function as it had 1–2 years previously. All save one of the surgical patients expected their postoperative shoulder to feel and function as it had at least 15 years earlier. The only patient who varied from this pattern, giving his current age as "baseline normal," had undergone rotator cuff repair of the opposite shoulder several years before and so had already experienced the procedure and its outcome.

When questioned about expectations for outcomes of treatment, most patients expected to regain 90% or more of normal function, expected steady improvement, and reported they would stop HEP if they experienced any pain or discomfort. The one patient with previous shoulder surgery estimated regaining only 50% of prior normal function. This individual had *objectively* regained about 90% function in the previously injured shoulder, but reported regaining only 75% of normal function, and expected a worse outcome for the current impairment. This exemplifies the CSM construct of an "overlearned" self-prototype, with exaggeration of a current deficit and projection of this onto future outcomes. All the participants had unrealistic expectations for timeline of recovery, estimating it would take 6 months or less. Forty percent of the entire group estimated it would take less than 4 months to regain full function, and none thought it would take more than a year.

The results of these interviews highlight that patient expectations about recovery of shoulder ROM may be unrealistic, both in terms of timeline and extent of recovery. The CSM predicts that patients use underlying prototypes or "anchors" of the "healthy self" as a comparison for desired outcomes. These anchors/prototypes may date back many years and not reflect that person's actual pre-injury "baseline." Other factors, such as lack of education on the typical course of musculoskeletal ailments, lack of willingness to experience pain in the context of healing, or unrealistic attributions of one's injury, may all moderate adherence to treatment choices and self-management. Because all patients reported expectations for steady improvement and progress without setback (even the "surgically experienced" patient), the experience of pain or other perceived setback may negatively impact a patient's adherence to PT due to perceived lack of efficacy. In general, patients failed to recognize that there might be overlap of discomfort from both PT and an underlying injury, or variability in symptoms.

Technology for Addressing Unrealistic Timelines and Expectations for Outcomes

The described surveys of patients entering PT for treatment of shoulder impairment found that the majority have unrealistic expectations for recovery, have difficulty in accurately assessing improvement, and express frustration about lack of positive feedback during PT. Technology such as the Kinect imaging sensor has the potential to address these misperceptions to improve adherence and outcomes from PT.

The best-case scenario for therapy is when the results, such as improved movement and less pain, match or exceed expectations. The worst case is that negative feedback such as pain and distress during or following PT overwhelms the perception of improved motion. Such immediate effects need to be seen and understood in terms of an extended time frame or pathway to recovery; otherwise adherence to a long-term therapy regimen is unlikely. Our Kinect application has the capability to record and store successive images of a patient's ROM representing progress over time; viewing stored images alongside current ROM allows the patient to see how his/her movement has improved from "worst function" to the present, providing concrete evidence of efficacy that overrides momentary doubts about benefit and negative feedback (e.g., pain during movement). Such images also provide a dynamic record of ROM, instead of clinician recall or static measurements recorded during prior PT sessions.

The authors have designed a software application (JU) that takes the camera image and translates it into a skeleton or "stick avatar" of the patient that is displayed on a screen in real time. As the patient proceeds through an ROM exercise, the avatar shows this range on the screen along with fiducial limb ROM measurements for each exercise. The system is also capable of simultaneously displaying a prerecorded avatar, that is, prior patient images or exemplar patient. The patient (and clinician) thus receive immediate feedback on patient ROM because the application can record and store successive patient images for later review, allowing them to observe progress over time. Feasibility testing was completed in a proof-of-concept trial on the surgical patients at "baseline" (preoperatively) and at 6 weeks and 3 months' postoperatively. At each visit shoulder ROM was measured by a clinician visually and with the Kinect. Motions assessed for all participants included forward elevation, external rotation with arm abducted and arm at side, and abduction.

The angle measurements as recorded by the Kinect showed a strong correlation to the clinician measurements ($R = 0.966$, 95% confidence interval 0.940–0.981), with no significant difference between the two ways of measurement ($t = -0.23$, $p = 0.81$). As anticipated, ROM was impaired at baseline on the side of injury, was even more restricted at 6 weeks' postoperatively (about the time when patients could start moving their shoulder), and improved significantly at 3 months.

These data demonstrate the feasibility and validity of the Kinect system to record angle measurements that are in line with, and not statistically different from, that measured by a clinician. The observed ROM over time showed the pattern that would be expected over the course of surgical management of a rotator cuff injury: decreased ROM at baseline, followed by an even greater decrease after 6 weeks of immobilization following surgery, and improvements over baseline by 3 months. The benefits of this system include the ability of clinician and patient to track their improvements over time with concrete data and measurements to provide the patient with positive feedback to override temporary doubts and lapses in motivation. The system is currently being tested in a randomized trial. All participants are imaged prospectively over the course of PT, but half view their progressive images at each visit. This application will eventually be deployed in the home setting by migrating the application to a tablet or smartphone and will include the ability to send ROM data directly to the clinician for monitoring. This approach could limit unnecessary follow-up visits and cut healthcare costs while allowing the patient to continue their PT at home with proper visual feedback and clinician updates to instill motivation over time. Similar ROM images and measures are being collected on normal, healthy subjects to get a preliminary sense of interindividual variability. This data may be used to develop "ideal ROM" avatars that can be displayed with individual patient images as target goals for recovery.

Conclusion

Moving forward, it is hoped that providing patients with accurate feedback on progress over time (such as that provided by the Kinect imagery) will override subjective perceptions of lack of progress and thus improve long-term adherence to treatment. Another implication of this research is that clinicians may improve patient adherence by assessing their expectations for recovery as part of their initial evaluation and directly addressing unrealistic expectations. This study did not evaluate whether changing a patient's expectations leads to improved outcomes, but it does suggest that patients with shoulder pain are underinformed and unrealistic about the usual course of their disease.

Trends in Clinical Health Psychology and Behavioral Medicine

C. Steven Richards[1] and Lee M. Cohen[2]

[1]*Department of Psyschological Sciences, Texas Tech University, Lubbock, TX, USA*
[2]*Department of Psychology, College of Liberal Arts, The University of Mississippi, Oxford, MS, USA*

Clinical health psychology and behavioral medicine are interesting and important specialty areas where various healthcare fields intersect. In this entry, we briefly discuss seven trends, that we believe, are shaping these fields, including (a) methodological sophistication, (b) chronic diseases, (c) diversity and inclusiveness, (d) biological issues, (e) translation of health psychology knowledge, (f) chronic psychopathology that is comorbid with health problems and diseases, and (g) social justice. We conclude this entry with a brief discussion of recommendations regarding theory, research, and practice to consider for the future.

Methodological Sophistication

After a review of the research in clinical health psychology and behavioral medicine, it is clear that the intricacy of the studies being published has progressed significantly in multiple ways. For instance, many studies include large and diverse samples of participants. Sampling effectively is one of the cornerstones of sound research and certainly in any area involving human participants. An example of a recent study that includes a large and diverse sample was conducted by Polenick, Renn, and Birditt (2018), where they studied the dyadic effects of depression on medical morbidity among 992 middle-aged and older-adult couples. One of the major findings of this study was that depressive symptoms in this population have long-term associations with medical morbidity, such as chronic health conditions.

Another indication of the current methodological sophistication in this area is an increased use of multi-variable, multi-trait, and multi-method measures, with sound psychometric properties. Such methodology permits the collection of a more thorough picture of the

First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

cognitive, emotional, behavioral, biological, and other health outcome variables relevant to the research questions being studied.

An interesting example is a study that explored the longitudinal pathways to alcohol use and abuse among 426 adolescents who had genetic risk factors for addiction, by Trucco, Villafuerte, Hussong, Burmeister, and Zucker (2018). These investigators predicted that the pathways under investigation would be moderated by depression and depressive relapse during the last wave of the study, which included adolescents aged 15–17 years. More specifically, it was expected that depression would be related to more substance use and would essentially facilitate the expression of the genetic risk factors. Trucco et al. (2018) also predicted that ineffective coping methods for stress would be a moderator, related to greater substance use. The investigators' predictions were supported: ongoing depression (or depressive relapse) over time, along with ineffective coping methods, appears to be a pathway that allows genetic risk factors to influence substance use and abuse. This study represents multiple research trends toward excellence in clinical health psychology and behavioral medicine, such as including a large sample ($N = 426$, plus a comparison sample), which was followed longitudinally over many years (ages 3–17, in 5 waves), with diverse measures (multi-method, multi-trait, and multi-source), and attention to both biological and psychological variables. Trucco et al. (2018) included measures of demographics, family history, temperament, coping, depression, aggression, substance use, and biological correlates such as gender, race, and genotyping. Data were obtained from multiple sources for the psychosocial variables. Moreover, this study provides a rich evidence base for future efforts at health promotion and intervention.

In summary, methodological sophistication is one of the important trends in research on clinical health psychology and behavioral medicine. Indeed, recent editorials by editors of some of the major journals in the field have boasted about this trend and called for it to continue (e.g., for discussions of methodological issues, see Appelbaum et al., 2018; Freedland, 2017; Lilienfeld, 2017).

Chronic Diseases

Another trend in clinical health psychology and behavioral medicine is an emphasis on psychosocial variables in the context of chronic diseases. There is tremendous interest and concern regarding highly prevalent chronic diseases such as heart disease, cancer, stroke, diabetes, arthritis, flu and other pandemic diseases, and so forth. These diseases are often listed in the top 5 or 10 causes of death from disease among adults across the industrialized world. Furthermore, psychosocial variables have been established as having important mediating, moderating, and health-promoting effects for the course and outcome of such diseases (e.g., for a readable review, see Taylor, 2018).

An example of an excellent study illustrating this trend is a recent study by Manne, Siegel, Heckman, and Kashy (2016). This study included 302 female patients with early-stage breast cancer, along with their spouses. For the most distressed patients, a couple-focused and supportive version of group therapy appeared to be the more-effective intervention for coping with psychosocial variables such as depression and anxiety. In contrast, for patients who were less distressed, a structured and skills-based version of group therapy appeared to be the most effective for reducing depression and anxiety, and in an associated manner, also improving health-promoting behaviors such as stronger adherence to medical regimens. This study successfully addressed some of the common research concerns among the psycho-oncology research community, such as including a relatively large sample, a longitudinal and randomized controlled design, and use of a broad array of measures.

There are also numerous excellent examples of research examining combined psychosocial and medical interventions for post-heart-attack patients that are represented by the ENRICHD and CREATE randomized controlled trials (Berkman et al., 2003; Lespérance et al., 2007). These large trials (with beginning sample sizes of 2,481 and 284, respectively) randomized participants to combinations of SSRI antidepressant medications and either cognitive behavior therapy (ENRICHD) or interpersonal psychotherapy (CREATE) or usual care with brief supportive counseling from clinic and healthcare staff.

In addition to the standard goals of better heart health and medical improvement after a heart event, the treatment goals included improvement in depression and social support (Berkman et al., 2003; Lespérance et al., 2007). Numerous correlational studies have indicated clear relationships between these psychosocial variables and long-term heart health in cardiac disease patients. Although a comprehensive summary of the results from the ENRICHD and CREATE trials is beyond the scope of this brief entry, a major finding was that the medication plus psychosocial intervention conditions indicated improvement in depression and social support over time. However, these psychosocial improvements were not associated with significantly fewer heart events or cardiac fatalities over time. Therefore, while the improvements observed during follow-up visits on the psychosocial measures was encouraging, there was disappointment that improvements in depression and social support over time did not translate into improvement in physical cardiac health and avoidance of future heart attacks. Nonetheless, these heart disease studies stand as excellent examples of sophisticated research on psychosocial processes associated with disease.

In summary, there have been numerous excellent studies regarding clinical health psychology, behavioral medicine, and chronic disease. Chronic diseases are major killers, however, and we need to learn more. Fortunately, there appears to be movement in this direction, although the large randomized controlled trials like those noted above are expensive and thus vulnerable to the funding patterns of major national granting agencies and foundations/societies focused on health, such as the National Institutes of Health (United States), the National Health Service (United Kingdom), the American Heart Association, and the American Cancer Society.

Diversity and Inclusiveness

We live in a diverse world and the benefits of inclusiveness are obvious. Therefore, many areas within clinical health psychology and behavioral medicine, as with other fields that engage in theory, research, and practice relevant to human beings, have witnessed a large increase in studies and interventions that focus on diversity and inclusiveness. From our perspective, this is one of the most important trends in clinical health psychology and behavioral medicine (e.g., see the editorial by Davila, 2017; and the special section overview, on sexual and gender minority health, by Davila & Safren, 2017).

An example of a determined effort to recruit a diverse sample is a study examining physical activity and depressive symptoms after treatment for breast cancer (Brunet, O'Loughlin, Gunnell, & Sabiston, 2018). The early research in this area was often limited to samples of entirely Caucasian women, within a small age range, who were relatively well educated and mostly married or living with a partner. In contrast, this large study of 201 women with breast cancer reflected efforts to recruit a more diverse sample, including a wider range of age, race, civil status, and education. This study also evidenced considerable diversity regarding medical variables such as stage of cancer, treatments received, and time since treatment completion. The investigators acknowledge, of course, that even more diverse samples will be helpful for future research. One of the major findings from this investigation is that more physical exercise was associated with less frequent depressive symptoms among participants after treatment for breast cancer; however, not all of the predicted relationships between depression and exercise were maintained longitudinally.

Another recent example of a study that included ambitious efforts to recruit a large and diverse sample is a study that examined the associations between pharmacotherapy for diabetes and immigrant status in the United States; this study was conducted by Hsueh et al. (2018). While a complete discussion regarding the many variables in this study that examined diversity is beyond the scope of this entry, if we focus solely on the race, ethnicity, and education variables used, there were numerous participants across several racial and ethnicity groups, including 28% non-Hispanic Black, 18% Mexican American, 8% other Hispanic, 6% multiracial, and 40% non-Hispanic White. Educational level completed was also quite diverse, ranging from ninth grade or lower to college graduate or above. One of the major findings included a clinically significant result that being foreign born was associated with significantly reduced odds of receiving insulin treatment (Hsueh et al., 2018). There were also some differential patterns of associations with treatment offerings and different racial/ethnic group membership. These results suggest that perhaps integrating diversity information about a patient's immigration status and racial/ethnic identity would allow for a more culturally sensitive care of diabetes.

In summary, we live in a diverse world, and additional research like the studies noted above is needed. It is essential that future studies make it a priority to recruit and assess diverse participants and consider relevant diversity variables.

Biological Issues

Traditional research on chronic health problems and diseases has characteristically paid considerable attention to biological factors. More recently, social scientists are paying increasingly more attention to such variables. Specifically, the fields of clinical health psychology and behavioral medicine appear to be moving toward a stronger biological focus (e.g., see editorials by Freedland, 2017; Lilienfeld, 2017). Furthermore, this increased focus on a biological emphasis is facilitated and enhanced by recent technology, such as MRI, PET, and CT scans. The sophistication and options available for biological assays of blood, urine, hormones, neurotransmitters, and so forth have expanded and become more accessible. Moreover, the ability to evaluate, store, and reexamine biological samples has grown tremendously (e.g., see discussions in Taylor, 2018).

An interesting example of a health psychology study that incorporates biological variables is the Trucco et al. study (2018), mentioned earlier in this entry. Trucco et al. (2018) included measures of genotyping, focusing on the polymorphisms from four genes, which were predicted to be relevant to the substance use variables being studied. A major finding was that depression and ineffective coping methods appear to be a pathway that allows genetic risk factors to influence substance use and abuse.

Another example of biological measures being utilized in recent clinical health psychology research is an investigation by Bakhshaie et al. (2018). The authors used a carbon monoxide analysis of breath samples as a method to verify the participants' smoking status. Similar biochemical verification methods have been used in numerous smoking cessation research studies, along with other studies on nicotine and tobacco use. One of the investigators' primary findings was that teaching the participants strategies to more effectively manage symptoms of anxiety and depression appeared to be associated with fewer withdrawal symptoms, and thus better outcomes, in a smoking cessation study (Bakhshaie et al., 2018).

In summary, the inclusion of biological variables in clinical health psychology and behavioral medicine research is becoming more common, more sophisticated, and more central to the questions being asked.

Translation of Health Psychology Knowledge

Research studies conducted in laboratories, with carefully controlled variables, under almost perfect conditions are important. However, it is also critical that findings be applicable in real-world situations. These real-world situations often involve imperfect conditions, limited resources, overworked healthcare providers, underserved patients, and numerous other challenges. Practical and cost-effective translations have found encouraging effectiveness in real-world settings, in part, by using mobile and online technologies, public health education campaigns, social service agencies, charitable organizations, and religious organizations (e.g., see the journal editorial in *Translational Behavioral Medicine* by Miller-Halegoua, Bowen, Diefenbach, & Tercyak, 2016).

O'Hara and his colleagues have conducted several randomized controlled trials and more naturalistic, low-cost intervention trials in healthcare clinics with depressed postpartum women. Their findings indicate that interpersonal psychotherapy interventions in the acute phase of depression treatment, and/or during maintenance treatment, are helpful for depressive relapse prevention among women who often had numerous health challenges and who were also caring for young children (e.g., Nylen et al., 2010; O'Hara, Stuart, Gorman, & Wenzel, 2000; Serge, Brock, & O'Hara, 2015). Moreover, these studies showed a transition themselves, from efficacy-like studies as seen in O'Hara et al. (2000) to more translational studies as seen in Serge et al. (2015). Thus, even in economically challenged and underserved populations being treated in real-world healthcare settings with limited resources, interpersonal psychotherapy has potential as both an acute and maintenance treatment for depression and as a treatment that can be translated into real-world settings (e.g., see Serge et al., 2015 for the most translational study in this series of investigations).

Another excellent translational study explored how to improve adherence to cognitive behavior therapy for insomnia (CBT-I; Dolsen et al., 2017). In this randomized trial for 188 adults with persistent insomnia, the investigators found strong support for the hypothesis that effective sleep the night before and the night after a treatment session will improve patients' adherence to many aspects of the treatment regimen. Additionally, it was found that CBT-I interventions usually improve the patient's sleep before and after a treatment session. Such sleep improvement, in turn, will improve treatment adherence, based on their findings. Given that adherence to treatment is a huge challenge for most psychosocial and medical interventions, this study is an example of a methodologically sophisticated study that may be generalizable to many healthcare environments, help clinicians and patients to improve treatment adherence, and make a significant difference in public health.

In summary, research in the fields of clinical health psychology and behavioral medicine is continuing to improve upon translating findings into practical methods that have clear applications in the real world.

Chronic Psychopathology That Is Comorbid With Health Problems and Diseases

Patients suffering from comorbid chronic psychopathology and physical health concerns commonly present in healthcare settings. As such, gaining a better understanding of the relationships between physical and mental health is essential if treatments are to advance. One example of a study that has examined this complicated relationship was conducted by Stice, Gau, Rohde, and Shaw (2017). This research team (as well as their colleagues in numerous related studies) investigated the risk factors that predict the various *DSM-5* eating disorders (American Psychiatric Association, 2013). Stice et al. (2017) evaluated a rich array of variables that might predict the future onset of each *DSM-5* eating disorder. These disorders included anorexia nervosa, bulimia nervosa, binge eating disorder, and purging disorder. With a sample of 1,272 young women (*M* age of 18.5 years), the investigators conducted diagnostic interviews every year for 3 years of follow-up assessment, following a series of their own prevention trials. In addition, they collected a vast amount of self-report and weight, height, and health data. It was found that the strongest predictors leading to the development of eating disorders were related to negative affect, such as depressive symptoms, and interpersonal difficulties. As with much of the research literature on eating disorders, pursuit of a “thin ideal” and the associated body dissatisfaction that often accompanies this goal was strongly correlated with extreme dieting, unhealthy weight control behaviors, and the negative affect and interpersonal difficulties mentioned above. Therefore, the investigators note that incorporating interventions for depression and interpersonal discord into prevention efforts for eating disorders may be an effective strategy.

In summary, some types of chronic psychopathology, such as depression, are frequently observed with a large number of physical health concerns and diseases. The best research and clinical work accounts and plans for such comorbidity.

Social Justice

Given that health concerns (both physical and mental) can be influenced greatly by the distribution of wealth and opportunities for personal activity, it is our opinion that issues related to social justice should be of concern to everyone. Research and practice in the fields of clinical health psychology and behavioral medicine, therefore, should reflect these concerns. Fortunately, much of the recent work in these fields has begun to consider such concerns, and the emphasis is increasing enough to justify calling it a “trend.”

A good example is the work of Yang, Chen, and Park (2016), who examined perceived housing discrimination and self-reported health. With a sample of 9,842 adults in 830 neighborhoods across Philadelphia, PA, the investigators were interested in whether certain neighborhood features matter in terms of overall health. Specifically, associations of increased perceived housing discrimination, and more negative self-reported health, were strengthened in neighborhoods with relatively high housing values; however these associations were weakened in neighborhoods with a broader range of housing values and diversity (i.e., income, parenthood, and ethnic minority status). Another interesting finding of this large study was that the statistical models for illustrating a negative relationship between perceived housing discrimination and self-reported health generally underestimate the relationship, unless the models also incorporate neighborhood features such as economic level, family diversity, and ethnic minority status. This large, sophisticated study by Yang et al. (2016) is an excellent example of research on the intersection of clinical health psychology, social justice, and multicultural issues.

In summary, there has been important research on social justice, health psychology, behavioral medicine, and a broad range of multicultural and diversity issues. This research area is growing rapidly, and it should help guide our future efforts in assessment, intervention, and follow-up.

Discussion

The trends discussed in this entry (while not all inclusive) appear to be among the most prominent, consistent, and frequently cited developments in the fields of clinical health psychology and behavioral medicine. While staying close to the data and what is recently published, we offer a few cautious recommendations about these trends.

The importance of the trend of sophisticated methodology cannot be exaggerated. The history of science suggests that it is only as good as its methods. Therefore, we applaud improvements in methodology such as larger and more diverse samples, multi-method and multi-source measures, and longitudinal data collection. This kind of ambitious, large, and sophisticated research, along with translation to the real world, requires skill, resources, and determination. We hope that the research and practice infrastructures will continue to support this important work.

The trend of an emphasis on chronic diseases is expected and necessary, especially considering the significant impact behavioral and emotional factors play on overall health status. Some very important research and translational efforts have been accomplished in this area, and we hope that this important work continues.

Our world is diverse. Therefore, our research, clinical work, and translational efforts should reflect diversity, broadly defined. In our opinion, the fields of clinical health psychology and behavioral medicine have made a considerable amount of progress on this issue. However, we would like these efforts to continue and expand.

Biology has been strongly associated with how we behave (including our personality traits). Moreover, the explosion in biological technology allows for more sophisticated assessments of biological variables. As such, over the past couple of decades, it has become increasingly more common in clinical health psychology and behavioral medicine research to incorporate more biological variables and to include more biological measures in clinical and translational efforts. This trend toward a stronger biological focus can be expensive, and the technical demands can be daunting, but we believe the benefits make it worthwhile. We predict that the incorporation of biological variables in health psychology research will become expected in the foreseeable future, moving the emphasis on biology from a trend to a centerpiece of the field.

The translation of health psychology knowledge into the real world of healthcare settings is an important trend in clinical health psychology and behavioral medicine. After all, if the results we read about in academic journals do not apply to actual clinical populations in typical healthcare settings, then the utility of these findings holds less meaning. Clearly, researchers in these fields are interested in improving the health status of as many people as possible, not just the "ideal candidate."

Chronic psychopathology is often comorbid with health problems and diseases. Depression is a good example, as it is associated with almost every health problem and disease on record. Depressive comorbidity is not helpful when it comes to our health, as, for example, the association of long-term depression with heart disease has many negative implications, including increased disability, disrupted close relationships, poorer adherence to medical and psychological regimens, increased problems at work and at home, further heart events, and increased rates of death from heart disease. Therefore, we can no longer afford to consider psychological and medical issues in isolation.

Last but not least, we discussed the importance of considering variables related to social justice. While progress has been made regarding the inclusion of variables relevant to social justice concerns as part of more traditional clinical health psychology and behavioral medicine studies, more emphasis regarding social justice variables clearly needs to be done. This work is exciting and important, and we need it if we are going to make progress for everyone.

Author Biographies

C. Steven Richards, PhD, is a professor of psychological sciences at Texas Tech University. His research interests include depression, clinical health psychology and behavioral medicine, comorbidity of health problems and psychopathology, self-control, and relapse prevention for depression. He has held 15 administrative positions during his faculty appointments at Texas Tech University, Syracuse University, and the University of Missouri–Columbia. Dr. Richards earned his PhD in clinical psychology at the State University of New York at Stony Brook (now Stony Brook University).

Lee M. Cohen, PhD, is dean of the College of Liberal Arts and professor in the Department of Psychology at the University of Mississippi. Dr. Cohen came to the University of Mississippi from Texas Tech University, where he served in a number of administrative roles including the director of the nationally accredited doctoral program in clinical psychology and the chair of the Department of Psychological Sciences. As a faculty member, he received several university-wide awards for his teaching and academic achievement. As a researcher, he received more than $1.5 million from funding agencies, including the US Department of Health and Human Services, the National Science Foundation, and the National Institutes of Health/National Institute on Drug Abuse. His research program examines the behavioral and physiological mechanisms that contribute to nicotine use, and he worked to develop optimal smoking cessation treatments. Dr. Cohen is a Fellow of the American Psychological Association and the Society of Behavioral Medicine. He received his PhD in clinical psychology from Oklahoma State University.

Biopsychosocial Practice in Health Psychology

Timothy P. Melchert

Department of Psychology, Marquette University, Milwaukee, WI, USA

The biopsychosocial approach has been fundamental to the practice of health psychology across the history of the specialization (e.g., Engel, 1977). Indeed, this perspective became so dominant that Suls and Rothman in 2004 concluded that "The conceptual base for health psychologists in their roles as researchers, practitioners, and policymakers is the *biopsychosocial model*" (p. 119:1; italics in the original). Despite its rapid and widespread adoption, however, the conceptual nature and precise meaning of the biopsychosocial approach was unclear, and critics viewed it as encouraging an uncritical eclectic approach to practice (e.g., Ghaemi, 2010). But scientific knowledge of health and functioning has advanced dramatically in recent years, and the scientific foundations supporting the practice of health psychology are far stronger as a result. The nature of the biopsychosocial framework underlying health psychology practice has consequently also evolved.

This chapter will outline the evolution of the biopsychosocial approach for understanding health and healthcare from a general metatheoretical framework that was often used to support an eclectic approach to practice to a solidly science-based approach grounded firmly in current scientific knowledge. It will show how scientific explanations of human health and functioning have advanced dramatically such that we now have a much more thorough understanding of the causes of disease and the behaviors that contribute to illness and health. This knowledge is critical for developing more effective prevention and treatment interventions in health psychology and in healthcare generally.

Evolution of the Biopsychosocial Approach to Health Psychology

George Engel introduced the "biopsychosocial model" for understanding health and healthcare in 1977 to counter what he viewed as the overemphasis on biology in medicine. Engel argued

First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

that healthcare needed to take a holistic, integrative approach to understand health, disease, and treatment. This perspective was an excellent fit for the new specialization of health psychology, which also focused on interactions between biological, psychological, and sociocultural influences on health and functioning. Engel's model appeared the year before Division 38, Health Psychology became established as a specialization within the American Psychological Association in 1978.

Engel's biopsychosocial model soon became highly influential throughout healthcare and is now widely regarded as the appropriate framework through which to understand health and healthcare. McLaren (1998) pointed out, however, that Engel misnamed his approach because he did not propose a *model* in the scientific sense of using observations, rules, and scientific laws to explain a class of phenomena, but instead used the term in its colloquial sense referring to a perspective or framework. Engel's approach technically refers to a metatheoretical framework that points to the range of factors that need to be considered to understand theory and research in medicine, but it does not refer to a scientific model of a falsifiable theory that attempts to explain a particular class of phenomena (Melchert, 2015). Engel's very general biopsychosocial framework has also been criticized for encouraging an uncritical eclecticism in behavioral healthcare because it can encompass a wide range of biological, psychological, and social interventions without requiring that they be linked to known mechanisms or processes (Ghaemi, 2010). It takes the same general approach as the various integrative and eclectic frameworks that were introduced in psychology about the same time and point to the range of factors that need to be considered to understand human psychology (e.g., Bronfenbrenner's, 1979 ecological model; Lazarus, 1976 *BASIC-ID* framework). Though these frameworks can be very useful in the early stages of researching a topic, they are not scientific models or theories that explain the behavior of particular mechanisms or systems.

There are several reasons why psychology relied on general metatheoretical frameworks to understand human development and functioning at the time the biopsychosocial model was introduced and health psychology became established as a specialization. Perhaps the most important underlying reason was that human development and functioning are so staggeringly complex that science had not yet progressed far enough to explain many of the processes involved (Melchert, 2015). Evolutionary theory still had not developed far enough to explain social behavior until the 1970s, functional magnetic resonance imaging (fMRI) was not used to observe brain function until the 1990s, and the human genome was not sequenced until the early 2000s. Given the limitations of scientific knowledge and technology at the time, all that was really possible was a metatheoretical perspective that focused attention on what appeared to be the correct range of variables that should be considered when attempting to understand many aspects of human behavior and functioning.

This situation has fundamentally changed, however, as a result of dramatic scientific progress in recent years. Replicated findings from experimental tests of falsifiable hypotheses have resulted in explanations of a steadily increasing number of biopsychosocial processes. Of course, knowledge of many biopsychosocial processes is still very limited, and many experimental findings have not yet been sufficiently tested and verified. As a result, many findings remain tentative and sometimes controversial, which is true at the frontiers of knowledge in any scientific discipline. But the overall trajectory is clear. Over the past couple decades, the behavioral, neurological, and biological sciences have advanced dramatically, and we now have verified explanations of many aspects of human psychology and biopsychosocial functioning.

Instead of referring to a general metatheoretical framework, the biopsychosocial approach is now understood to refer to the integrated body of scientific knowledge that explains human development and functioning in a manner entirely consistent with the rest of the natural sciences (Melchert, 2015). This approach does not rely on the customary practice of choosing one (or more) of the traditional theoretical orientations for conceptualizing cases in psychology (e.g., psychodynamic, behavioral, humanistic, cognitive), but instead relies on the growing body of scientific knowledge that explains biopsychosocial mechanisms and processes. The "biopsychosocial" term is not necessarily superior to alternative terms (such as Bronfenbrenner's "ecological" model) though it does have two distinct advantages. First, it is widely known and accepted throughout healthcare; indeed, it is accepted in many healthcare professions at levels similar to the way it is in health psychology. Second, and more importantly, it refers to the levels of natural organization that are integral to the understanding of human behavior and biopsychosocial functioning. All organic life is organized in a hierarchy of levels inherent in the natural world (i.e., from the subatomic to the level of atoms, molecules, organelles, cells, tissues, organs and organ systems, individual organisms, and, in the case of humans and many other social animals, families, communities, culture, and, for all organic life, the biosphere). The term "biopsychosocial" effectively captures the three broad, interacting levels of natural organization that are necessary for understanding human development and functioning.

The biopsychosocial framework is necessary for understanding physical as well as behavioral health and social functioning. Human health and behavior are fundamentally dependent on underlying biological structures and processes that interact with psychological factors, which in turn interact with social, cultural, and environmental processes. Appreciating the inextricably intertwined BPS domains of functioning is necessary for understanding all aspects of human functioning from the level of the particular mechanisms that control behavior (i.e., *proximate* explanations of behavior) to the level of explaining why humans are designed the way we are (i.e., the origins and functions of behavior, or *ultimate* explanations of behavior; Tinbergen, 1963).

Illustration: Current Biopsychosocial Perspective on the Primary Causes of Disease and Death

The impact of the steadily growing body of scientific knowledge regarding human health and disease can be illustrated by considering the current understanding of the primary causes of disease and death in the United States. The primary causes of morbidity and mortality are of course a main concern for health psychology research and practice. Detailed knowledge of many aspects of these topics, however, were unavailable when health psychology was founded four decades ago, but proximate and ultimate explanations for an increasing number of diseases and conditions are now available. A brief overview of this literature highlights the importance of recent scientific findings to education, practice, research, and prevention in health psychology.

Patterns of morbidity and mortality have changed dramatically in the United States and other parts of the industrialized world over the past century. At the end of the nineteenth century, the primary causes of illness and death began shifting from acute and infectious disease to chronic diseases associated with lifestyle and behavior, a shift that has been called the *epidemiological transition* (Gribble & Preston, 1993). The death rate from infectious disease was approximately 800 per 100,000 individuals in 1900 and fell to roughly 50 per 100,000 by 1950, where it has stayed since (Centers for Disease Control [CDC], 1999). Most of these deaths now involve influenza in elderly individuals, while other infectious diseases have been nearly or completely eliminated. Public health measures, vaccines, antiseptic practices in medicine, and antibiotics became so effective over the course of the twentieth century that the majority of Americans now suffer and die from chronic rather than acute infectious diseases.

The top five leading causes of death in the United States are now heart disease, cancer, chronic lower respiratory diseases, stroke, and accidents (CDC, 2013). Many of these conditions share a small number of underlying causes. At the very general level, the Institute of Medicine (2004) concluded that roughly 50% of overall morbidity and mortality in the United States is caused by behavior and lifestyle. In terms of more specific factors, smoking is the leading cause, accounting for 18.1% of all deaths (CDC, 2004); obesity is the second leading cause, accounting for 16.6% of all deaths (Mokdad, Marks, Stroup, & Gerberding, 2004); and alcohol consumption is the next most important factor, accounting for 3.5% of deaths. The World Health Organization (2008) arrived at similar conclusions regarding the global population and estimated that up to 80% of heart disease, stroke, and type 2 diabetes and more than one-third of cancers worldwide could be prevented by eliminating the shared risk factors of tobacco use, unhealthy diet, physical inactivity, and excessive alcohol use.

More detailed knowledge regarding both proximate and ultimate explanations of these diseases is also now available. Research from a range of biological, social science, and medical disciplines has clarified that the long evolution of hominins over the past 6 million years has resulted in capacities and vulnerabilities that are poorly suited to modern diets and behavioral patterns (Lieberman, 2013). Before the development of agriculture (starting 12,000 years ago in the Middle East and more recently in other areas of the world), humans were hunter-gatherers who ate primarily nuts, fruits, tubers, and some meat. Most of their food contained large amounts of fiber—in fact, chewing these foods actually consumed a large amount of time and energy; a typical meal might require thousands of chews (Lieberman, 2011). Before hybridization, the fruits they ate contained far less sugar than modern fruits (e.g., wild crab apples are similar to carrots in sweetness), the only really sweet food that could be consumed was honey, and the meat they ate from wild animals contained only a fraction of the fat found in modern farm-raised meat, fish, and poultry. Salt was not consumed in amounts larger than what was naturally present in plants and animals. Hunting and gathering (and even chewing) required large amounts of activity, and people were very lean (Lieberman, 2013).

Humans evolved to crave sweets and fats so that any excess calorie intake was quickly and easily converted into fat and people could survive periods of insufficient food intake. In contrast, since the agricultural revolution and especially since the industrial revolution, people typically eat large amounts of refined grains that contain little fiber, large amounts of sugar, and large amounts of fatty meats (Cordain et al., 2005). Humans' bodies evolved over millions of years to consume very different foods and be far more active than modern Americans. This has caused widespread problems related to high cholesterol, high blood pressure, obesity, and conditions that are caused by disuse such as back pain, osteoporosis, and dental problems, all of which are rare in hunter-gatherers (Lieberman, 2013).

Translating this growing knowledge regarding the causes of many of the most common modern medical conditions into effective treatments and prevention strategies has been challenging. The reasons for this are complex, but changing behaviors that contribute to the main causes of disease and death clearly can be difficult. Psychologists have long known that individuals can readily engage in a wide variety of behaviors that are unhealthy, self-defeating, and addictive even when they are aware of the consequences of their behavior.

Knowledge of the psychological mechanisms and processes underlying unhealthy behavior has also grown in recent years. Many issues are involved, but one prominent area of research illustrates the progress being made. It has long been known that automatic, subconscious cognitive processes operate in conjunction with reflective, conscious processes, and together they frequently produce seemingly irrational thoughts and behaviors. These two types of cognitive processing are often referred to as *System 1* and *System 2* thinking (Kahneman, 2012).

System 1 thinking is fast, automatic, largely unconscious, intuitive, reliant on affect, and conditioned emotional associations and produces a "quick and dirty" draft of reality that is often highly useful for responding to threats and opportunities. System 2 thinking, on the other hand, evolved much later, is slow and deliberate, and requires conscious effort to reason analytically and explicitly about the world. This system allows us to reason deductively and is less influenced by past events and feelings. It allows us, for example, to have a craving or a feeling such as anger or depression but not act on it due to awareness of long-term consequences or because it does not fit with one's values. System 2 thinking is lazy, however, and often accepts the version of events provided by System 1 (Kahneman, 2012). Clearly, changing unhealthy behavior patterns in the context of these two systems can be complicated.

Implications

Suls' and Rothman's (2004) statement regarding the conceptual base for health psychology is still accurate if "the biopsychosocial model" is replaced with "the biopsychosocial approach." When health psychology is approached as a clinical science grounded firmly in scientific knowledge of human health and functioning, then the term "model" needs to be used in its scientific sense. From this perspective, the biopsychosocial approach is a general metatheoretical framework that points to the levels of natural organization involved in human health and behavior and the corresponding body of scientific knowledge that provides proximate and ultimate explanations of health, disease, development, and functioning. This steadily growing body of knowledge provides a solid foundation for practicing evidence-based health psychology and will almost certainly lead to increasingly effective prevention and treatment interventions that can improve the health and well-being of the public.

When psychologists in the past entered medical units in hospitals to consult regarding psychological aspects of a case, they were sometimes apologetic and hesitant in their interactions with patients and other healthcare professionals. This attitude likely resulted in part from the equivocal support for the validity of the traditional theoretical orientations in psychology and the eclecticism associated with the biopsychosocial approach. Compared with the biological basis for much of medicine, the evidence supporting the biopsychosocial approach seemed weak. This is no longer the case. The scientific basis for understanding behavioral health and biopsychosocial functioning is now solidly based on verified research from across the biological, neurological, and behavioral sciences, and research suggests that psychosocial treatments are highly effective and sometimes more effective than many medical interventions (American Psychological Association [APA], 2012). There is certainly still much work to be done, but the scientific basis underlying health psychology is now solid. Clinicians can now interact with patients and other healthcare professionals with confidence that comes from having firm scientific foundations for practice that are entirely consistent with and supported by the rest of the natural sciences.

Author Biography

Timothy P. Melchert is a professor in the Department of Counselor Education and Counseling Psychology at Marquette University. He writes on the need to resolve theoretical and conceptual conflicts and confusion in professional psychology by adopting a unified science-based biopsychosocial framework for understanding human development, functioning, and behavior change.

Child and Family Health

Joaquin Borrego, Jr., Tabitha Fleming,
Elizabeth Ortiz-Gonzalez, and Amber Morrow

Department of Psychological Sciences, Texas Tech University, Lubbock, TX, USA

The health of a child can have a significant impact on the family. When a child has a medical illness (e.g., type 2 diabetes) or experiences a negative event (e.g., child maltreatment), the family, as well as other systems (e.g., communities), can be negatively impacted. The family is inevitably impacted whether it be an acute or chronic condition. This negative impact is especially significant for family members and others close to the child (e.g., friends, extended family members). Given this, it is imperative that inclusion of the family and other systems be taken into account when discussing children's health.

Some major public health concerns impacting children and families include, but not limited to, nutrition (an increase in obesity rates for both pediatric and adult populations, food insecurity for families living in poverty), chronic illness (e.g., asthma, cardiovascular disease, high blood pressure), pediatric and adult cancer, poor sleep hygiene, and child maltreatment (the child as victim and adult as the perpetrator). These, and other conditions, are very common in our society and are associated with additional health complications later in life.

Ecological Framework

A useful framework to help understand the complexity of child, family, and social relationships as they relate to health is the ecological framework. This conceptual framework is the work conducted by Urie Bronfenbrenner (1979) on the ecology of child development. Briefly, this conceptual model posits that the child and family operate in systems that are interrelated and reciprocal. Most immediate to the child is what is known as the *microsystem*. This system is the most immediate and includes those that are closely connected to the child such as siblings, parents, family, peers, and schools. Within this microsystem, there are subsystems that focus on relationships that the child has with peers, siblings, and the parents. The *mesosystem* involves the interactions and relationships that are developed between the different components of the

---

The Wiley Encyclopedia of Health Psychology: Volume 3: Clinical Health Psychology and Behavioral Medicine,
First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

microsystem. As examples, the mesosystem helps explain interactions and relationships formed between the family and the school, siblings and peers, etc. The *exosystem* involves the linkage between two settings that may directly or indirectly involve and impact the child. This can include extended family members, neighborhood, etc. The *macrosystem* is the most distant from the child but still has an influence on the child. Examples include social and cultural changes at a societal level that will inherently impact the child and family. A family's practices, values, beliefs, attitudes, and behaviors are shaped over time.

Bronfenbrenner's model has been applied to explain the complexities of the child and family within the context of health (Kazak, Alderfer, & Rader, 2017). The *social ecology model* helps identify the systems that are involved related to a child's health such as the family, hospitals, and school personnel (Kazak et al., 2017). As noted above, this is a useful conceptualization as it helps explain the intricate systems involved and the relationship between these systems. Examining these systems carefully can help identify contextual factors that may decrease the risk for continued health problems and increase resilience and adjustment for the child and family.

Impact of Children's Health on the Family

Children with medical illnesses can be very stressful for the family, especially siblings and parents or other caregivers. Illnesses in children can be stressful and even distressing for caregivers whether it be parents, guardians, or other caregivers such as a grandparent or close family friend (Cousino & Hazen, 2013). A child who is ill will miss school, and, depending on available family resources, some parents or guardians may need to miss work with or without pay. The literature from pediatric psychology suggests that a child with an illness can have a negative impact on siblings (Vermaes, van Susante, & van Bakel, 2012) and caregivers (Cousino & Hazen, 2013). There is also research to suggest that children with long, chronic illness experience difficulties across different domains in their life including academic and social problems (Pinquart & Teubert, 2012). In addition, children cannot manage their medical illness themselves, so they have to rely on family members for medical care. The level of parent or family involvement can range from being under-involved in the management of the child's illness to over-involvement such as overprotection of the child (Martire & Helgeson, 2017).

From an ecological framework, the child's negative health status has an impact within and across different systems. Within the family, a child's illness can impact his/her relationship with siblings and the parent–child relationship. These close family relationships have an impact on health (Chen, Brody, & Miller, 2017). In addition, the child's health status can also impact the relationship between parents or other caregivers. As noted above, a child with an illness can contribute to parenting stress, and, in turn, this can lead to discord in the marriage or the relationship. This discord can have a negative impact on relationship satisfaction. Parents and caregivers can become stressed and frustrated with the child or their partner in the relationship. A child missing significant amount of time from school or other events (e.g., sports-related activities) can also have a negative impact on peer relationships.

Factors Relevant to Healthcare

Health disparities can be defined as quantifiable differences in incidence, prevalence, mortality, and health indicators in certain populations or groups (e.g., Latinos, African Americans;

U.S. Surgeon General, 2001). Health disparities also include differences in access to healthcare in groups based on ethnicity/race, socioeconomic status (SES), and area of residence (Flores, 2010). This next section discusses factors that may contribute to health disparities.

Socioeconomic Status

Poverty can have a long-term deleterious impact on a child's psychological, emotional, physical, and behavioral development (Bradley & Corwyn, 2002; Yoshikawa, Aber, & Beardsee, 2012). In addition, years of research have identified profound health disparities associated with poverty (Gallo & Matthews, 2003). Particularly, families with means may provide their children with access to health services, education, and social connections that might not be available or less available to lower SES families (Lescano & Rahill, 2017). Research shows that there is a relationship between SES (an exosystemic factor) and health as SES can impact health outcomes even before birth. Growing evidence suggests that children from low SES families are at risk of suffering from neurodevelopmental abnormalities in utero, premature birth, and low birth weight (Bradley & Corwyn, 2002).

Unfortunately, low SES families are less likely to consistently follow an immunization schedule and have adequate access to healthcare and proper nutrition (Bradley & Corwyn, 2002). Nutrition has been identified as an important link between SES and psychological and physical well-being. Additionally, poor nutrition during childhood can negatively impact cognitive and behavioral development and contribute to an increase in morbidity in children. As previously mentioned, SES can contribute to biological and physiological changes in utero, during infancy, and during childhood. These disturbances create vulnerabilities that result in an overall decrease in health status and health problems that continue or manifest in adulthood. However, the degree of impact caused by low SES varies depending on how many years the child has spent in poverty and how young the child is when the family is living in poverty (Bradley & Corwyn).

Access to Healthcare

Lower SES families often have limited access to medical care, which often translates into deficient prenatal care during pregnancy and inadequate preventive care during childhood. Children from low SES families often do not have adequate immunizations, may not receive appropriate medical care when experiencing acute or chronic diseases, or may only take their children to the doctor when the disease is at an advanced stage (Bradley & Corwyn, 2002). Many of these families do not have financial means to purchase insurances and tend to rely on emergency rooms more or might avoid visiting the doctor altogether.

Ethnic Minorities and Healthcare

A disproportionate amount of families living at or below national poverty levels in the United States are ethnic and racial minorities. According to 2016 data, 22% of Black/African Americans and 19.4% of Hispanics (all races) live in poverty (U.S. Census Bureau, 2017). In contrast, 10.1% of those who identify as Asian and 8.8% of individuals who identify as White, not Hispanic, live in poverty (U.S. Census Bureau, 2017). Social disparities, low educational attainment, low income, and deficient housing contribute to the inequalities experienced by ethnic minority families (Sanders-Phillips, Settles-Reaves, Walker, & Brownlow, 2009).

Furthermore, even when adjusting for factors such as income and insurance coverage, ethnic minorities in the United States receive medical services that are of lower quality than European Americans (U.S. Surgeon General, 2001).

It is estimated that by 2020, ethnic minority children will outnumber European American children in the United States (U.S. Census Bureau, 2014). However, even when ethnic minority children are close to representing the numerical majority of the child population, profound disparities in access to healthcare remain. Research suggests that ethnic minorities are less likely to seek medical care (U.S. Surgeon General, 2001). This phenomenon can be explained by differences in beliefs and attitudes toward healthcare. Ethnic minority parents may not trust medical providers, and they may place a different emphasis on health. For example, Latino and African American parents often indicate that their doctors do not understand their children's needs (Flores, 2010). However, the intersectionality between ethnic minority status, low SES, and limited insurance coverage is a key factor that contributes to the underutilization of health services.

Racial disparities are evident when examining mortality rates in the United States. For example, childhood mortality rates tend to be significantly higher for African American children compared with European American children (Flores, 2010). African American children have the lowest immunization rates and present with high rates of obesity. The risk for obesity continues throughout adolescence, with African American female adolescents reporting a higher prevalence of obesity and needing but not getting medical care (Flores). Important disparities can be found in obesity rates, physical activity, and nutrition in Latino children as well. Research shows that Latino children have the highest rate of obesity when compared with other ethnic/racial groups (Flores).

The Influence of Culture

Psychologists and medical professionals alike are recognizing the importance and influence that culture has on different aspects of an individuals' life. Culture can shape attitudes, behaviors, practices, and values, to name a few. Culture can also influence how health distress is expressed in families, how families adjust, and how family relationships can impact health (Campos & Kim, 2017; Clay, 2017). In addition, culture has an influence on how individuals view the concept of the family. As an example, for some, the concept of who family and who is a caregiver only involves immediate family members (e.g., parents and siblings), and for others, the concept of family or caregiver is not restricted to the immediate family. As an example, in African American culture, it may be that a long-standing neighbor or friend is known as family and is not distinguished between other immediate family relatives. This is important to consider as it highlights the flexibility within which the different systems function for the child. From a cultural lens perspective, these systems are best conceptualized as flexible in parameters from one family to another.

Disparities in Access to Healthcare

Research suggests that lack of health insurance is a barrier to accessing quality healthcare (U.S. Surgeon General, 2001). This is particularly relevant for ethnic minority populations as being uninsured is a barrier for Latinos and African Americans attempting to access quality healthcare. For example, African American families are more likely to be uninsured and/or sporadically insured. Uninsured families typically experience delays and problems in accessing healthcare. Latino and African American children have an increased likelihood of not having access to a usual source of care or primary care physician (Flores, 2010). Moreover, Latino and African American children are less likely to be referred to see a medical specialist. Research indicates that higher hospitalization rates for ambulatory care and emergency department visits for African American children and African American and Latino children have a higher rate of avoidable hospital admissions (Flores). Overall, African American and Latino children experience disparities in the use of healthcare including less visits to the doctor (spending a year or more since the last physician visit) and less calls to the doctor's office.

Language

Other disparities in access that warrant attention include difficulties in communication. Research shows that Latino families are more likely to report difficulties with doctor–patient communication with their provider (Flores, 2010). This may be due to a language barrier between the family being more proficient and comfortable speaking Spanish and medical personnel not being proficient in Spanish. Children of Spanish-speaking parents are often placed in a position to interpret for their parents or provide their own information. Developmentally, depending on the child's age, the child may not be able to provide accurate information, may be embarrassed to convey personal information, or may provide distorted information to medical personnel. This can also be the case for any family whose preferred language is not English.

Discrimination and Health Disparities

Some ethnic minority children are exposed from a young age to prejudicial attitudes and racial discrimination, and contact with discrimination may contribute to feelings of hopelessness and lead to a poor self-concept (Sanders-Phillips et al., 2009). Moreover, an awareness of minority status, which is typically achieved in adolescence, might lead to an internalized devalued group membership and identity. Adversity and negative social experiences experienced by ethnic minority children may have a long-standing effect in physiological functioning. Moreover, research shows that chronic exposure to racial discrimination correlates with biological and psychological changes that may persist and might impact health outcomes in childhood. Fortunately, the family and other systems such as churches and schools are in a position to help children cope with prejudice and racism through teaching cultural pride and racial socialization. Research suggests that having a sense of ethnic/racial identity may reduce the risk against developing of internalizing behavior problems (Smith & Trimble, 2016).

Protective and Risk Factors

As with protective and risk factors associated with psychological disorders, a host of these factors are also correlated with medical disorders and negative health-related outcomes (Mash & Barkley, 2014). A risk factor can be defined as "a characteristic at the biological, psychological, family, community, or cultural level that precedes and is associated with a higher likelihood of problem outcomes," while a protective factor can be defined as "a characteristic at the biological, psychological, family, or community (including peers and culture) level that is associated with a lower likelihood of problem outcomes or that reduces the negative impact of a risk factor on problem outcomes" (National Research Council and Institute of Medicine, 2009, pp. xxvii–xxviii). Across the lifespan, protective and risk factors tend to vary according to developmental stage beginning in early childhood all the way through middle childhood, adolescence, and adulthood. However, some protective or risk factors are present in several stages over the course of development. These factors play different roles in shaping a child, and, in turn the family, thus it is important to be cognizant of each and their role in the child's health as well as in the outcomes associated.

In early childhood, secure attachment is crucial for healthy development that has implications later in life for emotion regulation, family relationships, and prosocial behavior (National Research Council and Institute of Medicine, 2009). Through building a foundation of consistent and positive and parent–child interactions, a secure relationship can be formed and solidified early, promoting healthy child development. A positive home environment can also contribute to development of executive functioning skills (e.g., problem-solving skills, language acquisition), encourage early childhood and lifelong positive psychological, emotional, and behavioral health (National Research Council and Institute of Medicine, 2009).

In middle childhood, it is increasingly important for children to successfully achieve appropriate developmental milestones such as academic achievement, following rules for appropriate behavior and positive peer relations. As noted earlier, academic and social problems can develop for children with chronic illnesses. A child's ability to master academic skills, along with making friends with peers, can contribute to protecting against poor health or overall negative outcomes. Additionally, the concept of resilience is a key component eliciting positive developmental outcomes in this stage of development (National Research Council and Institute of Medicine, 2009). The resilient ability to persevere despite adversity protects children in middle childhood from potentially problematic outcomes.

In adolescence, essential protective factors leading to positive development and child health include engagement in positive physical health habits, intellectual development, physiological and emotional development, and social development (National Research Council and Institute of Medicine, 2009). On an individualized level, adolescents who exhibit high sense of self-worth, emotional regulation, and good coping and problem-solving skills are more equip to avoid or minimize the impact of negative outcomes (National Research Council and Institute of Medicine, 2009). From a family and school perspective, protective factors in adolescence also include receiving extended family support and engaging in positive peer relationships. Further, different systems can each play a role in helping reduce health-compromising behaviors and increasing health-promoting behaviors in youth (Wilson, Coulon, & Huffman, 2017).

These protective factors associated with outcomes of children across the development are important to consider in contrast with the risk factors also associated. Across the lifespan, there are many risk factors associated with negative health outcomes that can be detrimental regardless of developmental stage. Such risk factors including child maltreatment, family dysfunction (e.g., poor family communication, avoidance of negative emotions) community and school risk factors (e.g., violence), and poverty can contribute to a host of problematic outcomes in children of all ages (National Research Council and Institute of Medicine, 2009).

Further, family dysfunction and disruption including divorce, a poor parent–child relationship, insecure attachment, and parental psychopathology can also elevate risk for negative outcomes in children across all developmental stages (National Research Council and Institute of Medicine, 2009). Additionally, community and school risk factors including victimization, bullying, academic failure, and association with deviant peers contribute to potential negative health outcomes in children (National Research Council and Institute of Medicine, 2009).

Conclusion

The health of the child and family has such an important and profound impact on each other. This reciprocal system, in turn, impacts other systems in the child's life such as development of peer relationships and academic performance in schools. We have a sufficient scientific knowledge base regarding prevention and early intervention programs that can assist in raising children with prosocial skills and having close family relationships (Biglan, 2015). In addition, we can now point to numerous social determinants of health that can have a negative impact on the child and family (Black, 2017). Having close family relationships can ameliorate some of the negative impact that acute and chronic medical conditions can have on the child, family, and other systems such as peers, schools, and communities. Practitioners and researchers alike are encouraged to closely examine the quality of the parent–child relationship as well as the quality of the sibling relationship and the caregiver's relationship. In addition to examining family cohesion, the degree to which the child and family have a positive and supportive social network should be taken into account. This can include the child's peer relationships and the family's network extended family members and friends through work, the child's school, and the community. At a broader level, schools and the healthcare system need to be examined in the context of child and family health.

Childhood Cancer

Dianna Boone, Savannah Davidson, Jordan Degelia, and Jason Van Allen

Clinical Psychology Program, Department of Psychological Sciences, Texas Tech University, Lubbock, TX, USA

Introduction

Pediatric cancers are newly diagnosed in approximately 14,000 youth in the United States each year (Howlader et al., 2013) and are the leading cause of death by disease for children (Heron et al., 2010). Acute lymphoblastic leukemia (ALL) is the most common form of pediatric cancer and is responsible for one-fourth of all childhood cancers and 75% of all cases of childhood leukemia (Belson, Kingsley, & Holmes, 2007). In 2014, nearly 16,000 children and adolescents were diagnosed with cancer in the United States. In addition, more than 80% of those diagnosed with pediatric cancer will survive at least 5 years after their diagnosis (Wessler, 2015). This chapter provides an overview of the short- and long-term effects of cancer on children and their families, with special attention paid to psychosocial outcomes and intervention efforts. The importance of medication adherence and the health challenges associated with survivorship are also discussed.

Psychosocial Functioning in Pediatric Cancer

Many studies have examined the impact of pediatric cancer on the psychological and emotional functioning of children, adolescents, and their families (Germann et al., 2015). The psychological effects of cancer therapy include increased levels of anxiety, depression, and posttraumatic stress (Dietz & Mulrooney, 2011). Studies have also indicated that children diagnosed with cancer have significantly higher internalizing symptoms (Sawyer, Antoniou, Toogood, & Rice, 1997) and a potentially higher risk of suicidal ideation than the general population (Recklitis et al., 2010). Research has illustrated that these psychosocial effects are typically experienced near the time of diagnosis and early in the treatment process (Compas et al., 2014; Kazak,

---

The Wiley Encyclopedia of Health Psychology: Volume 3: Clinical Health Psychology and Behavioral Medicine,
First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

Boeving, Alderfer, Hwang, & Reilly, 2005). However, some studies have also illustrated that children with cancer demonstrate better emotional functioning than comparison groups (Van Schoors, Caes, Verhofstadt, Goubert, & Alderfer, 2015) and have not shown higher rates of depression or posttraumatic stress than population norms (Germann et al., 2015).

Health-Related Quality of Life

A component of psychosocial functioning that may be affected by cancer is health related quality of life. Health-related quality of life (e.g., a broad multidimensional concept that usually includes self-reported measures of physical and mental health; Centers for Disease Control and Prevention, 2012) has also been found to be lower in children undergoing treatment for pediatric cancer when compared with the general population, particularly in the areas of physical complaints, motor functioning, and positive emotional functioning (Fakhry et al., 2013). It has also been found that among children with ALL, females, older children, and those with multiple medical complications were at a higher risk of poor quality of life (Fakhry et al., 2013). Demographic factors such as age, gender, type of cancer, treatment modality/intensity, and progression of illness have all been significantly related to health-related quality of life (Fakhry et al., 2013).

Depression and Anxiety

In addition to lower health-related quality of life, research has shown that increased levels of depression and anxiety can result from cancer treatment as well (Dietz & Mulrooney, 2011). Myers et al. (2014) examined the emotional and behavioral functioning of a large sample of children with ALL. Both child and parent reports were obtained on measures related to the child's behavior, anxiety, hyperactivity, aggression, and depression. These measures were given at three different time points (e.g., 1, 6, and 12 months after being given a diagnosis). The results revealed that on average, all of the child outcome variables were similar to population norms; however, more children scored in the at-risk range for depression at 1, 6, and 12 months (Myers et al., 2014). Children scored in the at-risk range for anxiety at 1 month only (Myers et al., 2014).

Similarly, Compas et al. (2014) examined anxiety and depression in a sample of children recently diagnosed with cancer. They found that based on reports from children and their caregivers, children in the sample experienced mild to moderate symptoms of anxiety and depression (Compas et al., 2014). Both of these studies reveal that anxiety and depression may be a significant problem for children after receiving a diagnosis of pediatric cancer (Myers et al., 2014).

Resiliency

Although pediatric cancer can result in negative psychosocial outcomes (e.g., increased depression and anxiety and lower quality of life), research has demonstrated that children can show healthy developmental trajectories despite a cancer diagnosis. This positive adaption, often termed resiliency (e.g., achieving positive outcomes despite exposure to significant levels of adversity), has been found to be significantly related to better adjustment (Germann et al., 2015). Germann et al. (2015) conducted a study to determine the pattern of resiliency and adjustment (measured by hope, anxiety, depression, and quality of life) in children between ages 8 and 18 as well as to examine the relationships between these variables. Overall, results demonstrated that pediatric cancer patients are resilient and that one's level of hope has the potential to maintain and promote adjustment and well-being in children with cancer (Germann et al., 2015). A systematic review was also conducted to examine family resiliency in the context of pediatric cancer. Van Schoors et al. (2015) found that although a diagnosis of pediatric cancer disrupts family functioning, most families are resilient and adapt well to receiving a pediatric cancer diagnosis.

Findings from these studies suggest that pediatric cancer patients may experience anxiety and depression, particularly near the time of diagnosis and early in the treatment process (Kazak et al., 2005; Pinquart & Shen, 2011). However, research also indicates that families demonstrate resiliency when facing pediatric cancer (Van Schoors et al., 2015). Thus, it may be important for researchers to develop interventions that promote positive psychosocial outcomes such as resiliency in children undergoing cancer treatment.

Family Adjustment to a Pediatric Cancer Diagnosis

Families of children with cancer are also at risk for poor adjustment outcomes, including posttraumatic stress symptoms (Rodriguez et al., 2012) and anxious and depressive symptoms (Pai et al., 2007). Research has demonstrated that the way a child's parents adjust after their child is diagnosed with cancer can be crucial to their child's adjustment following diagnosis (Rodriguez et al., 2016). Thus, interventions targeting parental adjustment can result in positive outcomes for their children (Fedele et al., 2013; Phipps et al., 2015). Fedele et al. (2013) conducted a study to determine if maternal distress predicted child adjustment outcomes and if a parent-focused interdisciplinary intervention positively affected children's adjustment. It was found that maternal distress predicted child internalizing symptoms, which suggests that interventions aiming to improve child adjustment outcomes should consider incorporating parent factors (Fedele et al., 2013). This study also found that the parent-focused intervention significantly reduced child internalizing symptoms, which indicates that psychological interventions for mothers of children newly diagnosed with cancer can positively influence child adjustment outcomes (Fedele et al., 2013).

In addition, research has demonstrated that certain sociodemographic factors can be associated with psychological distress in families facing pediatric cancer (Bemis et al., 2015). Bemis et al. (2015) found that factors representing sociodemographic disadvantage (i.e., single parenthood, lower family income, lower parental education, non-White race) may influence general perceived stress, cancer-related stressors, and psychological distress in families experiencing pediatric cancer (Bemis et al., 2015). The results of this study are important, as researchers will be able to develop effective interventions for families who are more likely to experience psychological distress (Bemis et al., 2015).

Overall, it is essential to understand the ways that children and families cope with the effects of cancer to develop optimal interventions for improving coping skills in children (Compas et al., 2014). It is important that interventions continue to focus on not only child psychosocial outcomes but family functioning as well.

Medication Adherence

Pediatric psychologists often collaborate with multidisciplinary teams in oncology to improve medication adherence. Despite the importance of taking medications as prescribed, some studies have shown that as many as 50% of pediatric cancer patients do not adhere to their maintenance treatment regimen (Kondryn, Edmondson, Hill, & Eden, 2011). Nonadherence can take many forms (e.g., not filling prescriptions, skipping or missing doses) and can be intentional (e.g., deciding not to take a medication because of side effects) or unintentional (e.g., forgetting; Hommel & Baldassano, 2010). Poorer adherence has been documented for regimens that are more time consuming and complex, and rates of nonadherence in pediatric chronic illness populations, especially among adolescents, are even higher than those in adult populations (Rapoff, 2010). Nonadherence to a medication regimen, especially for pediatric cancer patients, can potentially interfere with the efficacy of drug regimens, resulting in difficulties meeting treatment goals, more frequent visits to the emergency room, or increased hospitalizations.

Barriers to Medication Adherence

Medication adherence, particularly in adolescents with cancer, can be more challenging because adolescents are generally diagnosed with higher risk cancers than younger children; thus, adolescents have more complicated treatment plans (Hullmann, Brumley, & Schwartz, 2015). Hullmann et al. (2015) investigated parent and adolescent reported rates of, and reasons for, nonadherence, as well as the demographic, treatment and disease-related, and psychosocial correlates of nonadherence. They found that adolescent- and parent-reported adherence were significantly correlated, with approximately half of the sample reporting perfect adherence (Hullmann et al., 2015). The most common reason for missed medication reported by adolescents and caregivers was “just forgot” (Hullmann et al., 2015). Interestingly, for adolescents who endorsed perfect adherence, they reported having greater social support from their families (Hullmann et al., 2015). These results indicate that children receiving family support are more likely to adhere to their medication regimens (Hullmann et al., 2015).

Interventions That Aim to Promote Adherence

Due to the importance of medication adherence to positive health outcomes for pediatric cancer patients, interventions promoting medication adherence are necessary. Pai and McGrady (2015) recently conducted a literature review examining interventions that aimed to improve medication adherence in pediatric cancer patients. The results indicate that a multifaceted approach is needed to promote medication adherence in this population (Pai & McGrady, 2015). More specifically, these researchers suggest that multidisciplinary teams should combine “adherence-related assessments, education, anticipatory guidance, and documentation in standard clinical care” (Pai & McGrady, 2015). It was also concluded that medication adherence should be consistently monitored throughout the course of treatment (Pai & McGrady, 2015). Interventions targeting family support and psychosocial functioning with an educational component have also been shown to be more effective in improving medication adherence compared with control conditions (Pai & McGrady, 2015).

In sum, proper assessment of medication adherence in pediatric cancer patients is crucial. Nonadherence increases one’s risk of developing complications and can lead to treatment goals not being met. Although there are numerous barriers to medication adherence (e.g., side effects of medication, cost of treatment, poor planning), research has demonstrated that improving family involvement is helpful in encouraging medication adherence. Research on interventions to improve adherence in this population has demonstrated that adherence should be promoted through a multifaceted approach, include an educational component, and be monitored routinely and throughout the course of one's treatment (Pai & McGrady, 2015; Rohan et al., 2015).

Health Challenges Associated With Survivorship

After surviving pediatric cancer, the patient may experience other chronic health issues such as delayed growth, endocrinological problems, and neurocognitive impairment (Bhatia, 2005). Research has demonstrated that childhood cancer survivors are at a significantly greater risk of developing secondary cancers, cardiovascular disease, osteoporosis, and diabetes (Greving & Santacroce, 2005). Comorbid conditions can result from cancer treatment, genetic predisposition, or various lifestyle factors (Demark-Wahnefried, Aziz, Rowland, & Pinto, 2005).

Neurological Functioning After Cancer Treatment

Survivors of cancer are also at greater risk for adverse neurocognitive outcomes (Patel et al., 2014). Certain methods of treatment such as cranial radiation therapy put children at risk for "late effects" that emerge after cessation of treatment (Ness & Gurney, 2007). Long-term effects of treatment can include malignant brain tumors and neurocognitive deficits such as deficits in attention, executive functioning, memory, and processing speed (Butler & Mulhern, 2005; Patel et al., 2014).

However, interventions have demonstrated efficacy in treating these adverse neurocognitive effects resulting from cancer treatment (Patel et al., 2014). For example, Butler et al. (2008) designed a cognitive remediation intervention for pediatric cancer survivors with documented attention disturbance. Results indicated that the children showed small to modest improvements in academic achievement and parent-reported behavioral functioning (Butler et al., 2008). Similarly, Patel et al. (2014) conducted a study to evaluate the efficacy of a similar intervention directed toward parents of childhood cancer survivors with neurocognitive late effects, to improve targeted parenting skills, and therefore to improve their children's educational performance. Results revealed that children who participated in the intervention significantly increased their use of study strategies (Patel et al., 2014). Additionally, caregivers' self-efficacy to promote their child's school success increased after the intervention (Patel et al., 2014). These studies show that interventions can potentially improve cognitive functioning in child cancer survivors.

Increased Risk for Obesity

There is also an increased risk for weight gain and decreased physical activity following cancer treatment (Stern et al., 2015). For example, 5 years' posttreatment, 21% of all pediatric cancer survivors are classified as obese (BMI ≥ 95th percentile for age and gender) and 20% as overweight (BMI ≥ 85th percentile and ≤94th percentile for age and gender; Chow, Pihoker, Hunt, Wilkinson, & Friedman, 2007). Children with certain types of cancers (e.g., ALL and specific sarcomas) are at an even greater risk for obesity (Chow et al., 2007). Research has illustrated that the association between cancer treatment and future obesity may be due to cranial radiation and exposure to corticosteroids (Chow et al., 2007). Additionally, consumption of high fat foods and limited physical activity could influence posttreatment weight gain.

However, researchers have developed interventions that aim to promote healthy lifestyles for children after cancer treatment. Family-based interventions that treat pediatric obesity by promoting healthy lifestyle changes, physical activity, and dietary behaviors are effective, and it is likely that these types of interventions are also effective for child cancer survivors (Stern et al., 2015).

Conclusion

In sum, pediatric cancer is a prevalent and potentially life-threatening illness that affects the entire family (Long & Marsland, 2011; Ward, DeSantis, Robbins, Kohler, & Jemal, 2014). Although many families facing pediatric cancer show resiliency (Van Schoors et al., 2015), research indicates that these children often experience psychosocial problems including anxiety, depression, and posttraumatic stress (Dietz & Mulrooney, 2011; Seitz et al., 2010). In addition to psychosocial problems, children and adolescents may also experience late effects of cancer including neurocognitive deficits, such as with attention and concentration (Butler & Mulhern, 2005). Research in pediatric cancer indicates that there are often significant health challenges associated with survivorship, which include increased risk for obesity, delayed growth, endocrinological problems and neurocognitive impairment (Krivoy, Jenney, Mahajan, & Peretz Nahum, 2012), and other chronic illnesses (Bottomley & Kassner, 2003; Greving & Santacroce, 2005). Pediatric psychologists will continue to address and develop solutions to these challenges to promote resiliency and quality of life in pediatric cancer patients.

Ethical Issues for Psychologists in Medical Settings

Gerald P. Koocher[1] and Jeanne S. Hoffman[2,*]

[1]Department of Psychology, DePaul University, Chicago, IL, USA
[2]US Department of the Army, Washington, DC, USA

Over the past several decades, the numbers of psychologists practicing in health delivery systems have expanded as have the types of sites and roles of psychologists in these settings. This result follows the progress of research and practice in health psychology, behavioral medicine, and pediatric psychology but also tracks the evolution of the US healthcare system and specialty care settings. Ethical regulation of the practice of psychology began with the first code of ethics published in 1953 and has evolved as the scope of psychology has changed with the most recent revision adopted in 2010 (American Psychological Association [APA], 2010). The inclusion of psychology as a healthcare profession has resulted in new ethical challenges to practitioners. In response APA developed "Guidelines for Psychological Practices in Health Care Delivery Systems" (APA, 2013). These guidelines are aspirational rather than enforceable standards of care and are "intended to facilitate the continued systematic development of the profession and to help ensure a high level of professional practice" (APA, 2013). They also serve to highlight challenges to practitioners in this specific, but varied, specialty.

Working in the Medical Culture

Practicing medical psychology requires intercultural skills. Just as we expected psychologists to become knowledgeable about and sensitive to the culture of their patients, they must also acquire knowledge and sensitivity to the culture of the healthcare system. Medical culture has a different lexicon; requires an expanded knowledge of physical illnesses, their symptoms, and

treatments; has a powerful hierarchy, often with a physician as leader; requires flexibility with tolerance for multitasking, "stat" consultations, and interventions (from the Latin *statum*, meaning immediately); and may not understand or recognize the distinct capabilities, services, or ethical responsibilities of psychologists.

A degree of willingness to adapt and skill working across professional lines are required for any mental health professional planning to work in such settings. One must, for example, acquire a new lexicon of terminology that may seem paradoxical (e.g., a "progressive disease" is one that gets worse, and "positive findings" are a bad sign when discovered during a physical examination). Familiarity with the symptoms, course, and treatment of physical illnesses as well as an understanding of how medical hospitals and outpatient centers work (as distinct from mental hospitals, community mental health centers, or college counseling services) will prove very important.

Mental health practitioners in medical settings also must remain keenly aware of their skills and limitations in the context of healthcare regulations. These include interdisciplinary collaboration in outpatient settings, maintaining competencies, and attending to issues in hospital practice related to confidentiality and the Health Insurance Portability and Accountability Act (HIPAA). Many medical conditions can present in ways that suggest psychopathology, and having a medical degree does not ensure against diagnostic errors. Some physicians seem too willing at times to see physical complaints as psychological, and some mental health practitioners seem all too eager to go along with them. Similarly, some healthcare practitioners can become so focused of detecting or fighting a serious illness that the psychological needs of the patient get lost in the process.

Professional Integrity

Typically, mental health professionals working in medical settings will be employed under the supervision of physicians, historically hired in departments of psychiatry or pediatrics, but increasingly in subspecialty practices such as cardiology, endocrinology, gastroenterology, genetics, nephrology, oncology, or organ transplant services. At other times, they may be administratively organized in separate departments labeled behavioral health, medical psychology, or family services in an effort to avoid the stigma some associate with psychiatry and mental illness. They may provide assessment and intervention services to treat psychopathology but may also be involved in addressing medical nonadherence, symptom control (e.g., pain treatment or anxiety about pending medical procedures), screening for qualification as candidates for complex procedures (e.g., organ transplantation or gastric bypass), genetic counseling, or end-of-life care. Wherever they work, psychologists must take care not to surrender their professional integrity or standards (APA, 2013, *Guideline 1*) within this milieu. The *Guidelines* acknowledge that this may be challenging due to "constraints or pressures posed by other professions or systemic factors" (APA, 2013).

Consider the medical practice in which the office medical clerk asks every patient to complete brief depression and anxiety measures, scores them, and hand the scores over to a psychologist who writes a few sentences as an "assessment" of patients they have not personally interviewed. The patients' insurance is billed for the assessment screening that creates an unnecessary expense with no clear benefit for most patients. Consider the hospital outpatient clinic the administrator routinely overbooks all practitioners to allow for DNK (did not keep) or no-show appointments. On days when every patient shows up, they may be told, "The doctor is running late," with no mention of overbooking as the cause. This type of scheduling may not qualify as unreasonable in some circumstances where the practitioner's time with each patient is brief, but would certainly qualify as unreasonable for psychotherapy appointments. These examples may seem like good business practices aimed at increasing billing volume, but they do not meet the ethical test of holding the best interests of the patient paramount.

One should not assume that other professionals understand the training, services, standards, or ethics of psychologists. We can and should take steps to expand colleagues' knowledge of their potential contributions within these settings in accord with acceptable practice. Of course this also requires our profession's understanding the roles of the myriad professionals in complex medical systems. For example, do social workers perform psychotherapy or case management, do speech therapists provide behavioral treatment for feeding disorders, do pediatricians evaluate ADHD, do pharmacists address adherence issues, and who makes final decisions on how professional services are coded and billed?

Competence and Credentialing in Healthcare Delivery

Our ethics require us to practice only within the limits of our training and competence. As psychology has matured as a specialty in medical settings, specific core competences have evolved. An example of such core competencies was generated by the Interorganizational Work Group on Competencies for Primary Care Practice (McDaniel et al., 2014) and could be considered as a model for core competencies in other medical settings: science, systems, professionalism, interprofessional relationships, application of care, and teaching. At the same time, many of the roles we perform in medical settings have evolved with the rapid pace of change in medical care, requiring continuing learning and creative adaptation by experienced clinicians. Intellectual laziness and conceptual rigidity will lead to rapid failure in medical settings.

Healthcare delivery systems must, by law (42 U.S.C.233(h)(2)), require documented credentialing and privileging of its providers. Credentialing in this context involves "the process of assessing and confirming the qualifications of a licensed or certified health care provider" (Health Resources and Services Administration, 2007). Clinical privileges define the scope of services the individual is deemed qualified to provide within the organization. Staff appointments define the extent of participation in the governing bodies of medical institutions. The type of appointment for psychologists (e.g., full medical staff, allied health professional, consultant) and particular privileges (e.g., admitting, consulting, treating, or conducting research) varies between institutions.

Board certification of physicians has become a well-established standard, often required for their credentialing in medical settings. While the majority of psychologists have not sought board certification, those practicing in healthcare are more likely to have board certification (21.7%) (Robiner, Dixon, Miner, & Hong, 2012). The American Board of Professional Psychology (ABPP), founded in 1949, has become the body predominantly responsible for the granting of board certification with its specialties in clinical psychology, clinical health psychology, clinical child and adolescent psychology, clinical neuropsychology, and rehabilitation psychology the most relevant in healthcare practice. As psychologists increasingly become integrated team members in the evolving healthcare system, and with mounting emphasis on competence and safety within these institutions, the necessity for board certification as a commensurate credential with our colleagues is in the future of psychology.

Confidentiality

Confidentiality stands as the cornerstone of the therapeutic relationship, but the duty of confidentiality becomes nuanced and complex within medical systems. We owe preservation of confidentiality to individual patients, but medical settings include a community of providers that requires a network of confidentiality (Condie, Grossman, Robinson, & Condie, 2014). The psychologist should recognize that within these networks both formal and informal exchanges of information occur. In addition, differing views of confidentiality may be held by the patient, the family, the psychologist, the various other care providers, and also the medical institution. In certain areas such as pediatrics, the primary care provider has an expectation that all information will be shared. Families often have similar expectations even with adult patients.

Limits of confidentiality in medical settings are controlled by HIPAA, state law, or other government regulations that create conflicting demands at times. HIPAA allows providers to share information necessary for treatment and payment operations, but there may be circumstances when patients may rightly request that sensitive information be compartmentalized. For example, suppose that family members agree to screening as possible bone marrow donors for a child and genetic testing reveals that the person who believes he is the child's biological father turns out to be genetically unrelated. This incidental parentage discovery unrelated to the primary question (i.e., Is the putative father a good donor match?) could cause considerable emotional distress, if revealed. Similarly, consulting psychologist will routinely learn of sensitive emotional issues unrelated to immediate medical treatment needs of the patient. In the community of caregivers, some information should be shared on a need-to-know basis.

Electronic health records often make better integrated care possible, but it is important to understand and make appropriate use of role segregation. Once again, need-to-know becomes the key principle, but the psychologist needs to understand who will have access to what information and understand the potential consequences. For example, the patient registration clerk and the proctologist most likely should not have access to sensitive psychotherapy notes. Patients also have a right to know and consent to the sharing of their medical and mental health records. At an institutional level this typically occurs at the time of clinic registration or hospital admission, when the patient signs a standard HIPAA information document. However, many people do not read, understand, or remember the details. Therefore, the psychologist should repeat the necessary HIPAA cautions to patients when we begin to serve them in these settings.

Informed Consent

This process supports the basic ethical principle of autonomy and promotes trust between provider and patient. It also addresses some of the conundrums posed within a multidisciplinary care setting. Informed consent not only provides a patient with the risks, benefits, and alternatives to specific treatments but also delineates with whom a patient's information will be shared and the nature of the community of providers involved. We must remain mindful that consent is a process, rather than a single conversation or signature on a form. We must refresh the patient's understanding as changes that might affect their decisions occur.

The most recent APA Ethics Code (APA, 2010) acknowledges the need to address these complexities when Standards 3.07 "Third-Party Requests for Services" and 3.11 "Psychological

Services Delivered To Or Through Organizations" were modified to include the concept of client definition (Behnke, 2014). When psychologists work with children, families, or couples, this becomes most salient (Behnke, 2014; Koocher & Keith-Spiegel, 2016; Rae, Brunquell, & Sullivan, 2009) and is addressed in Standard 10.2, which mandates that the provider "take reasonable steps at the outset (1) which of the individuals are clients/patients and (2) the relationship the psychologist will have with each person" (APA, 2010).

Consent, assent, permission, and capacity are different concepts that demand parsing.

Consent implies three separate aspects—knowledge, voluntariness, and capacity (both legal and cognitive). The person seeking the consent must provide sufficient information for the person granting consent to understand fully what is being asked of them. It is not necessary to disclose every potential aspect of the situation, only those facts a reasonable person might need to formulate a decision. Voluntariness refers to the absence of coercion, duress, misrepresentation, or undue inducement. People can only give consent for themselves. Capacity refers to legal competence to give consent as well as the cognitive ability. Although all adults are deemed competent to give consent unless they are found to be incompetent, children are assumed incompetent to grant consent (Koocher & Keith-Spiegel, 2016).

The concept of capacity involves weighing the right to autonomy of the patient vs. beneficence and non-maleficence. For persons who are legally incapable of giving informed consent, such as children, adolescents, or adults lacking capacity, psychologists nevertheless must seek assent. This means that they must provide an appropriate explanation of the treatment or assessment, seek the individual's assent and consider the person's preferences or best interests, and seek appropriate permission from a legally authorized person, if such substitute consent is permitted or required by law. Children and adolescents are presumed to lack competence to consent, but the provider should determine the minor's ability to understand information offered about the nature and potential consequences of the pending decision (i.e., the risks and benefits of a specific treatment or action) and invite a clear preference based on the information presented.

The terms competency and capacity are often used interchangeably, but competence is a legal concept determined by a court or defined by law as in the case of minors. Capacity is determined by a qualified psychologist or physician based on the circumstances and jurisdiction. Questions of capacity arise in medical settings most often arise with refusals or discontinuation of treatment. If an articulate child, medical providers, or the parent/guardian disagrees on the necessity of medical treatment, a judicial decision may be requited.

Boundaries

Psychologists are trained to maintain boundaries, but working in medical settings, especially acute care settings, will present many unexpected challenges. The challenges might be categorized as boundary crossings versus boundary violations. The former is in service of the therapy and must be a considered action taking into account the general ethical principle of beneficence while a boundary violation results in harm to the patient. The context in which boundary crossings occur must be considered (Zur, 2017). The medical context is unique and may impose varying degrees of beneficent exigency. In other settings a psychologist does not make physical contact with a patient, but what if a patient in the final stages of life requests that the psychologist hold her hand? What if a patient requires oral suctioning to continue the therapeutic interaction? What if the therapist is assisting the patient remain calm during a procedure in which the patient's body is exposed? Does this violate the patient's right to dignity or promote coping? Context, contingency, and patient needs and rights must all be considered in the decision to deviate from standard operating procedures in psychotherapeutic practice.

Challenging Healthcare Contexts

In this brief chapter we cannot address all possible complicating contexts that will challenge psychologists in healthcare setting, but we have chosen a few that illustrate the range of ethical challenges that can arise. These include providing services in military medical settings, care of patients seeking organ transplantation, children with gender dysphoria, and patients with cystic fibrosis (CF). We selected this sampling because of the significant ethical issues that come up in providing care with these patients and setting contexts.

Military medical care provides some thought-provoking examples. A recent report by the Defense Health Board acknowledges such ethical challenges in its introduction (Defense Health Board, 2015). Clinical health psychologists practicing in military medical settings also face conflicts between their professional ethics, the challenges of working in a medical setting, and the requirement of following military policies and orders. Military medical settings range from very large medical institutions such as the Walter Reed National Military Medical Center to small embedded units in combat zones where the psychologist is the sole mental health provider. Depending on the site and role, the clinician may be a civilian employee or military personnel caring for active duty personnel or their dependents. While psychologists are required to avoid most multiple relationships, this is not always possible in military medical settings (Dobmeyer, 2013; Johnson, Ralph, & Johnson, 2005; Koocher & Keith-Spiegel, 2016; Staal & King, 2000). Examples include a psychologist serving on an aircraft carrier who was required to provide a urine sample for random drug testing only to find the only female observer available was one of her patients (Johnson et al., 2005) or a psychologist working in a family medicine clinic who received his medical care from a physician who was also his client (Dobmeyer, 2013).

In the military active duty psychologists are also officers and bound by law and policy "to hold subordinates accountable, to promote order and discipline and to place the mission above the interests of the individual service member" (Kennedy & Moore, 2008). What is a clinician to do when in the course of therapy another officer reveals that he is having an extramarital affair, an offense under the *Uniform Code of Military Justice* (UCMJ), or a pilot reports that he is taking stimulant medication for ADHD that is prohibited and considered a safety risk? Confidentiality also becomes much more complex issue in a system where commanders are entitled to information about a service member's medical or psychological condition and how its treatment may effect fitness for duty or deployability and all treatment is documented in a system-wide electronic medical record.

Cultural competency also comes into acute focus, as psychologists in military medical settings work within both the medical culture and the military culture. The latter may seem quite alien to civilian psychologists. The military culture is highly structured, hierarchical, with specific norms of behavior, specific belief systems, and even unique forms of language. The military subscribes to core values that have in common: duty, honor, and country. Families of service members live within this culture, and veterans often subscribe to military values long after their active service ends. Military psychologists understand this culture, but civilians must seek training or mentoring to ethically practice in these settings.

Organ transplantation is another arena in which psychologists provide invaluable services as members of transplant teams by evaluating potential recipients and their support systems, making recommendations to these teams, providing both clinical interventions and support to recipients and their families, and evaluation of candidates as living tissue or marrow donors. Each of these potential services comes with a myriad of ethical challenges. Confidentiality issues become very complex as information must be shared, especially the results of assessment of psychological or behavioral factors that could adversely affect the success of the transplant. Will the psychological status of the patient compromise success? How likely is the recipient to adhere to the complex post-transplant regimen? Of course, informed consent must be obtained for psychological evaluation or treatment, but can the patient truly refuse? Does consent qualify as voluntary if the alternative is death? Can the patient's support system refuse assessment since this will jeopardize the patient being accepted for transplant? What happens if a screened donor qualifies as a "good match" but has intense ambivalence about donating? How can we valance the ethical principles of beneficence and non-maleficence in transplant decisions?

Conflicting loyalties may lead to ethical dilemmas that force the psychologist to sort through the question of to whom one owes a duty of loyalty and in what hierarchy: the patient, the family, the donor, the medical teams, and the transplant center? Certainly issues of justice are a topic of great debate in transplant medicine. What if the potential recipient has cognitive or emotional impairments that might compromise success? Dual relationships are common. Can the psychologist who provides therapy and support also objectively evaluate the patient? Are other psychologists with the requisite skills and knowledge available to consult? The donor status can trigger other ethical issues. Is this to be a living donor? Are pressures being applied to donate? Is there a conflict between the possible harm to the donor and possible good to the recipient? Can a minor consent to donation of an organ in any event? What if the best donor for a parent is their child? In nonliving donation other issues arise: pressure applied to donor families when time is of the essence in harvesting the organ and psychological impact on families when donors are kept alive by mechanical means to facilitate harvest. Issues can even arise related to how death of the donor is determined: brain death or circulatory death.

Minors With Gender Dysphoria/Transgender Youth

Psychology has a unique and essential contribution to the treatment of this population both because of our knowledge set but also in our awareness of the ethical challenges embedded in this area of practice. While adults with these conditions have a more direct route to medical and surgical interventions, psychological assessment is still required. Children also require psychological evaluation, but ethical challenges become prominent when they present for treatment. The core of these challenges arises from the fact that gender identity and gender expression may change over time (Tishelman et al., 2015) and the percentage of gender diverse children decreases with age due to return to conformity with natal sex, or a determination they are gay, lesbian, or bisexual (APA, 2015). Ethical principles of beneficence and non-maleficence as well as autonomy must be addressed as well as the ethical standards of informed consent, assent, and capacity.

The typical course of treatment guided by psychosocial development principles suggests these differences. Young children expressing gender dysphoria are candidates for exploratory psychotherapy for the child, but often, primarily for parents. Prepubertal children are candidates for psychotherapy, assessment, and consideration of puberty suppression to give time for the child to mature cognitively in order to more fully understand the consequences of their decision. Pubertal children may be candidates for addition of use of cross-sex hormones to the treatment course to begin the transition to another sex. Adults may be prepared to consider sexual reassignment surgery. Assent becomes a particularly thorny issue with minors as they may not have the capacity to fully understand the course of treatment, irreversible consequences, or psychosocial challenges that they might face. But an additional issue involves the fact rates of autistic spectrum disorders are higher in the population of minors who express gender dysphoria, raising the fundamental question whether these youth with impaired social skills can fully understand the implications of gender modification. The APA guidelines on practice with transgender patients also caution practitioners to remain mindful of the cognitive processes of adolescents that might focus on immediate gratification to the detriment of a considered decision (APA, 2015). Again, we must adhere to the standards of competence and informed consent in order to prevent harm to these youth (non-maleficence) even as we strive to help them optimize adjustment as part of the treatment team.

Cystic Fibrosis

CF provides an excellent example of a life-threatening genetically transmitted (autosomal recessive) disease illness previously associated with childhood death. With new treatments CF has become a chronic disease with mean survival into the sixth decade of life. Successful treatment of CF involves a complex and unrelenting treatment regimen that imposes a significant burden on caretakers and patients alike. A burgeoning body of research on CF has begun to identify factors related to prognosis. As one might expect, adherence is an important factor that itself impacts other variables such as lung function and body weight that, in turn, influence long-term survival (Sawicki & Goss, 2015; Smith, Georgiopoulos, & Quittner, 2016). A recent, and growing, body of literature has found that rates of depression in individuals with CF and their caretakers rank well above comparison samples (Quittner et al., 2014). These higher rates of depression and anxiety link to decreased adherence as well as poorer lung function and lower body weight. As a result, the Cystic Fibrosis Foundation (CFF) Committee on Mental Health has recommended that individuals with CF ages 12 to adulthood as well as caretakers of all children and adolescents with CF be screened annually for depression and anxiety. For all children, adolescents, and adults with CF, storing of such results in their medical records would be expected, although with the same ethical consideration given to all mental health test and screening results. But what of the results of caretaker screenings? Should they be recorded in the caretaker's medical record or CF patient's? This becomes an ethical question that is being currently discussed on the CFF Mental Health Group Listserve and at the most recent CFF Conference. In addition, the prevention of CF via genetic screening and pregnancy termination raises sensitive questions for family members who may carry the gene.

Emerging Challenges

We have simply scratched the surface of the range of issues and contexts that raise ethical challenges for psychologists working in medical settings. Reflecting on the special challenges discussed here, it is clear that most have arisen as medical science has advanced. Inexorably with future advances, new ethical challenges to psychologists will emerge extend beyond psychologists' current knowledge and thereby increase responsibility to acquire working knowledge of these advances. Neuroimaging is one such area as is genetic modification and enhancement technologies. To these and to as yet unimagined technologies, psychologists must apply our basic ethical tenets but also strive to anticipate quandaries that might arise.

Solutions to Ethical Challenges

Just as working in medical settings is a team sport, solutions to ethical dilemmas require a team approach. Collegial consultation is key. Developing familiarity and routine discussions with colleagues across disciplines, consulting with experts including those involved in direct care, and third-party operations will be essential. National and state psychological associations will be a resource, but monitoring regulatory changes by licensing boards will also prove critical. Hospitals are required by Joint Commission to have ethics committees that exist to provide consultation. Perfection is not required, but knowledge of ethical principles, thoughtfulness, and efforts to avoid harm are.

Author Biographies

Gerald P. Koocher, PhD, ABPP, received his doctorate in clinical psychology from the University of Missouri. He is professor of psychology and dean of the College of Science and Health at DePaul University. He previously served as chief psychologist at Boston Children's Hospital and the Judge Baker Children's Center.

Jeanne S. Hoffman, PhD, ABPP, received her doctorate in developmental psychology and clinical respecialization from the University of Hawaii with a fellowship in pediatric psychology from Boston Children's Hospital and Judge Baker Children's Center. She currently is chief of the pediatric psychology clinic at Tripler Army Medical Center, Honolulu, Hawaii.

History of Clinical Health Psychology

Rachel Postupack and Ronald H. Rozensky

Department of Clinical and Health Psychology, College of Public Health and Health Professions, University of Florida, Gainesville, FL, USA

> Disease is not the accident of the individual, nor even of the generation, but of life itself. In some form, and to some degree or other, it is one of the permanent conditions of life.
>
> Henry David Thoreau

Health is a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity (World Health Organization, 1948). This formulation of health, adopted globally immediately after World War II, predates Engel's (1977) "new" "biopsychosocial" model of healthcare by decades and, as pointed out by Rozensky (2015), is as "new" as 190 CE when Galen postulated the integration of mind and body in medicine during the Roman Empire. Every textbook and article that discusses the history of clinical health psychology (Baum, Perry, & Tarbell, 2004; Belar, Deardorff, & Kelly, 1987; Friedman & Adler, 2007; Stone, Cohen, & Adler, 1979; Sweet, Rozensky, & Tovian, 1991) notes that "psychology has long been in the forefront of the scientific inquiry into the understanding of health" (Resnick & Rozensky, 1996, p. 1). While psychology clearly is a scientifically based discipline that both carries out research concerning health, disease, and treatment and provides direct clinical services to those who seek help with disease prevention or treatment for managing a wide range of medical diagnoses and problems, it was not until 2001 that "the American Psychological Association (APA) amended its mission statement to include the term 'health.'" The American Psychological Association (APA) stated that psychology's focus is to "advance as a science and a profession, and as a means to promoting health and human welfare" (Rozensky, Johnson, Goodheart, & Hammond, 2004, p. *xix*).

First recognized formally as specialty in 1997 by the APA (2015a), "Clinical Health Psychology applies scientific knowledge of the interrelationships among behavioral, emotional, cognitive, social and biological components in health and disease to: the promotion and maintenance of health; the prevention, treatment and rehabilitation of illness and disability; and the improvement of the health care system. The distinct focus of Clinical Health Psychology

The Wiley Encyclopedia of Health Psychology: Volume 3: Clinical Health Psychology and Behavioral Medicine,
First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

(also referred to as behavioral medicine, medical psychology and psychosomatic medicine) is at the juncture of physical and emotional illness, understanding and treating the overlapping challenges." This definition was built, in turn, on Matarazzo's (1980) definition as adopted by the APA Division of Health Psychology: "the aggregate of the specific educational, scientific, and professional contributions of the discipline of psychology to the promotion and maintenance of health, the prevention and treatment of illness, and the identification of etiologic and diagnostic correlated of health, illness, and related dysfunction" (p. 815).

Given these definitions, Belar (2008, p. 230) described both the venues in which health psychology services take place and the range of clinical issues addressed:

> Clinical health psychology services may be integrated with primary care, urgent care, tertiary care, and dental care, and occur in clinic, hospital-based, nursing care, rehabilitation, work site, and hospice settings.

Belar listed the nine problem areas addressed by clinical health psychologists:

1. Psychological factors secondary to disease, injury, or disability—which includes both normal adjustment reactions to posttraumatic stress disorders and all psychological diagnoses in the patient or family members.
2. Somatic presentations of psychological issues, which can include such issues as chest pain with panic attack.
3. Psychophysiological problems (e.g., pain, headache).
4. Physical symptoms or medical conditions responsive to psychological and behavioral health interventions (e.g., urinary and fecal incontinence, anticipatory nausea, asthma).
5. Somatic complications associated with behavioral issues such as poor adherence to healthcare regimens.
6. Psychological presentation of organic depression with hypothyroidism.
7. Psychological and behavioral aspects secondary to stressful medical procedures such as self-infections, dental procedures, and burn debridement.
8. Behavioral risk factors for disease, injury, or disability related to problematic health behaviors such as smoking, overeating, low exercise, and risk-taking.
9. Problems encountered by healthcare providers and healthcare systems such as provider–patient relationship issues, staff "burnout," assuring universal precautions, healthcare team behavior and cooperation, clinical pathway development, and quality assurance and program evaluation activities.

Psychology and Health

Paralleling the history of health psychology is the development of the US federal government's *Healthy People* initiative (Department of Health and Human Services [US], 1979) that establishes goals for improving the quality of the nation's health with objectives focused on health promotion and disease prevention (Healthy People 2020, http://www.healthypeople.gov/). Rozensky (2012a) stated that along with psychology's traditions of efficacy, effectiveness, and community-based research and treatment, the profession has engaged in this population-based approach to the scientific study and treatment of the human condition. Further, Rozensky (2012a) reviewed societal and healthcare trends impacting health service psychology including competency-based education, interprofessionalism, evidence-based care, and team-based, patient-centered care and changes in population demographics including a more diverse population that is aging with more chronic illness. As one of the recognized specialties under the broader umbrella of health service psychology, clinical health psychology has been a leader, throughout its history, in anticipating the various scenarios, or interactions of these trends, in preparing each new generation of health service psychologists to successfully function in an evolving research and healthcare environment.

With definitions in hand, trends in mind, and current clinical activities and services described, the history of clinical health psychology will be presented from the perspective of how the profession itself has advanced. This will include the scientific and clinical changes in the field as reflected in the evolution of philosophies and organizations that have promulgated a biopsychosocial understanding of health and illness.

Defining Health Psychology and the Formation of Professional Organizations

The evolution of clinical health psychology in becoming a recognized specialty is rooted in the development of definitions that include the interaction of cognitive, behavioral, emotional, and psychological processes and physical health and the formation of professional organizations that focus on science and practice in those domains. The ancient Greeks provided the philosophical basis for modern Western medicine by shifting the focus from supernatural causes to recognition of the importance of actual bodily factors in health. They theorized that illness was caused by an imbalance of the four bodily humors: blood, phlegm, choler (yellow bile), and melancholy (black bile). Health could be restored then by bringing balance to these fluids (Friedman & Adler, 2007). Galen, a Greek physician in the Roman Empire, posited that the dominant humor in an individual's balance determined temperament and vulnerability to illness (Maher & Maher, 1994). This early integration of mind and body was later de-emphasized in favor of focusing on primarily bodily or physical processes in the biomedical model.

In the early twentieth century, the split between mind and body was reflected in the distinction of psychiatry as a medical specialization focused on the influence of the mind to explain symptoms for which there was no biological basis. Interest in the contribution of mental disturbance to disease became the domain of the emerging field of psychosomatic medicine (Dunbar, 1943). Flanders Dunbar began the journal of *Psychosomatic Medicine* in 1938–1939, which is the official journal of the American Psychosomatic Society founded in 1942. Today their mission is to "promote and advance the scientific understanding and multidisciplinary integration of biological, psychological, behavioral, and social factors in human health and disease, and to foster the dissemination and application of this understanding in education and health care" (www.psychosomatic.org).

Moving into the 1960s and 1970s, growing insight into biological mechanisms prompted a philosophical shift in psychosomatic medicine to consider the bidirectional interactions between physiological and emotional states. George F. Solomon and Moos (1964) introduced the term *psychoneuroimmunology* (PNI) to refer to the theoretical connections between emotions, immunity, and disease. Research on stress and disease expanded and was based on the "fight or flight response" (Cannon, 1932) and understanding of physiological reactions to stress (Selye, 1956). Engel's (1977) descriptions of the biopsychosocial model contributed to the ongoing integration of the mind and body in contemporary healthcare science and practice. Herbert Benson demonstrated the utility of meditation or relaxation to counteract both acute and chronic stress while impacting health status in conditions like hypertension

(Benson, 1983). These discoveries among others provided an evidence base for the introduction of behavioral treatments into medical settings. Emphasis on the integration of mind and body became known as *behavioral medicine* (Birk, 1973). Interdisciplinary from its inception, contributors to the science and practice of behavioral medicine included professionals from a range of professions including physicians, psychologists, bio-behaviorists, and others. The Society of Behavioral Medicine and *Journal of Behavioral Medicine* were founded in 1978 to promote a "field concerned with the development of behavioral science knowledge and techniques relevant to the understanding of physical health and illness and the application of this knowledge and these techniques to prevention, diagnosis, treatment, and rehabilitation" (Schwartz & Weiss, 1978, p. 7).

In the 1980s *behavioral health* was distinguished from *behavioral medicine* as "an interdisciplinary field dedicated to promoting a philosophy of health that stresses *individual responsibility* in the application of behavioral and biomedical science knowledge and techniques to the *maintenance* of health and the *prevention* of illness and dysfunction by a variety of self-initiated individual or shared activities" (Matarazzo, 1980). It is within this focus on the individual and a personal ability to affect change that impacts health that psychologists found a professional niche to more specifically define their scientific and clinical competencies to encourage health promotion as well as address challenges associated with illness and its treatment. The field of *health psychology* was defined as promoting the integration of psychological knowledge and biomedical information as it applies to health promotion, prevention, diagnosis, treatment, and rehabilitation (APA, 2015b; Matarazzo, 1980). To assist in the development of a cohesive field of specialization then, George Stone established the *Journal of Health Psychology* in 1982. Then in 1994, the *Journal of Clinical Psychology in Medical Settings* (JCPMS) was founded by Ronald Rozensky to further the role of health service psychologists as scientists and practitioners in medical settings as they addressed diseases and medical problems (Rozensky, 2006).

Established in 1892 the APA advances the creation, communication, and application of psychological knowledge on the national level (APA, 2015c). Today APA is home to 54 divisions, which are special interest groups that represent topic areas germane to the range of clinical, scientific, educational, and public interest foci of psychologists. Movement toward the foundation of the division of health psychology began in 1973 when APA's Board of Scientific Affairs directed that health research should be reviewed and disseminated at scientific meetings. This decision was influenced by William Schofield's (1969) paper describing psychologists' roles in health service delivery. A section of interest was added to Division 18, Psychologists in Public Service, in 1975 specifically to increase the application of psychological principles to health research and patient care as well as disseminate the results of this work. Steven Weiss and Joseph Matarazzo advocated for the foundation of an APA division devoted to health psychology. Their efforts were successful when Division 38 Health Psychology was established in 1978. The division continues its mission to promote and disseminate health-related research through *The Health Psychologist* newsletter begun in 1979 and the *Health Psychology* journal that published its first issue 1980–1981 (Wallston, 1997). In August 2015 the Division of Health Psychology voted to change its name the Society for Health Psychology. It continues to provide an intellectual home to health psychologists and other professionals devoted to the intersection of psychological processes and physical health.

One venue that illustrates the robust growth of psychologists engaged in health and healthcare research, education, and clinical practice is number of psychologists in academic health centers and hospitals. Noting that environment as "a true healthcare home" for psychologists (p. 353), Rozensky (2012b) reviewed a series of published surveys from the early 1950s through the first decade of the twenty-first century carried out by such notables as Matarazzo and Mensh. The number of psychologist in medical school was less five per school in the 1950s to 20.7 per school in the late 1970s with at least 3,894 psychologists identified in academic medical settings at the end of the twentieth century (Williams & Wedding, 1999). Rozensky noted that the most recent data finds more than half (54.5%) of psychologists work in institutional settings with 12.4% in hospitals and 4.6% in medical school alone (APA, 2009).

In 1991, the American Board of Professional Psychology (ABPP) formally recognized clinical health psychology as a specialty in professional psychology and began granting board certification in the field based on peer evaluation (Belar & Jeffrey, 1995). In 1997 the APA (1997) archived a formal definition of the specialty of clinical health psychology, and it remains a recognized specialty to date. Today, contemporary clinical health psychologists are seen as working interprofessionally in clinical practice. They learn side by side with other healthcare professionals during their education and training in the context of the changes in healthcare both predating and promulgated by the implementation of the *Patient Protection and Affordable Care Act* (Public Law No: 111–148, 2010, March 23). As part of the evolution of health psychology's place in the healthcare system, the growing acceptance of the use of Health and Behavior (billing) Codes reflects both the system's integration of mind and body and the integration of psychologists on the healthcare team. Allowing clinical health psychologists to directly bill these Health and Behavior Codes for treating and helping patients manage specific medical problems reflects, financially, the recognition of both psychologists' healthcare competencies and systemic integration (Kessler, 2008) as not just mental health providers but members of the integrated healthcare team. Along with their clinical services and educational activities, health psychologists also participate in team science to ensure research integrates mind and body and ensures interprofessionalism as part of science (Rozensky, 2014).

Education and Training

Clinical health psychologists conduct research and practice at the intersection of physical and mental health in a variety of settings addressing diversified patient populations and problems. The formulation of education and training guidelines has been an essential component in the development and maintenance of professional competencies for both current and future psychologists (Fouad et al., 2009; Health Service Psychology Education Collaborative, 2013; Rodolfa et al., 2005).

In 1983 the Arden House National Working Conference on Education and Training established the first set of education and training guidelines for the field of clinical health psychology (Stone, 1983). The conference recommended that training at the doctoral level remain "broad and general" to develop an integration of theory, research, and practice based on knowledge and understanding of the biopsychosocial model. Predoctoral clinical internships completed in settings where both psychological and physical healthcare services take place were encouraged by the Arden House participants as a part of each student's professional development.

Competencies

In general, doctoral programs in health service psychology have maintained their commitment to the integration of science- and evidence-based practice (Belar & Perry, 1992) where students acquire foundations in scientific psychology, research, ethics, diversity, theory, and clinical practice (Kaslow, Graves, & Smith, 2012) as core competencies in their broad and general education and training. In that manner, curricula for programs with a specific major area of study in clinical health psychology include knowledge of biological, affective, cognitive, social, and cultural bases of health and illness. Additional education may be provided on special topics such as pathophysiology, psychoneuroimmunology, and pharmacology (Belar, 2008). Ideally training is conducted in clinical settings conducive to the development of competencies to conduct health-related clinical assessments and interventions, health-oriented research, and the competencies to function as a part of healthcare delivery system including consultation services and engagement in interprofessional, team-based collaboration (Belar, 2008; France et al., 2008). It was recommended that accreditation *for* health psychology training programs begin at the postdoctoral level (France et al., 2008), but it is clear that many accredited doctoral programs in health service psychology offer major areas of study in clinical health psychology.

France et al. (2008) provided a competency model for clinical health psychology that details knowledge and applied skills in assessment, intervention, consultation, research, training in supervision, and management administration. Kaslow, Dunn, and Smith (2008) detail the core foundational and functional competencies for health service psychologists practicing in academic health centers, while Kerns, Berry, Franstve, and Linton (2009) extend the description of competencies to issues related to developing lifelong competencies in clinical health psychology. Across competency models, the importance of ensuring clinical health psychologists possess the interprofessional competencies to function successfully within a healthcare team (Fouad & Grus, 2014) and understand the characteristics of a truly competent team (Interprofessional Education Collaborative, 2011) is key to the ongoing evolution of the specialty of clinical health psychology.

Specialization

A specialty is defined as an area of psychological practice that requires advanced knowledge and skills acquired through an organized sequence of education and training (Commission for the Recognition of Specialties and Proficiencies in Professional Psychology, 2015; CRSPPP). Specialization allows professionals to focus on content that they must learn, refresh, and maintain to retain competence in a field as it continues to develop (Kaslow et al., 2012; Rozensky & Kaslow, 2012). The Commission for the Recognition of Specialties and Proficiencies in Professional Psychology (CRSPPP) establishes policies and procedures that are used by APA to review and recognize health service specialties with clinical health psychology being one of those recognized specialties. To identify individual specialists, individuals competent to deliver quality health psychology services, the ABPP (www.abpp.org) offers board certification for practitioners at the postdoctoral level who pass a peer-review, competency-based exam. Achieving board certification is particularly helpful for clinical health psychologists who work in integrated medical settings because board certification is considered the standard of practice for our colleagues in medicine and related health professions (Rozensky & Kaslow, 2012).

Clinical health psychologists face the ongoing challenge of learning and maintaining a current, relevant, evidence-based perspective to meet the ethical requirements of competent practice within their specialty. To help students and professionals describe their level of education and training in clinical health psychology, the Council of Clinical Health Psychology Training Programs (CCHPTP) developed the Clinical Health Psychology Specialty Taxonomy (http://cospp.org/guidelines) based on the APA policy designed to ensure consistent descriptions of the levels of education and training within specialties across the sequence of learning from graduate school, to internship, and through post-licensure, lifelong learning (Rozensky, Grus, Nutt, Carlson, Eisman, & Nelson, 2015). That CCHPTP taxonomy lists the expectation for a major area of study in clinical health psychology at each stage of training. Recognizing that each year there is a continuing influx of new scientific and clinical information and that there is a decreasing half-life of professional knowledge, each psychologist must establish a commitment to lifelong learning on the part of the competencies required of being a specialist (Wise et al., 2010). Incorporating the lifelong learning process into the broader context of the competency movement involves the evaluation of professional skills, practices, and outcomes (Neimeyer & Taylor, 2011). In addition to formal structures for continuing education and competency-based assessments, a self-study/self-assessment can be used to develop learning plans for specialization throughout a professional's career (Belar et al., 2001). Clinical health psychology has embraced a competency-based model of education and training from the early days of the Arden House Conference through professional psychology's evolution to a "culture of competence" (Roberts, Borden, Christiansen, & Lopez, 2005, p. 359).

Clinical Health Psychology, the 2010s, and Beyond

Each step in the history of clinical health psychology has been motivated by the spirit of that time—spirit based on politics within and external to the profession, scientific developments in psychology and medicine, technological evolution, vicissitudes in contemporary healthcare and healthcare financing, and changes in educational philosophy. The future of clinical health psychology will be based on contemporary *zeitgeist* composed of those same motivating forces today and tomorrow.

Contemporary clinical health psychology exists within the broader context of healthcare reform as detailed in the *Patient Protection and Affordable Care Act* (Public Law No: 111–148, 2010, March 23) and its ongoing implementation. That law recognizes the importance of evidence-based healthcare, quality care including credentialing and specialization, team based, and interprofessionalism in both education and practice (Rozensky, 2011, 2013). And clearly, education and training in all branches of health service psychology, including clinical health psychology, must address these issues in its curricula and practical training (Rozensky, 2014).

In order to understand where clinical health psychologists will be employed in the future, a clear national workforce analysis philosophy must be operationalized, and data collected and studied in order to inform educators and practitioners alike as to societal need and employment opportunities (Rozensky, Grus, Belar, Nelson, & Kohout, 2007). Questions like how many psychologists will be needed in primary care, in cardiac care, in rehabilitation psychology, in psycho-oncology, etc. will help the field have a picture of the future and provide direction to students and early career psychologists planning their education and practice focus.

Many scholars have described the history and successful evolution of the specialty of clinical health psychology and highlighted the various individuals and organizations that have helped define the education, training, science, and practice of clinical health psychologists. This history reflects a robust science whose application is key to helping those who wish to learn to prevent disease, improve their health, or seek to manage their illness or their reaction to that illness. Clinical health psychologists clearly are dedicated to improving the human condition, and each recognizes, in their day-to-day work, what Shakespeare said some 400 years ago, "What wound does not heal but by degree?"

Author Biographies

Rachel Postupack, MS, completed her graduate education in the Department of Clinical and Health Psychology at the University of Florida, where she is currently completing her predoctoral internship. She is focusing her clinical experiences on providing services to underserved medical populations. Her research has focused on pain, distress, cytokines, coping, and quality of life for patients with cancer.

Ronald H. Rozensky, PhD, ABPP, is a professor in the Department of Clinical and Health Psychology in the College of Public Health and Health Professions at the University of Florida where he served as department chair and associate dean for International Programs. He is the founding editor of the *Journal of Clinical Psychology in Medical Settings* and board certified in both clinical and clinical health psychology.

Older Adults and Perspectives for Researchers and Clinicians Working in Health Psychology and Behavioral Medicine

Louise Sharpe

School of Psychology, Faculty of Science, The University of Sydney, Sydney, NSW, Australia

Background

It is well established that there is an aging trend in the population among most Western nations and that this trend is also being seen increasingly in developing nations (e.g., Arean, Hegel, Vannoy, Fan & Unuzter, 2008; Cuijpers, van Straten, & Smit, 2006). As the population ages, people continue to develop chronic illnesses, such as cardiovascular conditions, respiratory problems, diabetes, pain, and cancer. However, the way in which these conditions are medically managed has improved, such that the life expectancy of patients diagnosed with these illnesses is increasing. The consequence of improved medical care for chronic illness is that older adults are still living for longer with the burden of chronic physical illnesses than they previously have. Chronic physical illness impacts on a person's ability to engage in important activities, and as a result most chronic physical illnesses have been shown to be associated with poorer quality of life. Indeed, the majority of the health psychology or behavioral medicine research has focused on individual illnesses (such as pain or diabetes or cancer) in trying to understand the impact of experience chronic illness on people's life. However, the major risk factors for disease are common across conditions. For example, smoking, physical inactivity, and obesity confer risk of cardiovascular disease, stroke, respiratory disease, cancer, and diabetes. All of these illnesses are also more common in older adults. Hence, there is an increasing problem that has been labeled "multi-morbidity" where people are living not with a single medical condition, but with a combination of multiple physical health problems. For example, in a recent population-based study in the United Kingdom, one-quarter of people

attending primary care settings had multi-morbidity, and the risk for multi-morbidity is strongly associated with age. That is, only 7% of those under 45 years of age experienced multi-morbidity, whereas over half of all elderly participants (51% of those over 65) had multi-morbidity (Mujica-Mota et al., 2015). The increase in prevalence of multi-morbidity notes an important change in the management of older adults in health psychology or behavioral medicine. As previously mentioned, health psychology has followed the lead of medical education and research, whereby studies are funded to examine the relationships between different diseases and psychological constructs. However, if the majority of older adults experience multi-morbidity rather than having a single illness, this poses a significant challenge to the way in which we study and treat older adults with multi-morbidity.

Consequences of Multi-morbidity

Multi-morbidity in older adults is associated with a number of consequences. Firstly, people who have more than one physical condition are often prescribed medications separately for each of their conditions. Therefore, older adults often have a complex medical regimen to follow, involving a range of medications that frequently have contraindications and produce side effects. Secondly, many chronic physical illnesses are accompanied by symptoms that can be difficult to manage, such as pain or fatigue. These symptoms are often secondary to the underlying pathologies (e.g., neuropathies in diabetes or angina in cardiovascular disease), but sometimes are seen as more constraining to the individual. As a result of the illness and/or the symptoms or treatments of that illness, individuals typically will have an increase in disability associated with multi-morbidity, which can lead to increased social isolation and a general reduction in physical activity. In some cases, disability can become sufficiently incapacitating to require long-term formal or informal care. These consequences compound to increase the risk of the development of psychological disorders. While there is no good evidence to suggest that older adults have higher rates of depression and anxiety overall (indeed anxiety disorders appear to be lower among older people), multi-morbidity does increase the risk of depressive disorders (Read, Sharpe, Modini, & Dear, 2017). Further, as patients become more disabled and frail, it is increasingly common for them to develop a fear of falling.

Adherence to Medication

Adherence to medication is a major problem across all age ranges and conditions, with a large proportion of people not taking their medications as prescribed. Nonadherence to medication most commonly refers to patients either not taking medications that are prescribed or not taking them as prescribed, including taking larger doses of medication than recommended. There are a number of reasons why older adults might be particularly at risk for nonadherence, including more complex medication regimens to follow, mild cognitive impairment that is common among older people, and the fact that prescribed polypharmacy can give rise to more unwanted side effects and interactions than taking a single medication. Indeed, a qualitative study of nonadherence among the elderly determined that the barriers toward adherence included concern about taking too much medication, a lack of information about the risks and benefits of medicines, a desire to share decision making in the medical setting that is not fulfilled, and the difficulties of trying to coordinate different treatments prescribed by different providers (Haverhals et al., 2011). There have been attempts to use both simple and complex interventions to improve adherence specifically in older adults (Higgins & Regan, 2004) and among older adults requiring polypharmacy in particular (Cooper et al., 2015). While both identified small, statistically significant effects on improving adherence, per se, there was little evidence in either review that improving adherence influenced clinically significant outcomes (e.g., hospital admissions), and both noted that the quality of individual studies was poor. Few interventions were noted to be theoretically derived, and as such, this would be an important area of future research.

Management of Pain and Fatigue Among Older People

Pain and fatigue are the two of the most common symptoms of illness and both associated with poorer quality of life and increased depression. While the relationship between poorer psychological outcomes (such as depression) and pain and fatigue is likely bidirectional, there are very good chronic disease self-management approaches that appear to result in improvements in reported symptoms of fatigue and pain experienced in the context of illness. Importantly, however, these self-management approaches help the patients learn to pace their activities and develop coping skills to better manage their symptoms. There is a long history across individual illnesses of using chronic self-management approaches to improve health outcomes for patients; however, there is now strong evidence that such approaches can be used rolled out in primary settings with successful outcomes in terms of reducing pain, fatigue, and depression among those with chronic illness (Ory et al., 2013). While this study was not specifically with older adults, per se, the average age of participants was 65. In those studies that have attempted to replicate chronic disease self-management approaches with older adults, they have generally been effective. Since both pain and fatigue are among the strongest predictors of depression among older adults, offering opportunities for chronic disease self-management approaches in primary care settings is an evidence-based way in which clinicians can help patients learn to reduce these symptoms, or at least the impact of these symptoms on their daily lives.

Increasing Disability and Frailty

The consequence of the aging process itself is that people's ability for physical activity declines over time; however, this natural part of the aging process is compounded by the presence of one or more physical health conditions. This can lead to older people giving up their valued activities, which not only further increases their disability but also contributes to secondary effects such as social isolation and depression. As older people become more disabled and more unwell, they can become at risk of developing frailty. Frailty is a condition that is seen predominantly in older adults, which is often associated with a sudden decline in functioning associated with a particular stressor (e.g., an illness, a fall), which sparks a sudden decline in functioning. Typically, the functional decline is seen in a range of indicators, such as increased fatigue, weight loss, weakness, an inability to walk at a usual rate, and a reduction in energy expenditure (see Clegg, Young, Iliffe, Rikkert, & Rockwood, 2013). Frailty typically occurs when there is dysfunction in a range of major organ systems (e.g., inflammatory, hematological, neuromuscular, endocrine, hormonal, adiposity), but it is when abnormalities are detected across multiple systems that patients are at a higher risk of developing frailty (Clegg et al., 2013). Frailty has important implications for older patients because it is strongly associated with increased dependence and the need for care, delirium, falls, and a higher rate of mortality.

The Need for Formal and Informal Caring

When elderly people become frail, the level of care that they need increases, and, as such, the development of frailty can often mark the transition from the bulk of care being informal care to requiring the majority of care provision to be formalized. Informal care refers to care that is provided to a person by someone in their family or community when the recipient of care is no longer able to provide that care for themselves. In most societies, the majority of care is provided informally; some studies estimate that up to 90% of care is informally provided (Adelman, Tmanova, Delgado, Dion, & Lachs, 2014). Although formal and informal care are often described separately, in reality, much informal caring is supplement by organized and formal caring, and indeed, the availability of some formal care can reduce the need for the recipient of care requiring a more permanent formalized care plan, such as transition to a nursing home. The majority of care recipients, where possible, prefer to be cared for in the community by informal carers. From a health economics position, informal caring is extremely important as the costs of formal care provision are substantially higher. However, health psychology has become increasingly interested in the consequences of informal caregiving in recent years. There is strong evidence from a range of sources that providing care is associated with increased distress, depression, and caregiver burden. Most of the research into caregiver burden has been in the dementia literature, but increasingly it is recognized that caregiver burden is an important problem for those who provide care. It is recommended to reduce the burden that doctors are aware of who is the primary caregiver and allow them to have some role in decision making and care planning, where possible. It is also recommended that caregiver burden be assessed and that caregivers be offered both practical support (e.g., respite) and help with learning skills for dealing with the caring role, where necessary (Adelman et al., 2014). Where caregiver burden is a problem, there are a number of meta-analyses that confirm the efficacy of psychoeducational programs for caregivers, although the majority are with caregivers of those with dementia. However, effects sizes are modest. Hence, for clinicians, these offer viable alternatives to helping patients struggling with caregiver burden. However, there is a clear gap in the literature to research the efficacy of caregiver interventions for a broader set of caregivers, most notably interventions adapted to the needs of the caregivers of older people with multi-morbidity are absent from the literature.

Fear of Falling

In addition to the physical concerns that accompany illness in later life, and the psychological consequences for those who provide care to older adults, there are a number of psychological issues that also emerge for the elderly themselves. Data strongly support the fact that anxiety disorders are actually less common among older adults. A number of potential explanations for this drop in prevalence have been discussed in the literature. It has been suggested that this could be a cohort effect, such that those who are currently in the elderly age group were encouraged to be more stoic, and hence anxiety has always been lower in this cohort. It has also been suggested that it may be a physiological phenomenon, such that people's level of arousal generally reduces with aging and so the physical manifestations of anxiety reduce. Another suggestion has been that people learn better methods of coping as they age, through experience, and hence they are less likely to find anxiety overwhelming in later life. However, an alternative suggestion is that it could be that current diagnostic systems are based upon the concerns of younger adults and that the concerns of older adults are different. One unique fear among older people is the fear of falling.

Fear of falling is very common among older people and for good reason. Particularly in the frail elderly, falls are a leading cause of serious injury, increase the risk that an older person will be discharged from an acute hospital setting to a formal care setting, and have a risk of subsequent mortality. Hence, it is unsurprising that as people age, fears of falling develop. Anxiety is typically manifested when an individual appraises a risk as likely and the consequences as important. Given that estimates suggest that as many as one in three older adults fall each year, then older adults are arguably sensible to be mindful of the risk of falling. Moreover, particularly those with medical conditions that include symptoms of balance disturbance or dizziness, the risk is greater. Similarly, the consequences of falling among the elderly, particularly the frail elderly, are serious, and more so for those with conditions like osteoporosis where the risk of serious injury is heightened. While understandable that older people may be fearful of falling, one of the strongest predictors of actually falling is the fear of falling itself. One likely mechanism for this relationship is the fact that those who are more fearful of falling avoid physical activity and the reduction in physical activity actually leads to greater disability that in turn is thought to increase the risk of falling. As such, the most strongly evidence-based intervention for fear of falling in the elderly is exercise. A recent meta-analytic review found that there was an estimated reduction across available studies of 37% for all falls, but importantly even larger reductions of 43% of severe injuries following falls and a 61% reduction in falls resulting in a fracture (El-Khoury, Cassou, Charles, & Dargent-Molina, 2013). There is less evidence to support psychological approaches to managing fear of falling, and this is a likely area for future research. There is evidence that more complex, multifaceted programs (e.g., including balance training, home modifications) produce larger results than exercise alone. There are currently relatively few randomized controlled trials of psychosocial interventions as an adjunct to exercise reported in the literature. Those that are available have adopted a cognitive behavioral orientation and shown good results on measures of fear of falling, and some have shown improvements in mobility. However, researchers need to determine whether adding a psychosocial component to a predominantly exercise-based intervention will enhance the efficacy of these programs on the primary outcome of falls prevention, as well as subjective self-reports.

Management of Depression in Older Adults with Chronic Physical Health Problems

As with anxiety, there is little evidence to suggest that older people are more likely to become depressed than young adults. However, having one or more chronic physical illnesses is a risk factor for the development of late-life depression. As with younger adults with depression, there is evidence that late life can be treated with the same types of interventions that are efficacious in younger adults, that is, antidepressant medication and psychotherapy. Although there are considerably fewer studies of interventions in the treatment of late-life depression compared with the number with younger people, there is nonetheless strong meta-analytic evidence to show that both pharmacotherapy and psychotherapy are efficacious in the treatment of depression among the elderly (Pinquart, Duberstein, & Lyness, 2006). Importantly, cognitive behavioral therapy, problem-solving therapy, and reminiscence therapy all have sufficient trials demonstrating efficacy that we can consider all three to be strong evidence-based alternative therapies for late-life depression (Pinquart, Duberstein, & Lyness, 2007). However, there are some limitations to the evidence base for those patients with chronic physical health problems. Although many of the trials of late-life depression include patients with physical health problems, some trials specifically exclude patients with complex health needs. Indeed, Pinquart et al. (2007) found evidence that the inclusion of participants with physical health problems was associated with smaller effect sizes across studies. Few studies have compared the efficacy of different interventions (e.g., cognitive behavior therapy and problem-solving therapy), and few studies have specifically targeted patients with chronic ill health problems or multi-morbidity and clinical depression (see Sharpe et al., 2012). As such, there is a pressing need for researchers to investigate the most efficacious ways in which to treat late-life depression in patients with complex medical needs, who are by virtue of their physical health problems more likely to be depressed. There have been some excellent attempts to incorporate collaborative care management (Unützer et al., 2002) or prevention (van't Veer-Tazelaar et al., 2009) of late-life depression. The success of problem-solving therapy in these trials indicates that problem-solving therapy is an effective treatment for patients with late-life depression and complex needs, although we need more comparative research to determine the relative efficacy of problem-solving therapy and other forms of psychotherapy.

Author Biography

Louise Sharpe, PhD, is professor in the School of Psychology at the University of London and associate head for research education. Professor Sharpe completed her undergraduate degree and postgraduate training as a clinical psychologist at the University of Sydney and received her PhD from the University of London. As a researcher, Professor Sharpe has published more than 170 peer-reviewed papers and received more than $5 million from funding agencies, including the National Health and Medical Research Council and the Australian Research Council. Her research program examines adjustment to illness and involves the development and evaluation of psychosocial interventions for people with chronic physical illness. She has been awarded the Ian M. Campbell award from the Australian Psychological Society for her contributions to clinical psychology and the Distinguished Career Award from the Australian Association of Cognitive Behavioural Therapy for her research and clinical practice of cognitive behavior therapy.

Pediatric Psychology

Dianna Boone, Thomas J. Parkman, and Jason Van Allen

Clinical Psychology Program, Department of Psychological Sciences, Texas Tech University, Lubbock, TX, USA

Introduction

Pediatric psychology is defined by the Society of Pediatric Psychology as "an integrated field of science and practice in which the principles of psychology are applied within the context of pediatric health" (American Psychological Association, 2009). Pediatric psychologists can work in a variety of settings with children with a wide range of chronic illnesses including asthma, cancer, diabetes, obesity, pediatric sleep problems, sickle cell disease, and others (Aylward, Bender, Graces, & Roberts, 2009; Roberts, Biggs, Jackson, & Steele, 2011). The scope of practice for a pediatric psychologist can include screening for psychopathology in healthcare settings, developing interventions for children with chronic illnesses, and promoting the health and development of children and adolescents from all disease groups (Spirito et al., 2003). Pediatric psychologists are in great demand due to the prevalence of pediatric chronic conditions in the United States. For example, in the United States, 13,000 children are diagnosed with cancer each year, 13,000 children are diagnosed with type 1 diabetes, and 9 million children suffer from asthma (Compas, Jaser, Dunn, & Rodriguez, 2012). Obesity during childhood and adolescence is also a serious public health problem in the United States (Ogden, Carroll, Kit, & Flegal, 2014), and medical trauma results in many pediatric hospital admissions each year (Compas et al., 2012).

This chapter provides an overview of the clinical applications of pediatric health psychology including the importance of adjustment to new diagnoses and medication adherence. This chapter also discusses the various forms of treatment delivery and how the settings and modalities of treatments are changing. Finally, this chapter will discuss cultural and diversity issues in pediatric health psychology.

The Wiley Encyclopedia of Health Psychology: Volume 3: Clinical Health Psychology and Behavioral Medicine,
First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

Adjustment to Diagnosis

Due to advances in the treatment of chronic illnesses, pediatric illnesses that were once fatal can now be treated much more effectively than in previous decades (Mokkink, Van der Lee, Grootenhuis, Offringa, & Heymans, 2008). These improved outcomes are a result of successful early detection and diagnosis, as well as effective treatment of many previously life-threatening illnesses (Compas et al., 2012). As a result, children and adolescents now have to adjust to living with chronic illnesses and medical conditions. These chronic illnesses present children, adolescents, and their families with significant stress that can contribute to emotional and behavioral problems as well as interfere with adherence to treatment regimens (Compas et al., 2012). Further, many pediatric illnesses are worsened by stress encountered in other aspects of children's lives. It is therefore essential to understand the ways that children and adolescents adjust to living with a chronic condition in order to develop effective interventions to enhance coping and adjustment.

Adjustment to Chronic Versus Acute Illnesses

Adjustment to a pediatric illness can be different for each child, depending on if he or she receives a diagnosis of a chronic illness versus a diagnosis of an acute illness. An acute illness is differentiated from a chronic illness by the speed of symptom onset and the duration of symptoms. An acute illness is a condition of short duration that starts quickly and has severe symptoms. However, a chronic illness is a health problem that lasts 3 months or more, affects a child's normal activities, and requires frequent hospitalizations, home healthcare, and/or extensive medical care (Mokkink et al., 2008). Research has revealed that chronic conditions may result in greater psychological and physical stress than acute illnesses that resolve quickly (Marin, Chen, Munch, & Miller, 2009). Individuals with a chronic illness may experience more psychological stress, especially during childhood or adolescence, because the illness can threaten one's identity, affect one's body image, and disrupt one's lifestyle (Gignac, Cott, & Badley, 2000). Chronic conditions are also typically characterized by different phases over the course of an individual's lifetime (e.g., acute periods, stable periods, remissions), in which each phase presents its own physical and psychological problems. In addition, one's family life could be dramatically altered due to a pediatric chronic illness, resulting in unfilled roles, loss of income, and costs of treatment. As a result, individual and familial adjustment to chronic illness is an important predictor of long-term outcomes.

Generally speaking, researchers have examined a variety of stress responses in children and adolescents, emphasizing both controlled responses and automatic responses (Compas et al., 2012). Automatic stress responses include "temperamentally based and conditioned ways of reacting to stress such as emotional and physiological arousal, automatic thoughts, and conditioned behaviors" (Compas et al., 2012). However, in order to effectively cope with stress, controlled responses are typically preferred, which involve things children and adolescents do to manage and adapt to stress (Compas et al., 2012). Overall, the strategies a child or adolescent uses to manage stress can provide an idea as to how they will adjust or cope with a chronic illness. It is important to note, however, that when coping with health- and illness-related stressors, the controllability or perceived controllability of the stressor may be a key dimension in determining the efficacy of particular coping strategies (Osowiecki & Compas, 1998).

Interventions That Improve Adjustment

In recent years, researchers have developed interventions that aim to reduce stress and improve coping strategies in children after being diagnosed with a pediatric illness. For example, Kassam-Adams et al. (2015) assessed the effectiveness and feasibility of a web-based intervention aimed to reduce the stress of children who recently suffered an injury or were diagnosed with a chronic illness. Children ages 8–12 years were randomized to either a coping intervention (e.g., an interactive web-based game promoting coping strategies) or a 12-week wait list (Kassam-Adams et al., 2015). Outcome measures included child PTSD symptoms and pediatric quality of life. This study demonstrated that a novel, interactive, game-like web-based intervention for children exposed to medical trauma is feasible to deliver and has the potential to prevent posttraumatic stress after being diagnosed with a medical illness (Kassam-Adams et al., 2015).

Interventions targeting caregivers have also been developed, in light of research demonstrating an association between parental functioning and children's adjustment to a chronic illness (Palermo, Law, Essner, Jessen-Fiddick, & Eccleston, 2014). For instance, Palermo et al. (2014) examined the effectiveness and feasibility of a problem-solving skills training (PSST) intervention to reduce distress in caregivers of children with chronic pain. This study revealed that the parent-focused PSST intervention was effective in reducing distress among caregivers of children and adults with a variety of medical problems (Palermo et al., 2014). Results suggest that a PSST intervention is a feasible and acceptable intervention for parents of children with chronic pain. The intervention used in this study has the potential to help children with other chronic illnesses develop coping strategies and enable them to function effectively in their daily lives (Palermo et al., 2014).

In sum, chronic illnesses present children and their families with significant stress that can contribute to psychosocial problems, such as depression and anxiety, nonadherence to medication regimens, and disruptions to family life (Compas et al., 2012). These interventions have shown that they can help improve coping strategies and reduce stress in children adjusting to life with a chronic illness. Researchers need to continue examining how children and families adjust to pediatric illnesses to further inform and develop interventions.

Medication Adherence

The term "adherence" refers to the extent to which a person's behavior (e.g., taking medication, following a diet, and/or implementing lifestyle changes) corresponds with recommendations from a healthcare provider (World Health Organization [WHO], 2006). The assessment and treatment of medication adherence has become essential to improving health outcomes as the prevalence of pediatric chronic illnesses has increased (Quittner, Modi, Lemanek, Levers-Landis, & Rapoff, 2008). Research has illustrated that the overall treatment adherence rate is approximately 50% for pediatric populations (Rapoff, 1999). Nonadherence to medical regimes can potentially interfere with the efficacy of medications, resulting in failure to reach treatment goals, increased visits to the emergency room, and increased hospitalizations (Lee et al., 2014). In addition, other negative consequences of nonadherence include inappropriate changes in treatment regimens, decreased quality of life (Fredericks et al., 2008), incorrect medication dosage adjustments, and increased costs, among others (Lee et al., 2014).

Barriers That Affect Medication Adherence

Medication adherence in pediatric populations presents unique challenges. Types of barriers that are associated with poor medication adherence in pediatric patients include cognitive factors (e.g., forgetting, poor planning), aversive medication properties or difficulties ingesting medication (e.g., hard to swallow, bad taste, vomiting, spitting), high cost of medication, or voluntary resistance toward taking the medication (Hommel & Baldassano, 2010; Lee et al., 2014; Simons, McCormick, Mee, & Blount, 2009). Medication adherence can be especially difficult for young pediatric patients who may not understand the purpose of their medication and who depend on their caregivers to administer their prescribed medication (Lee et al., 2014). Thus, it is extremely important that both children and their caregivers participate in the medication adherence process.

In addition, it is also common for adolescents to not regularly follow their medication regimens (Staples & Bravender, 2002). Factors that could negatively impact adolescents' medication adherence include embarrassment, stigmatization, and inability to self-regulate (e.g., ability to control one's behaviors, emotions, and cognitions; Berg et al., 2014). Berg et al. (2014) found that self-regulation in a number of domains (i.e., general executive functioning, attention, self-control, and emotion regulation) was associated with adolescents' adherence behaviors in a sample of youths with type 1 diabetes, such that youths who reported lower self-regulation abilities demonstrated worse adherence behaviors than those who reported higher self-regulation abilities.

In addition, barriers to adherence have been associated with negative psychosocial outcomes such as less family cohesion, less emotional expression, and greater conflict among family members (Simons & Blount, 2007), which highlights the importance of efforts aimed to reduce barriers and improve pediatric adherence.

Treatment Delivery

Recently, Western medicine is recognizing the importance of viewing patient care from the biopsychosocial model, which emphasizes the interplay of biological, psychological, and social factors as they either influence the maintenance of health or acquire the capacity to cause illness (Smith & Nicassio, 1995). The importance of approaching treatment from this holistic standpoint is so salient and necessary that it has been endorsed and adopted by the WHO (2002). Consequently, pediatric psychologists are now delivering treatment for acute and chronic pediatric physical and behavioral health conditions in a number of diverse settings. Such settings include inpatient and outpatient medical or psychiatric facilities and pediatric primary care clinics (Borschuk, Jones, Parker, & Crewe, 2015).

In these medical environments, pediatric psychologists are typically an integral component of integrated teams composed of psychologists, doctors, nurses, caseworkers, and even administrators who work collaboratively to determine the best course of treatment for the patient (Butler et al., 2008). One of the charges of the pediatric psychologist in this setting is to provide secondary care via psychodiagnostic assessment. Psychometric tests are often used in this environment in order to identify treatment needs, assist with differential diagnoses, monitor treatment progress, and facilitate risk management (Wahass, 2005). Assessments of intelligence, personality, mental status, motivation, health behavior, and presence of psychopathology are typically conducted by the pediatric psychologist and are useful aids in ensuring children receive the highest standard of care.

Another charge of pediatric psychologists in medical settings is to provide primary care via behavioral interventions (e.g., cognitive behavioral therapy) targeted at treating or even preventing behavioral disturbances or psychopathology (e.g., anxiety) that may be exacerbating the child's presenting concerns or impeding their recovery (Borschuk et al., 2015). Although limited, research does suggest that behavioral health interventions are effective at mitigating anxiety (Kolko et al., 2014), behavioral problems (Berkovits, O'Brien, Carter, & Eyberg, 2010), and depression (Richardson, McCauley, & Katon, 2009).

Other crucial roles of pediatric psychologists include facilitating communication among medical professionals, managing difficult interpersonal situations between patients and their families, and providing grief counseling as necessary. Finally, the pediatric health psychologist also facilitates the post-discharge outpatient follow-ups in order to ensure the child is adhering to their treatment regimen, there are no residual complications, and, if necessary, the psychologist is prepared to provide referrals to community-based care providers (Kolko & Perrin, 2014).

With increasing frequency children are receiving care via community-based programs and facilities, such as schools (Borschuk et al., 2015). In fact, research suggests that more children are receiving services in community-based outpatient clinics (satellite healthcare facilities that provide health and wellness services outside of the primary care setting) and schools than they are in primary or specialty care clinics (National Survey on Drug Use & Health, 2009). The utility of the pediatric psychologist in the community can be found in their ability to facilitate support groups for children seeking emotional support due to terminal illnesses or chronic pain, assist in medication/treatment adherence, and administer psychometric tests of functioning (Straub, 2014). Furthermore, pediatric psychologists in the community setting also aim to disseminate public health information and provide psychoeducation to children regarding illnesses and disease prevention (Straub, 2014).

The Use of Telemedicine to Treat Pediatric Illnesses

Telemedicine can be broadly defined as the use of telecommunications technologies to provide medical information and services (Perednia & Allen, 1995). The use of telemedicine can help overcome barriers such as geographic challenges, a lack of healthcare specialists, and social and economic barriers (Marcin, Shaikh, & Steinhorn, 2016; Van Allen, Davis, & Lassen, 2011). In recent years, telemedicine has been increasingly used for pediatric health services, and research supports the utility of interventions incorporating telemedicine for children in rural settings (Van Allen et al., 2011). For example, Davis et al. (2013) demonstrated that a telemedicine intervention was equally as effective as an intervention involving visits from a physician in improving children's BMI, behavior problems, and dietary and physical activity behaviors. This study also demonstrated that telemedicine or similar methods of telehealth can be a feasible method of treatment delivery of empirically supported treatment interventions (Davis, Sampilo, Gallagher, Landrum, & Malone, 2013). Similarly, a study conducted by Chorianopoulou, Lialiou, Mechili, Mantas, and Diomidous (2015) also revealed that the utilization of telemedicine resulted in improved access to specialized healthcare, reduced hospitalizations, and emergency room visits in a sample of children from a rural population (Chorianopoulou et al., 2015). Izquierdo et al. (2009) found that children with diabetes who received telemedicine had lower hemoglobin A1c levels and reported higher levels of pediatric quality of life, compared with children who received usual care. Children in the telemedicine group also reported a reduction in urgent diabetes-related calls initiated by the school nurse and fewer hospitalizations and emergency department visits (Izquierdo et al., 2009). In addition, Romano, Hernandez, Gaylor, Howard, and Knox (2001) investigated whether specialist care delivered by telemedicine would result in comparable improvements in quality of life and asthma symptoms, compared with face-to-face encounters with specialists. The results indicated that patients reported an increase in mean number of symptom-free days, a reduction in mean symptom scores, and improvements in quality of life (Romano et al., 2001).

It is likely that more interventions will be delivered through telemedicine technologies in the near future. The use of telemedicine and digital technologies can help children and families overcome numerous geographic and economic barriers as well as increase access to interventions and other forms of treatment.

Cultural/Ethical Disparities, Culturally Competent Care, and Future Directions

Disparities within the realm of pediatric psychology are predominantly driven by variables such as race, ethnicity, and socioeconomic status. Unfortunately, children of color, especially those born into low-income families, lag behind their more affluent, majority peers in health status (Cheng, Dreyer, & Jenkins, 2009). This is of particular concern given the fact that such disparities that arise during childhood positively correlate with chronic illness as an adult (Braveman & Barclay, 2009). Also, the dearth of available pediatric psychologists in underprivileged or rural areas is also a force driving these disparities in health status.

These disparities point to the need for pediatric psychology to embrace and practice culturally competent care, care that is sensitive to the needs, health literacy, and health beliefs of pediatric patients and their families (Cheng, Emmanuel, Levy, & Jenkins, 2015). Current research demonstrates that health promotion and prevention interventions may be more effective in improving quality of care and patient safety if they are tailored to the cultural identity of the target population. However, there is a paucity of research as to what constitutes a "culturally sensitive" intervention, and whether such an initiative could be capable of facilitating greater changes in behavior than non-culturally specific interventions is unclear (Resnicow et al., 2002).

With that said, there are a number of measures the field of pediatric psychology can enact in order to ameliorate disparities in health status among children of racial and ethnic minorities and socioeconomic status. Research suggests that almost all children in the United States have annual well-child visits (Bloom, Cohen, & Freeman, 2011); thus, increasing the involvement of pediatric psychologists in the primary care setting—in the role of gatekeeper to behavioral health services—will have the effect of fostering normative development and decreasing health disparities. Furthermore, given the powerful deleterious effect of socioeconomic status on service availability, the field of pediatric health psychology must seek to make access to its services more universally accessible and cost-effective. This can be done through the proliferation of pediatric psychologists throughout community-based care providers, perhaps with the future aid of government or community cost subsidization.

Conclusion

Pediatric psychology is a rapidly expanding field of psychology. Pediatric psychologists work in a multitude of professional settings in the evaluation and treatment of children who present with a wide range of chronic illnesses. It is critical to understand how children and families adjust to pediatric illness to further inform and develop more effective interventions for these individuals. Pediatric psychologists work with children and families, in conjunction with physicians, to reinforce the importance of medication adherence to maximize positive health outcomes. Pediatric psychologists are working with children in schools and community settings, not just the primary care setting, to promote medical and mental health. The use of telemedicine and digital technologies has become important delivery systems for providing education and interventions for children and families in the rural setting. Identifying pertinent cultural variables and considerations are critical for effective health promotion and prevention interventions. Pediatric psychologists and researchers must continue to develop evidence-based treatments and examine resilience factors (e.g., self-esteem, internal locus of control, motivation, health behaviors, coping strategies, emotional regulation) that prevent children from developing chronic illnesses and a lower quality of life. Through these measures, the field of pediatric psychology can ensure that children grow into healthy and well-adjusted adults.

Author Biographies

Dianna Boone, MA, is a second year student in the Clinical Psychology Program at Texas Tech University, under the mentorship of Dr. Jason Van Allen. She received her MA in Rehabilitation and Mental Health Counseling from the University of South Florida. Her research interests include pediatric psychology and childhood obesity.

Thomas J. Parkman, BS. T.J. is a third year clinical psychology doctoral student and research assistant in the ENERGY Lab at Texas Tech University, under the mentorship of Dr. Jason Van Allen, PhD. T.J.'s interests rest within the realms of pediatric health psychology and behavioral medicine.

Jason Van Allen, PhD. Jason is an assistant professor in the Clinical Psychology Program at Texas Tech University. He received his PhD in Clinical Child Psychology from the University of Kansas, and his research focuses on pediatric psychology and childhood obesity.

Reproductive Health

Jennifer L. Brown[1] and Nicole K. Gause[2]

[1]*Department of Psychiatry and Behavioral Neuroscience, University of Cincinnati College of Medicine, Cincinnati, OH, USA*
[2]*Department of Psychology, University of Cincinnati, Cincinnati, OH, USA*

As defined by the World Health Organization (WHO), reproductive health refers to the well-being of reproductive processes throughout all stages of life; this includes the ability to have satisfying and safe sex, as well as the ability to reproduce (WHO, 2016a). Additionally, reproductive health involves the capability to decide when and how often to engage in sexual and reproductive behaviors (WHO, 2016a). According to the WHO, to maintain reproductive health, men and women should also have access to safe, effective, and affordable contraception, as well as access to healthcare services that facilitate healthy pregnancies and childbirths (WHO, 2016a).

This chapter provides an overview of reproductive health issues that may be of clinical relevance to a health psychologist. Effective strategies for conducting sexual health histories to assess patients' sexual behavior engagement and sexual orientation are provided. Sexual behaviors that are associated with increased risk for adverse sexual health consequences such as sexually transmitted infections (STIs) and unintended pregnancies are described. Epidemiological data regarding STI prevalence is provided, as well as an overview of efficacious human immunodeficiency virus (HIV) and STI prevention intervention approaches. Modern contraceptive options that provide safe, effective methods of pregnancy prevention are discussed. Disorders related to patients' sexual health including sexual dysfunction disorders, hypersexuality, and paraphilic disorders are discussed, as well as relevant diagnostic considerations and efficacious treatment options. A brief summary of sexual behavior engagement from a developmental perspective is provided at the end of the chapter.

First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

Sexual Behaviors

There is a wide variety of activities that individuals engage in to express their sexuality (Crooks & Baur, 2008). Abstinence and celibacy refer to the act of refraining from engaging in certain sexual behaviors or any sexual behaviors. Self-stimulation of one's genitals for the purpose of sexual pleasure is a sexual behavior known as masturbation. Sexual behaviors such as kissing and touching stimulate the erogenous zones of oneself and one's partner. Individuals may also sexually stimulate a partner via oral stimulation of a partner's genitals. Terms such as oral sex (referring broadly to oral–genital stimulation), cunnilingus (oral stimulation of the vulva), and fellatio (oral stimulation of the penis) describe oral–genital sexual behaviors. Anal stimulation may involve touching around the anus or penile insertion in the anus (often referred to as anal sex). Penile insertion in a female's vagina is referred to as penile–vaginal intercourse, as well as other terms such as vaginal sex or coitus. There is great variability between individuals in how frequently these and other sexual behaviors occur; this variability may be due to a number of factors, including age and the perceived social acceptability of certain behaviors.

Furthermore, reasons for engaging in sexual behaviors may differ among individuals and even within the same individual depending on situational circumstances. People may engage in sexual behaviors in order to experience sexual pleasure, sexual arousal, or orgasm. Motivation for sexual behaviors may also involve a desire to procreate. Some individuals may engage in sexual behaviors to earn money or acquire other goods or services; prostitution is the exchange of a sexual behavior for monetary or other compensation. Unfortunately, there are circumstances under which engagement in sexual behaviors is coerced or nonconsensual (e.g., rape), a form of abuse (e.g., child sexual abuse), or a means of sexual exploitation (e.g., pedophilia). Even when sexual behavior is intended and consensual, it may have unintended consequences (e.g., unplanned pregnancy) or put one at risk for HIV and other STI.

A comprehensive general health history should include a sexual history to assess for engagement in risky sexual behaviors, as well as for potential sexual dysfunction (Peck, 2001). Structured patient questionnaires may also be incorporated into sexual histories. The core domains that should be assessed when gathering sexual history information are sexual practices (i.e., which specific behaviors the individual engages in), any concerns related to sexual functioning, information regarding sexual partners (e.g., number of partners, partners' sex(es), relationship status), use of pregnancy prevention method(s), use of STI/HIV prevention method(s), and STI and/or pregnancy history. Gathering this information requires providers discuss sensitive topics; this may make some providers uneasy or uncomfortable and result in avoidance of performing a comprehensive sexual history assessment (Peck, 2001). Provider discomfort in discussing sexual health may cause patient embarrassment or discomfort, which may in turn have a negative impact on provider–patient rapport and the accuracy of a patient's self-reported sexual information. Furthermore, failure to perform a comprehensive sexual history assessment could interfere with patient care and may result in incorrect diagnoses or not providing appropriate referrals and treatments. In order to increase patient comfort, build rapport, and obtain the most accurate information, providers should promote open communication, emphasize confidentiality surrounding patient disclosure, employ open-ended questions, and utilize neutral language when discussing sexual behaviors and sexual health topics (Peck, 2001).

Sexual Orientation

Sexual orientation refers to the sex or sexes to which one is attracted. Although an individual may be sexually attracted to a particular sex or sexes, he or she may not necessarily identify with the corresponding sexual orientation. Further, an individual may engage in sexual behaviors that are associated with particular sexual orientations (e.g., a man who reports sex with other men), but not identify with that particular sexual orientation; in this example, this man would endorse being heterosexual as opposed to homosexual or bisexual. Some argue that sexual orientation is an aspect of an individual's broader sense of identity, which is not only based on their sexual attractions but also on group membership with others who share a similar attraction. Sexual orientation is often classified by society according to distinct categories; individuals are either heterosexual (sexually attracted to the opposite sex), homosexual/lesbian/gay (sexually attracted to the same sex), or bisexual (sexually attracted to both sexes). However, some have suggested that sexual orientation may perhaps be better understood as existing along a continuum (Crooks & Baur, 2008). For example, Kinsey, Pomeroy, and Martin (1948) proposed in their early work that sexual orientation be viewed as a range from "exclusively heterosexual with no homosexual" to "exclusively homosexual with no heterosexual" attractions and/or sexual contact.

Individuals who identify as lesbian, gay, bisexual, or transgender (LGBT) experience a variety of health disparities, including increased STI prevalence, decreased screening for cervical cancer, and experiences of abuse or violence. Knowing a patient's sexual orientation can help to identify potential areas of concern to be addressed via further assessment or treatment. Using information obtained via a sexual history assessment not only improves patient care at the individual level but also has the potential to reduce health disparities among LGBT individuals. Sexual orientation can be assessed by asking a patient whether he or she (a) identifies with a particular sexual orientation (e.g., "Do you consider yourself (i) lesbian, gay, or homosexual; (ii) straight or heterosexual; (iii) bisexual; (iv) something else; (v) don't know?") and whether he or she (b) has any potential concerns related to his/her sexual orientation (e.g., "Do you have concerns related to your sexual orientation?"). In addition, *gender identity* should be assessed by asking patients about their (a) self-identified gender identity (e.g., "Do you identify as (i) male, (ii) female, (iii) female to male/transgender male, (iv) male to female/transgender female, (v) gender queer/neither exclusively male nor female, (vi) additional/other category?") and asking patients about their (b) sex assigned at birth (e.g., male, female). Given that the LGBT community encounters heightened stigma and discrimination, it is especially important that providers ensure patients' confidentiality and that assessment of sexual orientation and gender identity are conducted in a nonthreatening, nonjudgmental and appropriate manner.

Sexual Risk Behaviors

Estimates of the number of newly acquired HIV infections per year in the United States remain relatively stable, with approximately 50,000 incident cases diagnosed annually (Centers for Disease Control and Prevention [CDC], 2015c). Globally, there were approximately 2.1 million incident HIV cases in 2015 (WHO, 2016b). Furthermore, HIV prevalence continues to rise globally, with an estimated 36.7 million people now living with HIV worldwide (WHO, 2016b). In the United States, Black/African Americans and Hispanic/Latinos have higher HIV prevalence rates as compared with other racial or ethnic groups (CDC, 2015b, 2016a). In addition, men who have sex with men (MSM) are disproportionately affected by HIV in the United States (CDC, 2015a). Unlike trends that emerged early in the HIV epidemic, US women (particularly racial/ethnic minority women) who have sex with men have also experienced increased incident HIV infections in recent years (CDC, 2016b).

In addition to HIV, there are a number of other STIs including bacterial vaginosis (BV), chlamydia, gonorrhea, viral hepatitis, genital herpes, human papillomavirus, pelvic inflammatory disease (PID), syphilis, and trichomoniasis. Negative health consequences may result from STI, and untreated STI may result in increased biological susceptibility to HIV. MSM, and racial/ethnic minority MSM in particular, experience elevated rates of STIs including chlamydia, gonorrhea, syphilis, and, as noted in a previous section, HIV (CDC, 2015a). Furthermore, individuals between the ages of 15 and 24 years of age (i.e., emerging adults), and racial/ethnic minority adolescents in particular, experience elevated rates of chlamydia and gonorrhea (CDC, 2014a).

Certain sexual behaviors, as well as substance use, may increase STI/HIV risk. For example, engaging in sex without a condom, having multiple sexual partners, or injecting drugs (and needle sharing) may increase likelihood of STI/HIV exposure. Moreover, there are structural factors that affect STI/HIV exposure risk; for example, community STI/HIV prevalence and access to adequate STI/HIV testing or treatment services as well as access to needle exchange programs affect STI and HIV prevalence. A comprehensive assessment of engagement in behaviors that increase STI/HIV risk facilitates and informs appropriate STI/HIV testing and treatment recommendations. Practitioners should assess for engagement in key behaviors that may increase an individual's STI/HIV risk; these include (a) condom use for vaginal and anal sex, (b) frequency of particular sexual behaviors (e.g., frequency of anal sex), (c) number of sexual partners, and (d) use of injection drugs and related behaviors (e.g., needle sharing). Of course, given the personal and sensitive nature of these behaviors, supplementing a face-to-face patient sexual history assessment interview with paper-and-pencil or computerized measures may enhance the accuracy of patients' self-reported behaviors. Furthermore, focusing on shorter, more discrete time periods (e.g., "How often in the *past month* have you had vaginal sex without a condom?") rather than extended time periods (e.g., "How often in your *lifetime* have you had vaginal sex without a condom?") may improve the accuracy with which patients report their behaviors. Providers should deliver appropriate risk reduction counseling (e.g., encouraging consistent condom use) to patients who report engaging in sexual risk behaviors and may also want to consider further STI/HIV testing in accordance with national guidelines for high-risk patients. For example, the US CDC recommends that all sexually active women under the age of 25 be annually screened for chlamydia (CDC, 2015d).

STI/HIV Prevention Intervention Approaches

Behavioral intervention strategies focus on decreasing high-risk practices (e.g., non-condom-protected sexual encounters and sharing of contaminated needles) to reduce and prevent the spread of STI/HIV. Indeed, there are a number of behavioral STI/HIV prevention approaches that have been reviewed, evaluated, and identified as efficacious behavioral HIV prevention interventions by the CDC (2014b). These behavioral intervention approaches utilize a variety of intervention modalities (e.g., one on one, small group) and generally target at-risk populations (e.g., MSM, African American adolescents; CDC, 2014b). For example, HORIZONS (DiClemente et al., 2009) is an STI/HIV prevention intervention that is gender and culturally tailored for African American young women. This particular intervention includes two group-based sessions designed to reduce sexual risk behavior engagement and incident STI among African American adolescents; results from the original randomized controlled trial indicated that HORIZONS increased condom use practices and reduced incident chlamydial infections (DiClemente et al., 2009). When used alone, behavioral interventions may reduce STI/HIV incidence, as well as engagement in risky sexual behaviors, use of contaminated needles, and other behaviors that increase STI/HIV risk.

The HIV prevention "toolkit" has expanded to include biomedical approaches as adjuncts to efficacious behavioral strategies. Biomedical HIV prevention approaches include a diverse set of strategies at different stages of product development, of varying efficacy, and at various stages of approval, including (a) microbicides that are applied to the vagina or the rectum; (b) pre-exposure prophylaxis (PrEP) antiretroviral (ARV) medications (ARV medications for high-risk seronegative persons); (c) post-exposure prophylaxis (PEP) drugs (use of ARV medications following HIV exposure); (d) HIV vaccination; (e) medical male circumcision; (f) HIV testing, linkage, and retention in HIV care ("test and treat"); and (g) enhanced ARV adherence among HIV-seropositive individuals (treatment as prevention). While the use of microbicides and an HIV vaccination have not been established as efficacious or approved for widespread use, they present possible avenues to pursue in future research; should efficacious treatments be established, they may offer additional means to curtail the HIV epidemic. Medical male circumcision, test-and-treat interventions, and ARV medication adherence strategies have demonstrated promise in reducing HIV transmission risk. In 2012, the US Food and Drug Administration approved Truvada (emtricitabine/tenofovir disoproxil fumarate) as a PrEP medication to be used in conjunction with safer sexual practices to prevent the spread of HIV. Combination HIV prevention approaches that integrate both efficacious behavioral and biomedical strategies may enhance the potential to reduce HIV transmission among certain high-risk populations (Brown, Sales, & DiClemente, 2014).

Contraceptive Methods

There are a variety of contraceptive methods available, which may be more or less desirable depending on an individual's reproductive healthcare needs and preferences. Contraceptive methods vary in the degree of pregnancy prevention efficacy, STI prevention efficacy, and availability, which may also impact an individual's contraceptive method choices. Male condoms are effective at preventing pregnancy and protect against STI; they are widely available and do not require a prescription or doctor visit. Hormonal contraceptives include oral contraceptive pills, contraceptive patch, vaginal ring, implants, intrauterine devices (IUD), and Depo-Provera, which consists of monthly injections. According to the American Sexual Health Association (ASHA), oral contraceptives are 92–97% effective in preventing pregnancy (ASHA, 2013); however they do not protect against STI and they require a prescription. The contraceptive patch delivers hormones transdermally; it is 92% effective in preventing pregnancy, does not protect against STI, and requires a prescription. The vaginal ring (e.g., NuvaRing) is 92% effective in preventing pregnancy, does not protect against STI, requires a prescription, and must be inserted and removed by a medical professional. Hormonal implants (e.g., Implanon) are inserted beneath the dermis by a medical professional; they are 99.99% effective in preventing pregnancy, but do not protect against STI (ASHA, 2013). Hormonal IUD (e.g., Mirena) are 99.99% effective in preventing pregnancy, but do not protect against STI; they require a prescription and must be inserted and removed by a medical professional. Depo-Provera is a monthly injection that is 99.7% effective in preventing pregnancy, but does not protect against STI; it requires a prescription and must be administered by a medical professional (ASHA, 2013). Overall, hormonal contraceptives are highly effective in preventing pregnancy, when used correctly and consistently; however male condoms are the only form of contraception that is also effective in preventing STI/HIV (ASHA, 2013).

For over a decade, promoting the use of multiple prevention strategies (i.e., dual protection) to reduce the risk of both unintended pregnancy and STI/HIV has been recognized as "best practice" by medical practitioners and researchers (Workowski & Berman, 2006). Various protection strategies exist and can be combined to reduce both unintended pregnancy and STI/HIV, including hormonal contraception used in conjunction with correct and consistent condom use, STI/HIV screening of sex partner(s), decreasing number of sex partners, monogamy, and abstinence. These strategies, when used conjointly, enhance both pregnancy and STI/HIV prevention. Moreover, it is important to consider the unique social milieu within which these strategies occur, particularly regarding negotiation between sex partners, cost of the protection methods, potential side effects of the methods, acceptability, and other barriers.

Sexual Dysfunction

The Diagnostic and Statistical Manual of Mental Disorders (5th ed.; *DSM-5*; American Psychiatric Association [APA], 2013) outlines a group of disorders that are specifically related to sexual dysfunctions. These disorders are characterized by clinically significant disturbances in an individual's ability to respond to sexual stimulation or to experience sexual pleasure. The onset and frequency of a particular disturbance are important considerations in classifying a sexual dysfunction, as this information may be helpful in determining the etiology of the sexual dysfunction and appropriate treatment interventions.

Some sexual dysfunctions are gender specific, whereas others may apply to both males and females (e.g., substance/medication-induced sexual dysfunction). Male hypoactive sexual desire disorder is a gender-specific condition marked by a lack (either persistent absence or recurrent absence) of sexual thoughts/fantasies or a deficit in desire for sexual activity. Similarly, female sexual interest/arousal disorder includes a lack of or significantly reduced sexual interest or arousal/pleasure. Male erectile disorder is indicated by the presence of at least one of the following symptoms: difficulty obtaining an erection during sexual activity, difficulty maintaining an erection during sexual activity, or a decrease in erectile rigidity. Premature ejaculation is a persistent or recurrent pattern of early (within 1 min following penetration) ejaculation during partnered sexual activity, whereas delayed ejaculation is either a significant delay in ejaculation or infrequency or absence of ejaculation. Correspondingly, female orgasmic disorder is a delay in infrequency of or absence of orgasm or reduced orgasm intensity. Genito-pelvic pain/penetration disorder (a female-specific disorder) includes one or more of the following symptoms, which generally tend to be co-occurring: (a) difficulty having intercourse, (b) genito-pelvic pain during intercourse, (c) fear of pain or vaginal penetration, and (d) tension or tightening of the pelvic floor muscles during intercourse (APA, 2013).

According to the APA (2013), healthcare and mental healthcare providers should consider several important factors when assessing a potential sexual dysfunction: (a) partner factors (e.g., partner's sexual or health-related problems), (b) relationship factors (e.g., discord in desires, difficulties with communication), (c) individual vulnerability (e.g., body image issues, history of sexual/emotional abuse), (d) psychiatric comorbidity (e.g., depression, anxiety, PTSD), (e) other stressors (e.g., job loss, bereavement), (f) cultural or religious factors (e.g., inhibitions or prohibitions regarding sexual behaviors, attitudes toward sexuality), (g) aging (normative age-related reductions in sexual responses and physical activity), and (h) medical factors impacting prognosis, course, or treatment of a sexual dysfunction. Before diagnosing a sexual dysfunction, the possibility that symptoms result from inadequate sexual stimulation must be ruled out. Additionally, symptoms must be present in all or most sexual encounters

(75–100% of sexual encounters), for at least 6 months, and not otherwise attributable to a nonsexual mental disorder, relationship discord, other stressors, the effects of a substance/medication, or a medical condition (APA, 2013).

Restoration of sexual functioning and the experience of sexual pleasure are the focus of treatment approaches for sexual dysfunctions. Efficacious interventions for sexual dysfunctions include cognitive behavioral therapy (CBT) (e.g., stimulus control, cognitive restructuring), behavioral therapy (e.g., systematic desensitization, relaxation), psychoeducation/sexual education, and couples therapy. A lack of sexual desire may be addressed by using cognitive restructuring techniques to explore negative attitudes about sex and replace those views with new ways of thinking about sex. Arousal disorders may also be treated with cognitive restructuring (in this case targeting beliefs about sex and sexual abilities), as well as with behavioral interventions such as relaxation, systematic desensitization, and sensate focusing. Sensate focusing involves encouraging a couple to experience pleasure from both sexual and nonsexual forms of touch. Treatments for erectile dysfunction typically target sexual performance anxiety and sexual self-esteem. Behavioral treatments for premature ejaculation involve having a man learn to withstand stimulation and postpone ejaculation for increasingly longer periods of time; this approach has been shown to be particularly effective. Treatments for female orgasm disorders encourage realistic expectations about sexual pleasure and comfort with one's body and sexual desires, as well as gradual self-stimulation and relaxation exercises. Relaxation training is also used to treat painful or unpleasurable intercourse that cannot otherwise be attributed to a medical condition. Pharmacological and medical interventions are also available for sexual dysfunctions; these approaches may be used in combination with psychotherapy.

Hypersexuality

In the United States, hypersexual disorder has an estimated prevalence rate of 3–6% and is thought to occur mostly in men (Kuzma & Black, 2009). The specific behaviors that are considered hypersexual and the etiology of hypersexuality are debated upon in the literature (Brown, Gause, & Garos, 2020; Moser, 2011; Winters, 2010).

Hypersexual disorder was not included in the DSM-5 (APA, 2013); as such there are no formal clinical guidelines or diagnostic criteria for hypersexuality. However, the proposed theories of hypersexuality often include the following symptoms: a subjective loss of control; disinhibited sexual activity, which can involve culturally normative or nonnormative sexual behaviors; the presence of subjective distress; continuation of the behavior(s) in spite of escalating negative consequences; and significant impairment in areas of social, educational, occupational, or relationship functioning (Brown et al., 2020). An assessment of a potential hypersexual disorder should include a thorough sexual history, psychosocial history, psychiatric history, substance use history, relationship history, and medical history, including assessment for sexually transmitted diseases, unplanned pregnancies, abortions, and other medical conditions. In addition, it is important that the clinician assess for disorders that often co-occur with hypersexual behaviors, such as bipolar disorder, anxiety, mood disorders (Kafka & Hennen, 2002; Krueger & Kaplan, 2001; Reid & Carpenter, 2009), substance abuse, and ADHD (Krueger & Kaplan, 2001), as well as other characteristics such as impulsive behavior and emotional dysregulation (Reid, Carpenter, Spackman, & Willes, 2008; Reid, Stein, & Carpenter, 2011).

The treatment of hypersexuality is often multi-method and typically involves some form of psychotherapy. CBT is often used to identify triggers for hypersexual impulses or behaviors, manage sexual urges, and change negative, self-defeating internalized beliefs. In addition, mindfulness interventions that teach patients to focus on the present and steer patients away from worrisome or distressing thoughts (Kabat, 1990; Kingston, Dooley, Bates, Lawlor, & Malone, 2007) are efficacious (Reid, Garos, Hook, & Hook, 2014). Treatment approaches should also include a relapse prevention component and determine if the patient's behavior puts him or her as risk for occupational, legal, health, or other severe consequences. Family and couples therapy may also be part of treatment for hypersexuality, as this disorder can have devastating effects on families and intimate partnerships or marriages. Group therapy and self-help groups (e.g., Sex Addicts Anonymous) often augment treatment. Pharmacological medications have been shown to be efficacious in reducing sexual urges and obsessive sex-related thoughts. Selective serotonin reuptake inhibitors (Bradford, 2001; Coleman, Gratzer, Nesvacil, & Raymond, 2000) and antiandrogens have demonstrated promising effects in reducing sexual drive and desire (Guay, 2009). These drugs may be combined with psychotherapeutic treatments that target hypersexuality.

Paraphilic Disorders

As described in the DSM-5, a paraphilia is "…any intense and persistent sexual interest other than sexual interest in genital stimulation or preparatory fondling with phenotypically normal, physically mature, consenting human partners" (APA, 2013, p. 685). In order for a paraphilia to be considered a paraphilic disorder, it must cause an individual either distress or impairment, or be a paraphilia that entails personal harm, or risk of harm to others when or if it is satisfied (APA, 2013). Paraphilic disorders include voyeuristic disorder (sexual pleasure or excitement from spying on others in private activities), exhibitionistic disorder (exposing one's genitals), frotteuristic disorder (touching or rubbing against a non-consenting individual), sexual masochism disorder (undergoing personal humiliation, bondage, or suffering), sexual sadism disorder (inflicting humiliation, bondage, or suffering on another), pedophilic disorder (sexual attraction toward children), fetishistic disorder (sexual attraction to nonliving objects or a highly specific sexual focus on nongenital body parts), and transvestic disorder (sexual arousal from cross-dressing; APA, 2013). The sexual behaviors individuals with a particular paraphilia may engage in to fulfill their sexual urges or desires may pose potential harm or negative consequences to others, and they may even be classified as criminal offenses. Furthermore, it is not uncommon for multiple paraphilic disorders to co-occur or be comorbid with other psychological diagnoses (e.g., depressive disorders; APA, 2013).

When assessing for possible paraphilic disorders, a clinician should investigate of the specific nature of the paraphilia and potential negative consequences of the paraphilia (APA, 2013). It is important to note that individuals who report a paraphilia without negative consequences, or with the potential to harm others if/when the sexual desire is fulfilled, do not meet DSM-5 criteria for a paraphilic disorder (APA, 2013). Both clinical interviews and self-report measures may be used by clinicians to assess for possible paraphilic disorders. CBT, intensive community supervision, and adjunctive pharmaceutical treatments (Briken & Kafka, 2007) are among the available efficacious treatments for paraphilic disorders. Pharmaceutical treatments may either lower testosterone levels or treat potential comorbid psychological conditions (e.g., depressive disorders).

Sexual Behavior Engagement Across the Lifespan

Sexual activity changes across the lifespan, and sexual development varies between individuals (Crooks & Baur, 2008). Sexual behaviors that occur during childhood may include self-stimulation of the genitals or play that may be viewed as sexual in nature (e.g., "playing doctor" with other children). During adolescence and puberty secondary sex characteristics (e.g., breasts, pubic hair) develop and result in dramatic physical changes. Sexual activity typically increases during adolescence, including both self-stimulation behavior and sexual behaviors with partners. Engagement in sexual behavior as people age throughout adulthood varies. During older adulthood, engagement in sexual activities often correlates with sexual activity levels in earlier adulthood. Sexual activity during older adulthood may be adversely affected by co-occurring health conditions and physical limitations.

Author Biographies

Jennifer L. Brown is an associate professor in the Department of Psychiatry and Behavioral Neuroscience at the University of Cincinnati. She is a licensed clinical psychologist who specializes in the development and evaluation of HIV prevention interventions. Her research aims to reduce health disparities and improve individuals' reproductive health.

Nicole K. Gause is a clinical psychology doctoral student at the University of Cincinnati. Her research and clinical interests include sexual risk behaviors among populations that are disproportionately affected by HIV/STI, substance use among HIV-infected populations, and the etiology and treatment of substance use disorders.

Schools, Eating, and Health Psychology

Catherine Cook-Cottone and Rebecca K. Vujnovic

Department of Psychology, University at Buffalo, The State University of New York, Buffalo, NY, USA

Introduction

This chapter focuses on the development of the healthy and successful student with specific attention to the development of healthy eating and physical self-care behaviors. Since the beginning of public education, school personnel have understood that in order to teach students, they must first be physically and emotionally well. It is not possible to fully achieve academic potential without a solid physical and emotional foundation to support learning. Therefore, in addition to the substantial charge of providing a strong academic education, schools must also address the physical and mental health of their students. Further, some suggest that by providing a healthy structure for physical and mental health, schools help students thrive, reaching their fullest potential in both academic and personal life. It is now well accepted that physical and mental health are deeply intertwined within a reciprocal process that either increases risk and pathology or decreases risk and promotes healing and positive development. Hence, consideration and promotion of physical health is now considered a necessary ingredient in psychological and educational interventions. With this understanding the field of health psychology has grown and along with it the notion of the *healthy school* (Cook-Cottone, Tribole, & Tylka, 2013). Research showing the negative effects of stress and the role of nutrition and physical self-care on both physical and mental health continues to grow. Accordingly, school personnel have become increasingly important in the delivery of health and health psychology interventions in schools (e.g., Cook-Cottone et al., 2013).

The school setting is the ideal place that impacts all children, delivers effective services, and promotes change from the individual to the systemic levels in a manner that can have a positive

impact on academics. Specifically in terms of health promotion, schools can help to address issues critical for enhancing resilience and health, as well as to reduce social class disparities in both physical and mental health, to enhance subjective well-being (Cook-Cottone et al., 2013; Shoshani & Steinmetz, 2013; Stephens, Markus, & Fryberg, 2012). A review of the literature suggests that subjective well-being (i.e., life satisfaction, presence of positive affect, absence of negative emotional experiences, and self-efficacy) be associated with several positive constructs, including academic achievement (Shoshani & Steinmetz, 2013). Within the school setting, models of change to promote well-being must address both the individual student characteristics and skills, as well as the larger structural level influences, such as material resources (e.g., access to healthy food, safe places to exercise, and access to quality healthcare; Stephens et al., 2012).

Consistent with the focus on system, community, and school-level factors in the promotion of health, the World Health Organization (WHO, 2015) defines a health-promoting school as a school that is constantly strengthening its capacity as a health setting, within which students can live, learn, and work. This is done by fostering health and striving to provide a healthy school environment through the provision of school services, curriculum, collaborative projects within the community, and programs for mental health promotion (WHO, 2015). It is critical to engage key stakeholders (e.g., health and education officials, teachers, parents, health providers, and community leaders) in making the school a healthy place to learn (Cook-Cottone et al., 2013; WHO, 2015). As such, schools and communities must implement policies and practices that respect individual dignity and well-being to allow many chances for success. The school, and not simply the students or the family, is striving to improve the health of all students, families, school personnel, and community members (WHO, 2015).

Specific to eating behaviors, there are several ways that students can move toward risk and disorder. The three primary clinical disorders are anorexia nervosa (AN), bulimia nervosa (BN), and binge eating disorder (BED) (American Psychiatric Association [APA], 2013). Specifically, AN is marked by a strong drive for and pursuit of thinness, body dissatisfaction, disordered body image, and behavior organized around weight loss (APA, 2013; Cook-Cottone et al., 2013). Although BN also involves dissatisfaction with the body, BN is characterized by difficulty with self-regulation that manifests in a cyclic behavioral pattern of bingeing on food and compensatory behaviors intended to either counter the caloric intake through exercise or purging (e.g., vomiting, use of laxative; APA, 2013; Cook-Cottone, 2015a). BED involves repeated binge episode in which the individual eats much more than typical in a discrete amount of time (APA, 2013). BED is also believed to involve difficulties with emotion and self-regulation (Cook-Cottone, 2015; Cook-Cottone et al., 2013). Although not considered to be a clinical eating disorder, but directly associated with weight, obesity results from a chronic disruption of the energy balance (i.e., energy intake and energy expenditure; Cook-Cottone et al., 2013; Loos & Bouchard, 2003). It is believed that current societal conditions (e.g., easy access to energy-dense foods and increased sedentary activities) among Westernized cultures have led to rapid increases in obesity rates (Cook-Cottone et al., 2013).

Although AN and BN are somewhat rare, affecting less than approximately 1–3% and 5–11% of the population, respectively (APA, 2013), rates suggest that over 20% of students may struggle at some point with clinical-level disorders associated with eating (Cook-Cottone et al., 2013). Further, if children and adolescents in the overweight category are included, *well over half* of the student population could feasibly struggle at some point with food, exercise, and self-care (Cook-Cottone, 2013). Thus, collectively, AN, BN, BED, and obesity affect a substantial number of children in schools.

The Healthy Student

The healthy student approach views each student within the context of his or her individual strengths and challenges and takes into account the influences of the family, school, community, and cultural supports and risk factors. The individual student behaviors are not seen in isolation; thus, the student's struggle for nutritional and physical health and stress management is not viewed as a failure of individual willpower or personal effort. Rather, the student, the school, and the community take ownership of their own responsibility to provide a healthy context from which the individual can make choices that serve their physical and mental health. Accordingly, the self is most effectively conceptualized as a self in which sociocultural context and individual physical and mental health characteristics both play a role in individual positive development, health, and self-regulation.

More recent models of the self-integrate physical well-being and balance the role of cognitions and emotions and the role of sociocultural context (Cook-Cottone, 2006, 2015a; Cook-Cottone et al., 2013; Stephens, et al., 2012). The attuned representational model of self (Cook-Cottone, 2006) demonstrates the role of the internal aspects of self such as cognitive, emotional, and the physical self. The physical self is viewed as a base for emotional and cognitive well-being. For example, daily nutrition, hydration, and exercise provide a stable physiological framework for emotional stability and positive cognitive functioning. See Cook-Cottone et al. (2013) and Cook-Cottone (2015b) for a detailed description of the role of self-care practices in well-being.

When self-care is intact, the aspects of the internal system work in an attuned manner to serve the functioning of the self within the sociocultural context (Cook-Cottone, 2006, 2015a). Basic structural conditions present within the student's sociocultural contexts (e.g., access to healthy food, school educational practices, school resources and funding, community and larger cultural values and priorities) as well as family influences also play a role in student well-being and performance (Cook-Cottone, 2006; Stephens et al., 2012). These processes are viewed as reciprocal, as the student' ability to engage in active self-care of his or her physical, emotional, and cognitive needs supports the student's ability to manage the challenges presented by sociocultural context. Conversely, the practices, supports, and tools provided within and by those in the sociocultural context (e.g., school program and practices) can enhance the students development of self-care and self-regulation tools (Cook-Cottone, 2006; Cook-Cottone et al., 2013). The self functions to witness and manage the internal aspects of self within the context of the external aspects of self. The self that presents to the world, school friend, teachers, and family members is an aggregation of the ongoing attunement or aggregated risk manifest by the ongoing dynamics within the self-system (Cook-Cottone, 2006; Cook-Cottone et al., 2013). See Cook-Cottone (2006) or Cook-Cottone (2015) for a full description of the model.

In order to increase understanding regarding school health and well-being promotion within the school setting, the history and foundations of the three-tier approach to school-based interventions are described. Next, health promotion approaches, including the promotion of healthy eating and positive mind and body relationships, will be described within the context of the three-tier approach in schools. To illustrate the approach, mind–body and eating-related interventions will be presented as examples of service provision within the three-tier model.

Health Psychology and the History of the Three-Tier Model

The three-tier model of prevention became a classification system pertinent to the field of prevention and public health, highlighting the importance of promoting and maintaining public health, rather than solely focusing on the prevention of disease (Leavell & Clark, 1953, 1958, 1965). The first tier became known as the primary prevention level, intended for the promotion of health and well-being and to provide specific protection against onset of disease. The primary prevention level included the implementation of procedures (i.e., immunizations, genetic screening) to identify potential risk and to intercept such risk prior to infection of the disease. Subsequently, secondary prevention was intended for early detection and timely treatment to prevent infection from spreading to others or to limit prolonged disability in the individual. Finally, the tertiary level of prevention was considered for the treatment of symptoms, rehabilitation, and limitations of the consequence of the disease to prevent progression or premature death (Leavell & Clark, 1953, 1958, 1965) Since its establishment, the fields of preventative health, medicine, and the social sciences have adopted this framework, although definitions of these three categories have varied across disciplines (Machlem, 2013). By the 1990s, the field of prevention adopted the terminologies endorsed by the Institute of Medicine (IOM): universal, selective, and indicated (Strein, Kuhn-McKearin, & Finney, 2014).

At the same time, the field of education increasingly embraced the prevention model framework for several reasons, including the increased development and research documenting the efficacy of evidence-based interventions, the promotion of well-being, and the increasing levels of need among students along with the recognition of the limitation of resources and cost-effectiveness. Further, such a multitier model accommodated recommendations outlined by the National Association of School Psychologists (NASP, 2010) that recommended a ratio of one school psychologist to every 500–700 students, depending on the need within the student population (NASP, 2010). This tremendously high ratio of students to school psychologists highlights the necessity of using a prevention model for the provision of services, as direct service to treat all individuals in need of services would be impossible.

Applied within the school framework, the three-tier model is incredibly effective for providing services to all students, especially as school personnel are frequently the first line of defense against emerging eating disorders and health problems related to obesity (Cook-Cottone et al., 2013). The first of the three tiers is Tier 1, the universal level, and is conceptualized as the core instructional or social-behavioral program. Tier 1 programs are research supported and aim to have an impact on the majority of students by meeting the needs of 80–90% of students. Accordingly, the majority of students, including those who may be at risk for concerns, respond sufficiently to this level of programming (Stoiber, 2014). Tier 2 is the targeted level of supports that are intended to serve a smaller group of students who require increased support to enhance the core programs at the Tier 1 level (Stoiber, 2014). Tier 3 is the intensive level and is the highest level of intensity. Tier 3 is designed to be individualized and strategically aligned with the needs of the individual student being serviced. This level is intended to be implemented for the smallest percentage of students, 1–5% of students who continue to require supports beyond those in the first two tiers (Stoiber, 2014).

Tier 1: Approaches for the Promotion of Health and Well-Being

Tier 1 approaches for health and well-being promotion are interventions at the universal level. In general, they are core instructional or social-behavioral programs that are implemented for all students within the school and likely to be sufficient in meeting the needs of the majority of students (Stoiber, 2014). There is a long-standing history in the provision of universal programs in education that illustrate the link between physical health and learning. For example, school lunch programs were among the first interventions provided within the school setting to address a foundational health need that was notably interfering with student learning (Cook-Cottone et al., 2013). Since first initiated, school-based programs to promote nutrition and physical health have grown substantially. These programs have developed to include large-scale federally funded school lunch programs, integrate physical and health education, and target all levels of well-being support from counseling services to family support. Current implementation issues hinge on funding, challenges related to scheduling and time constraints, and finding evidence-based programs that meet school needs.

Beyond the provision of school lunches, there is emerging evidence that universal practices designed to promote well-being and health are effective in schools (Cook-Cottone et al., 2013; Shoshani & Steinmetz, 2013). However, research is in the early stages; much of the evidence is based on pilot studies or short-term controlled trials as opposed to more rigorous randomized trials. At the universal level, there is a significant need for higher-quality research with randomized controlled trials and assessment of long-term outcomes (Serwacki & Cook-Cottone, 2012; Shoshani & Steinmetz, 2013). A review of available research related to universal programs has identified several key factors across programs that were believed to play a role in student well-being at the universal level, including the cultivation of positive emotions, gratitude, and hope, goal setting, and development of character strengths (Shoshani & Steinmetz, 2013). These foci can easily be woven into daily curriculum, although some schools integrate such themes more formally through structured social emotional learning (SEL) programs. Overall research on SEL programs indicates that they result in an increase in student well-being (Ashdown & Bernard, 2012; Durlack, Weissberg, Dynamicki, Taylor, & Schellinger, 2011). Benefits include increased emotional regulation, self-awareness, stress management, relationship skills, and social awareness and have demonstrated an impact on learning (Ashdown & Bernard, 2012; Durlack et al., 2011). These larger-scale, often school- and district-wide approaches provide a foundational context for more specific programs that focus on healthy eating and physical health promotion.

Effective implementation of school and district-wide interventions requires an organization around a set of principles, which facilitates communication and aligns efforts. Cook-Cottone et al. (2013) present an approach to the *healthy student*, which includes three essential components: (a) intuitive eating and nutrition, (b) healthy physical activity, and (c) mindfulness, self-care, and emotion regulation. It is important that the overall focus is on promoting health, rather than avoiding obesity (Cook-Cottone et al., 2013). To do this schools must adopt a *transcontextual approach* in which adults within schools, families, and the community work together to provide a healthy environment (Cook-Cottone et al., 2013). This approach helps the entire community "walk the walk" of healthy eating, physical exercise, and mindful self-care. The entire school community is encouraged to embrace a focus on overall health over weight and weight loss. This community must also create a zero-tolerance policy for teasing and bullying, especially related to weight. Additionally, students, teachers, and families should be provided with opportunities to learn about nutrition. Nutrition education should also be included in health class and other appropriate sections of the curriculum. Farm-to-school programs and school farm program can enhance student knowledge of food sourcing, agriculture, botany, and nutrition. Further, through collaboration between school lunch providers and food vendors, the school should provide an environment full of healthy food choices with minimal exposure to unhealthy, competing foods (i.e., foods that have little nutritional value and are offered as a purchasing option during meal times, outside of, or as part of the school meal program; Cook-Cottone et al., 2013). Finally, opportunities for physical activity and access to water throughout the school day are also critical for supporting and promoting overall health (Cook-Cottone et al., 2013).

One approach that can be applied at the universal level and is aligned with the positive psychology paradigm is the Health at Every Size (HAES) program. The HAES program is based on supporting a fundamental understanding of the body, suggesting that an individual is more likely to treat his or her body with respect and care, as well as provide his or her body with good nutrition and exercise, if an individual likes their body (Mukai, Kambara, & Sasaki, 2013). Research suggests that when the body is experienced with a sense of shame, an individual may be more likely to engage in self-neglect and self-destructive eating behaviors and is less likely to engage in physical exercise, nutrition, and self-care (e.g., Duarte, Pinto-Gouveia, & Ferreira, 2014). The HAES principles include (a) a respect and acceptance of the body (all body types, shapes, and sizes), (b) a focus on making physical activity enjoyable, (c) a decreased focus on food (i.e., not using food as an external reward for achievement or behavior or as a way of celebrating achievement), and (d) a decreased focus on weight and body shaming. These HAES general principles can be readily applied to the school setting (Cook-Cottone et al., 2013). For example, there is no need to weigh students in school when they are routinely monitored by their primary healthcare provider or during their individual school physical (Cook-Cottone et al., 2013). For some students, the school weighing day is the beginning of their eating disorder story. This policy has been criticized not only for the risk it induces but also for the frequent lack of connection with any intervention to address variations in body mass index. Finally, schools should help students focus on being present, active, and living fully in their present body no matter its shape or size (Cook-Cottone et al., 2013). There are several programs that have been shown effective in promoting healthy eating behavior and a positive relationship with the body: Planet Health (Austin et al., 2012; Gortmaker et al., 1999), New Moves (Neumark-Sztainer et al., 2010), Healthy Buddies (Stock et al., 2007), and Learning Gardens.

It is important to note that mindfulness and mindful self-care strategies are also central to the healthy student approach and schools are increasingly integrating them into their daily classroom practices and social and emotional learning programs. Mindful practice and self-care are ways of being present in your mind and body that allows for a shift from externally oriented stimuli and standards to an ongoing presence with your own experience. Specifically, mindfulness includes formal mindful practices such as meditation, yoga, and systematic relaxation, as well as an increase in mindful awareness throughout the day. For example, a student could eat lunch, practice his or her instrument, do math, and read mindfully. Although more rigorous research is needed, mindful practices, yoga, and mindful awareness are believed to reduce risk for eating disorder behavior and increase student well-being (Cook-Cottone et al., 2013; Greenberg & Harris, 2012; Scime & Cook-Cottone, 2008; Serwacki & Cook-Cottone, 2012). For an expanded review of school-wide interventions, see Cook-Cottone et al. (2013). Overall, within the context of honoring and respecting bodies of all shapes and sizes, the district-wide focus is on respect for the body and the body's wisdom to know when and what to eat, healthy physical exercise, and mindful practice and self-care.

Tier 2: Approaches to Facilitate Healthy Eating Behaviors and Self-Care

Tier 2 approaches are targeted level supports that are intended to serve a smaller group of students who require increased support to enhance the core programs at the Tier 1 level programs (Stoiber, 2014). Tier 2 programs often target a specific risk group (e.g., elite athletes) or students already showing risk factors (e.g., dieting, body dissatisfaction) without manifesting full diagnostic criteria. There are many different types of programs that range from those that focus on physical exercise, or are solely focused on nutrition and eating or mood regulation and distress tolerance, to integrated programs that include both yoga and didactic skills training (e.g., media literacy, assertiveness, emotion regulation; see Cook-Cottone et al. (2013) for a review of school-based programs).

Here, two examples are provided as illustrations of a Tier 2 approach. First, Martinsen et al. (2014) designed and studied an eating disorder prevention intervention for elite high school athletes that addressed self-confidence, motivation, growth and development, and sports nutrition as related to health, eating disorders, and performance. Results indicated that those in the intervention group showed no onset of clinical eating disorder, whereas control group members showed significant increases in eating disordered behavior. Other programs have focused on students who are referred to the intervention due to suspect increased risk. Programs such as *Girls Growing in Wellness and Balance: Yoga and Life Skills to Empower* use yoga, and a risk-based curriculum can be used as a Tier 2 intervention for girls at risk for eating disorders. This program has been found, in controlled trials, to reduce body dissatisfaction, increase self-care, and decreased drive for thinness (Cook-Cottone, Kane, Keddie, & Haugli, 2013; Scime & Cook-Cottone, 2008; Serwacki & Cook-Cottone, 2012). However, there is still much work needed before there is a strong evidence base supporting a variety of Tier 2 interventions. Specifically relevant for school settings are issues such as dosage of the intervention may matter. For example, how much yoga, mindfulness, or prevention curriculum is needed to create change (Cook-Cottone, 2013)? Notably, dissonance-based programs in which students are led through a process of media literacy, psychoeducation on the thin ideal, activities designed to help students internalize a healthy body weight perspective and counter the thin ideal have also found to be effective (Rohde et al., 2014).

Tier 3: Assessing and Supporting Students With Eating Problems

Once a student is showing symptoms of a disorder, there should be considered for a Tier 3 level of intervention. Tier 3 is the highest level of intensity and is designed to be intensive, individualized, and strategically aligned with the student's individual needs (Stoiber, 2014). Screening and assessment can help identify those students who are in need of more intensive interventions. The SCOFF is a brief five-item screening instrument that can be very helpful. The questions are the following: (S) "Do you make yourself sick (vomit) because you feel comfortably full?" (C) "Do you worry that you have lost control over how much you eat?" (O) "Have you recently lost more than one stone (i.e., 15 pounds) in a 3-month period?" (F) "Do you believe yourself to be fat when others say you are thin?" (F) "Would you say the food dominates your life?" (Solmi, Hatch, Hotopf, Treasure, & Micali, 2015) Other behaviors of concern include eating in the absence of hunger, emotional eating, body dissatisfaction, and distortions in or over concern with body image (Cook-Cottone et al., 2013). For a more detailed review of screening and assessment tools for disordered eating, refer to Cook-Cottone et al. (2013), Berg and Peterson (2013), and Palmer (2014).

Following screening and assessment, if it is determined that the student is at risk for disordered eating, a referral should be made to an eating disorder specialist. Treatment may be done either on an inpatient or outpatient basis depending on the level of symptomatology and the patient's health status (Cook-Cottone et al., 2013). Those with clinical-level eating disorders require comprehensive and multifaceted care (American Academy of Pediatrics [AAP], 2003). The treatment of disordered eating utilizes a multidisciplinary team that specializes in the treatment of eating issues that includes a medical doctor specializing in eating disorders, a mental health specialist, and a nutritionist (Cook-Cottone et al., 2013). See Cook-Cottone and Vujnovic (2015) for a review of evidence-based interventions for children and adolescents with eating disorders.

Although treatment is likely to occur outside of the school setting, adequate support in the school setting can be a critical part of the treatment and recovery process. Support of the treatment of disordered eating can be most effectively done within the context of a prevention-oriented school atmosphere already promoting zero tolerance of in-school advertising, body teasing, and encouraging healthy nutritional behaviors and opportunities for positive physical activity (e.g., soccer, yoga classes, track, swimming; Cook-Cottone et al., 2013). If a student requires hospitalization or day treatment, providing support for the student's transition back to school is vital to recovery maintenance (Manley, Rickson, & Standeven, 2000). Student needs may include supportive counseling, medical monitoring, release from physical education classes, meal monitoring, and communication with the treatment team and family (Cook-Cottone et al., 2013). Special academic accommodations may be necessary, which include adjusted workload, alternative assignments for some physical education requirements, extended time on assignments and tests, tutoring for missed coursework, copies of class notes, and access to quiet study locations (Cook-Cottone et al., 2013; Manley et al., 2000). Given the medical complications sometimes involved in more chronic or severe cases, the school nurse may play an important role (Cook-Cottone et al., 2013). In-school counseling can nicely augment outpatient treatment team efforts via relaxation work, supportive and reflective listening, and short-term, solution-focused or problem-solving approaches for in-school issues. In addition, the treatment team therapist may have specific objectives with which he or she would like supported within the school setting (Cook-Cottone et al., 2013). Other areas of school support for those with disordered eating include supporting student during meals, alternative assignments in physical education and health classes, and flexibility and support with academic assignments and attendance (Cook-Cottone et al., 2013).

Conclusion

Physical and mental health provides the foundation for student learning. Today, schools have increasing responsibility for the provision of education beyond academics and are now charged with supporting overall well-being, not only for their students but also for families, school staff, and members of the larger community. One important deterrent to health is the increasing prevalence of eating disorders and obesity, with over half of the student population potentially struggling with food, exercise, and self-care. Addressing well-being and health in the school setting is best conceptualized in a three-tier approach, focusing not on the avoidance of the disorder itself, but on providing a level of programming to all students to support health and wellness within the school community. At the Tier 1 universal level, programs target all students and are usually implemented at the larger school or district-wide levels, focusing on healthy eating and physical health promotion. At the Tier 2 selective level, programs are intended to be implemented only to a smaller group of students and often target a specific risk group or students already showing risk factors. At this level, programming is varied and focuses on the students' needs. Thus, programs for use at Tier 2 might include those that focus on physical exercise, nutrition and eating, or mood regulation and distress tolerance. Tier 2 programs with a more broad focus integrate both yoga and didactic skills training to support well-being. Finally, at the Tier 3 indicated level, treatment is likely to occur outside of the school setting, making coordination and support for treatment in the school setting essential.

Students may require accommodations to support treatment progress and maintenance, and communication with treatment providers is important. Overall, schools provide an important setting for supporting health and well-being in the school and community.

Author Biographies

Catherine Cook-Cottone, PhD, is a licensed psychologist, registered yoga teacher, professor at SUNY at Buffalo, and co-editor in chief of *Eating Disorders: The Journal of treatment and Prevention*. She is founder and president of Yogis in Service, Inc., a not-for-profit organization. Her research specializes in embodied self-regulation (i.e., yoga, mindfulness, and self-care) and psychosocial disorders (e.g., eating disorders, trauma). She has written 6 books and over 60 peer-reviewed articles and book chapters.

Rebecca K. Vujnovic, PhD, is a licensed psychologist and nationally certified school psychologist. She is director of the University at Buffalo, State University of New York School Psychology Program. She maintains a private practice specializing in youth with attention and anxiety disorders. She has authored a workbook to support the management of anxiety through mindfulness strategies anxiety and has published 4 book chapters and 12 research articles.

Sport and Exercise in Health Psychology

Erika D. Van Dyke[1,2] and Judy L. Van Raalte[2]

[2]Department of Psychology, Springfield College, Springfield, MA, USA

Sport and exercise psychology is a field devoted to understanding biological, psychological, and social influences on performance and well-being, as well as the ways in which these forces interact to influence participation in sport and exercise (e.g., Biddle, 2000). Scientific findings and practical applications derived from sport and exercise psychology are of direct relevance to health psychology. That is, sport, exercise, and physical activity contribute to health outcomes. Understanding the factors that influence participation in sport, exercise, and physical activity can facilitate the development of effective interventions. Important health-related factors may also be considered concurrently with sport, exercise, and physical activity.

Physical Activity, Sport, and Exercise as a Cause

Much of the health psychology literature pertaining to sport and exercise is focused on the ways in which participation in physical activity influences aspects of health and well-being. Particular attention has been paid to the effects of sport and exercise on cognition, mood, personal factors, and psychobiological processes. A body of literature indicates that fit older adults display superior cognitive functioning relative to their less fit counterparts. These results are dependent on the task, with attention-demanding and rapid tasks showing the most pronounced effects (Boutcher, 2000). Meta-analyses further show that physical activity enhances cognition among both healthy elderly people and those with cognitive impairment and dementia (Colcombe & Kramer, 2003). Such cognitive benefits may accrue to exercisers because engaging in regular aerobic exercise minimizes age-related declines in brain volume and increases brain volume (Colcombe et al., 2006). Among the elderly, physical activity is associated with larger gray

matter volumes and reduced brain volume losses due to neurodegeneration (Raji et al., 2016). Because the specific brain regions positively affected by physical activity are also related to Alzheimer's disease and mild cognitive impairment, physical activity is believed to reduce the risk of developing such cognitive deficits (Raji et al., 2016). Further research is needed to clarify the dose–response relationship between physical activity and cognition, as well as to discover the underlying mechanisms by which physical activity exerts its effects on cognitive functioning (Boutcher, 2000; Carron, Hausenblas, & Estabrooks, 2003).

People who engage in regular physical activity often report that exercise makes them feel good (Leith, 2010). Indeed, research indicates that exercise reduces anxiety, depression, and confusion as measured by the Profile of Mood States (POMS) (McNair, Lorr, & Droppleman, 1971). Given these findings, it is not surprising that there has been a proliferation of research on the influence of physical activity behaviors on mood and affect particularly in the areas of anxiety and depression.

The state anxiety-reducing effects of physical activity are clear (the relationship between physical activity and trait anxiety is addressed below with other personality factors). Review papers report low to moderate reductions in anxiety following bouts of physical activity (Leith, 2010). Exercising for at least 15 min can reduce state anxiety for several hours post-exercise (Leith, 2010). The anxiety-reducing effects of physical activity have most commonly been found for aerobic, rhythmic activities including running, walking, cycling, and swimming (Leith, 2010). Both aerobic and non-aerobic forms of exercise reduce anxiety symptoms (Jayakody, Gunadasa, & Hosker, 2014). Although much research indicates that reductions in anxiety are found following physical activity regardless of the intensity of the exercise (Leith, 2010), some research with competitive athletes and exercisers has shown that high-intensity physical training is associated with increases in anxiety and negative affective states (Szabo, 2000). Exercise prescription recommendations may therefore be best focused on low- to moderate-intensity physical activity for anxiety reduction.

Physical activity is as effective as other known treatments (e.g., hypnosis, meditation, and relaxation) in reducing anxiety (Carron et al., 2003). Among individuals with clinically defined anxiety disorders including social phobia and panic disorder, exercise can reduce symptoms of anxiety and offers additional benefits compared with medication or psychological treatment alone (Jayakody et al., 2014). Similar positive effects of physical activity have been found with youth sport athletes who experience lower levels of anxiety in social situations (Schumacher Dimech & Seiler, 2011). Taken together, various sport and exercise behaviors have been found effective in reducing state anxiety.

Mild forms of nonclinical depression often abate without intervention in a relatively short amount of time. When treatment is sought, medication and psychotherapy are traditional methods that can alleviate symptoms of depression (Leith, 2010). Several meta-analyses dating back to the 1990s show that exercise reduces depression in individuals relative to non-exercising controls (North, McCullagh, & Tran, 1990), that these benefits accrue from both aerobic and anaerobic exercise, and that exercise is as effective a treatment for depression as other established methods including forms of psychotherapy and relaxation (North et al., 1990). Antidepressant effects have been most widely found in exercise programs of at least 10 weeks in length, with bouts of moderate-intensity activity performed for 15–30 min three times per week (Leith, 2010). Although high-intensity exercise has also been shown to effectively reduce symptoms of depression (Leith, 2010), the potential for individuals to experience negative affective responses at high intensities may make moderate-intensity activity a preferred approach for participants (Ekkekakis, Parfitt, & Petruzzello, 2011). Given the relatively few adverse side effects of exercise relative to the many health benefits, these findings have encouraging implications for including exercise in treatment prescriptions for depression.

Personality is a complex phenomenon—one that is relatively stable and enduring but also dynamic and modifiable (Carron et al., 2003). That is, people's personalities include characteristics displayed across a broad range of situations, as well as some characteristics that are malleable and subject to change. Physical activity has been found to be related to aspects of personality including trait anxiety, body image, and self-esteem.

Regular participation in sport and aerobic exercises (e.g., jogging, walking, cycling, swimming, and aerobic dance) is related to significant reductions in trait anxiety. People who engage in exercise programs of at least 9 weeks typically experience reductions in trait anxiety regardless of the exercise intensity level tested (Leith, 2010). A minimum of 20 min of exercise performed three times per week is necessary to promote a positive influence on trait anxiety (Leith, 2010). Thus, physical activity is associated with favorable effects on both state and trait forms of anxiety.

Body image has also been found to be positively related to involvement in sport and exercise (Hausenblas & Fallon, 2006; Hausenblas & Symons Downs, 2001). For instance, exercisers tend to have more favorable body image than non-exercisers, and body image is thought to improve throughout the course of exercise programs (Hausenblas & Fallon, 2006). When considering the body image of athletes in particular, athletes report more positive body image than non-athletes, and college athletes' body image is more positive than club/recreational athletes (Hausenblas & Symons Downs, 2001). However, involvement in sports that emphasize highly trained and lean bodies may contribute to body image disturbances (Carter, 2009). Additional research exploring the relationship between physical activity and body image may provide a strong foundation for the development of evidence-based interventions designed to reduce body image disturbances (Hausenblas & Symons Downs, 2001).

Physical activity has been shown to have a positive influence on self-esteem via such mechanisms as enhanced body image, body satisfaction, body acceptance, physical competence, and personal control over the body (Fox, 2000). Weight training and aerobic exercise programs of at least 12 weeks have the strongest self-esteem enhancing benefits (Fox, 2000; Leith, 2010). Physical self-esteem (Bowker, 2006) and perceived sport competence (Wagnsson, Lindwall, & Gustafsson, 2014) mediate the relationship between adolescent sport participation and self-esteem. Adult involvement in competitive physical activity can have adverse effects on self-esteem and self-concept (Leith, 2010), but such effects may be contingent upon the population in question. Competitive sport athletes report significantly higher self-esteem and self-concept than non-athletes. Among adolescent competitive sport athletes, competitive orientation is a positive predictor of self-esteem and self-concept (Findlay & Bowker, 2009). In sum, sport and exercise have been shown to positively influence self-esteem and self-concept, both directly and via the mediating roles of physical competence and body image-related constructs.

Psychobiological factors such as sleep, reactivity to stress, pain, and injury have all been explored in terms of their relationships to physical activity. Acute exercise has small to moderate effects on slow-wave sleep, rapid eye movement (REM) sleep, REM latency, and total sleep time (Youngstedt, O'Connor, & Dishman, 1997). With regard to the timing of the exercise bout relative to sleep, the majority of studies are conducted with good sleepers and include exercise bouts that are completed at least four hours before the onset of sleep, thus making it difficult to explore hypotheses related to the disruptive effects of exercise on sleep. It should be noted, however, that some individuals involved in physical activity just 30 min prior to bedtime do not experience sleep disruption (Youngstedt et al., 1997). These results suggest that evenings may serve as an ideal time for individuals with later preferences to exercise (Youngstedt, 2000).

Exercise and physical activity reduce reactivity to psychosocial stressors (Crews & Landers, 1987). Aerobically fit individuals often have reduced reactivity to psychosocial stress relative to their unfit counterparts (Crews & Landers, 1987). Exercise can be an effective way to cope with stress or can serve as an "inoculator" whereby repeated exposure to exercise enhances the ability to handle psychosocial stressors. Students who regularly use sport and exercise as coping strategies tend to have high stress tolerance (Bland, Melton, Bigham, & Welle, 2014). These results highlight the value of physical activity, exercise, and sport as effective coping mechanisms for reducing stress reactivity.

Pain is a common, and for some activities an integral, part of engaging in sport and exercise (Carron et al., 2003). Interestingly, exercise also has pain-reducing effects, although the specific mechanisms by which exercise achieves these analgesic effects are not fully understood (Koltyn, 2000). Aerobic and strengthening exercises reduce musculoskeletal pain tied to labor, menstruation, fibromyalgia, low back issues, and forms of arthritis (Carron et al., 2003). Pain tolerance and pain threshold increase following acute bouts of exercise, and ratings of the intensity of a pain stimulus decrease following exercise (Koltyn, 2000). Elite athletes have higher pain thresholds than non-athletes and control participants (Koltyn, 2000). Anecdotal evidence suggests that athletes and dancers may continue to perform vigorous exercise while injured and report afterward that they did not experience pain (Koltyn, 2000). Such accounts highlight how pain perception can be altered by engaging in sport and exercise. Parallel processing models of pain suggest that sport and exercise activities can serve a distraction function, keeping attention directed toward task-relevant stimuli and away from pain (Brewer & Redmond, 2017).

A common cost associated with participation in sport and exercise is injury. Cognitive emotional and behavioral responses to sport injury have been documented in the literature (Brewer & Redmond, 2017). Cognitive appraisals range from relatively benign (e.g., "my body can use a rest anyway") to very distressed (e.g., "this is the worst thing that ever happened to me"). Negative emotional responses typically occur immediately post injury, including experiences of anger, anxiety, bitterness, confusion, depression, disappointment, devastation, fear, frustration, helplessness, resentment, and shock. Effective coping behaviors and adherence to sport injury rehabilitation can speed the process of recovery from sport injury (Brewer & Redmond, 2017). Positive emotions as well as mixed feelings of apprehension, excitement, and fear of reinjury often occur as return to sport and physical activity near. Although sport, exercise, and physical activity can lead to injury, physical activity behaviors, particularly forms of strength training, have also been associated with lowered risk of injury in both youth and adults (Leppänen, Aaltonen Parkkari, Heinonen, & Kujala, 2014; Rössler et al., 2014). Thus, strength and exercise-based activities can be effective in preventing the occurrence of injury in sport and exercise settings.

Physical Activity, Sport, and Exercise as an Effect

Social factors such as group cohesion, leadership, group size, and social support have been studied with a particular focus on their effects on participation in sport, exercise, and physical activity. Group cohesion has been explored as a primary factor in individual adherence to physical activity. Perceptions of group cohesion are associated with individual adherence across several different physical activity behaviors including group fitness classes, recreational team sports, and elite team sports (Carron, Widmeyer, & Brawley, 1988). Perceptions of cohesion are higher among regular exercise class attendees than among dropouts in both university fitness class and private club fitness class settings (Spink & Carron, 1994). Although the specific aspects of group cohesion and moderators (e.g., belonging, enjoyment) that are related to individual adherence vary across settings, the overall conclusions highlight the value of cohesion in sports teams and exercise groups for fostering adherence to physical activity (Carron et al., 1988).

In the sport domain, coaches and peers high in transformational leadership qualities have positive influences on competitive team sport athletes (Price & Weiss, 2013). Specifically, transformational leadership behaviors such as inspirational motivation, idealized influence-individualized consideration, and intellectual stimulation are linked to greater team cohesion, enjoyment, confidence, perceived competence, and intrinsic motivation, variables likely to have a positive impact on athletes' participation in sport (Price & Weiss, 2013). In exercise settings, however, individual intentions to participate in fitness classes are not primarily dependent upon leadership style. Rather, leadership style contributes to group environment, and this interaction favorably influences enjoyment of exercise (Fox, Rejeski, & Gauvin, 2000). Thus, leadership characteristics exert influence at both individual and group levels to impact the experiences people have in physical activity.

In the context of recreational sport, increasing team size has been found to decrease perceptions of both enjoyment and cohesion (Widmeyer, Brawley, & Carron, 1990). In exercise settings, there is a curvilinear relationship between group size and attendance/retention such that small and large classes are best attended (Carron, Brawley, & Widmeyer, 1990). Exercisers' satisfaction is related to class size in a linear fashion such that the larger the class, the less satisfaction, perhaps due to reductions in individualized attention, reinforcement, and instruction from group leaders in larger groups (Carron et al., 1990).

Exercisers' perceptions of social support from their families and important others are associated with exercise behavior, cognitions pertaining to exercise participation, and attitudes regarding exercise experiences (Carron, Hausenblas, & Mack, 1996). Structural equation modeling has shown that social support has an indirect influence on exercise behavior that is mediated by self-efficacy (Duncan & Stoolmiller, 1993). That is, social support enhances self-efficacy, which is in turn related to increases in exercise behavior. Social support is also a key influence on the sport-related behaviors of youth, adolescents, and adults (Beets, Cardinal, & Alderman, 2010; Johnson, Kubik, & McMorris, 2011; Santi, Bruton, Pietrantoni, & Mellalieu, 2014). Direct parental involvement in sport activities with children, parental presence or supervision of sport activities, and parental encouragement and praise of children's' physical activity behaviors all foster youth physical activity (Beets et al., 2010). Social support from friends and school staff are associated with increased participation in sports teams among adolescents (Johnson et al., 2011). Supportive coaches and teammates increase participation in masters teams and nonobligatory training sessions (Santi et al., 2014). There is strong evidence that social support is positively related to physical activity, exercise, and sport involvement across the lifespan.

Physical Activity, Sport, and Exercise and Concurrent Factors

Several factors such as exercise dependence, eating disorders, and substance use issues, as well as individual demographic/biological and psychological characteristics, have been found to occur concurrently with sport and exercise behavior. Individuals experiencing exercise dependence exercise to such an extent that they may sustain injury, feel controlled by their physical activity, and experience a range of problematic physiological, cognitive, and affective symptoms when deprived of physical activity (Szabo, 2000). Symptoms of exercise deprivation experienced by exercise-dependent people include confusion, impaired concentration, anxiety, depression, irritability, hostility, anger, tension, guilt, frustration, decreased self-esteem, muscle soreness, disturbed sleep, lethargy, fatigue, increased galvanic skin response, gastrointestinal problems, and decreased vigor (Carron et al., 2003). The specific amount of exercise that is "too much" and leads to exercise dependence has yet to be determined. Factors associated with the development of exercise dependence include high levels of strenuous exercise, perfectionism, and self-efficacy (Hausenblas & Symons Downs, 2002). Clarification of conceptual and definitional issues related to exercise dependence may allow researchers to gain a deeper understanding of this phenomenon.

High levels of athleticism and exercise have been found to co-occur with eating disorder symptoms (Szabo, 2000). Athletes, particularly male athletes, report more eating disorder symptoms than non-athletes (Hausenblas & Carron, 1999). Male and female athletes in aesthetic sports and in sports involving weight categories are at heightened risk of developing eating disorder symptoms (Szabo, 2000). The subjective evaluation inherent to aesthetic sport outcomes and the heightened attention toward maintaining a certain body appearance and/or weight are considered probable explanations for these relationships (Hausenblas & Carron, 1999). Among female collegiate athletes, symptoms of eating disorders are related to sociocultural pressure for thinness, negative appraisals of athletic achievement, and anxiety about athletic performance (Williamson et al., 1995). Physical activity in and of itself is not necessarily related to eating disorders (Szabo, 2000). Indeed, walking exercise regimens are effective in managing binge eating disorders among obese women (Levine, Marcus, & Moulton, 1996). Furthermore, anorexia often leads to fatigue that can necessitate reductions in physical activity (Carron et al., 2003). Only a small percentage of exercisers appear to experience eating disorder symptoms (Szabo, 2000).

Exercise is associated with a number of positive health outcomes. Physical activity is often incorporated into alcohol treatment programs, and exercise training is effective in helping to alleviate alcohol dependency (Gutgesell & Canterbury, 1999). Additionally, exercise has been found to significantly increase abstinence rates, ease withdrawal symptoms, and reduce symptoms of anxiety and depression among individuals with substance use disorders (Wang, Wang, Wang, Li, & Zhou, 2014). When exploring substance abuse among high school and college athletes, however, participation on sports teams is associated with higher use of alcohol but lower use of cigarettes and illegal drugs than non-athletes (Lisha & Sussman, 2010). Thus, sport participation may serve a protective function against the use of cigarettes and illegal drugs.

With regard to performance-enhancing substances, anabolic–androgenic steroid use is particularly salient in the context of sport and exercise. Athletes are more likely to use anabolic–androgenic steroids than non-athletes (Sagoe, Molde, Andreassen, Torsheim, & Pallesen, 2014). Both male gender and involvement in power sports are predictive of future anabolic–androgenic steroid use (Wichstrøm, 2006). Given the known adverse health effects of using anabolic–androgenic steroids (Momaya, Fawal, & Estes, 2015), this is an area within sport and exercise warranting continued attention. Although engaging in sport and exercise may provide a protective function relative to the use of some substances, participation in physical activity is also predictive of substance use, particularly the use of alcohol and anabolic–androgenic steroids.

Several noteworthy trends have been identified connecting demographic factors and participation in sport and exercise. Physical activity tends to decline with advancing age across the lifespan (Carron et al., 2003). From preschool-age children to older adults, males typically engage in more moderate to vigorous physical activity than females. This trend may be partially due to sociocultural differences. Ethnic differences also exist relative to sedentary lifestyles, with 54% of Hispanic Americans, 52% of Black or African Americans, 46% of American Indians, 42% of Asians or Pacific Islanders, and 36% of White Americans being sedentary (USDHHS, 2000). Regarding occupation trends, blue-collar workers are less inclined to engage in leisure time physical activity than white-collar workers, potentially due to the impression that job-related tasks are sufficient for health benefits or to the physical fatigue associated with blue-collar jobs. Education is positively associated with leisure time physical activity, and levels of parental education are also positively related to the physical activity of their children. Healthy individuals tend to be more active than people with physical and mental health conditions (Carron et al., 2003).

Frequently reported barriers to participating in physical activity include lack of time, lack of access to facilities, and lack of safe environments (Carron et al., 2003). People who have more positive attitudes toward exercise and who have strong intentions to exercise are more likely to actually engage in physical activity behaviors. In addition, people tend to do the things that they enjoy. Thus, those who enjoy participating in sport and exercise are likely to be motivated to engage in these activities. Although the majority of people know that physical activity is good for health, many people are still not regularly active. This identified gap between knowledge and behavior indicates that interventions aiming to enhance physical activity levels should focus on more than the provision of knowledge regarding the health benefits of physical activity (Carron et al., 2003). Affective responses to exercise may be an area toward which focus might be appropriately placed given the notion that people are more likely to engage in physical activity if the experience is enjoyable (Ekkekakis et al., 2011).

Involvement in physical activity, sport, and exercise is related to biological, psychological, and social factors as well as overall health and well-being. Biological, psychological, and social factors also interact to influence participation in various physical activity behaviors. Engaging in physical activity, sport, and exercise may therefore be viewed as a cause of health outcomes, as an effect of the context and social environment, and as co-occurring with other personal health factors. Thus, a mounting body of evidence irrevocably ties sport and exercise to health psychology and highlights the importance of physical activity for maintaining physical and mental health across the lifespan.

Author Biographies

Erika D. Van Dyke received her master of science degree in athletic counseling from Springfield College and is currently a doctoral student of sport and exercise psychology at West Virginia University. She is a certified group exercise instructor through the Athletics and Fitness Association of America and is a member of both the Association for Applied Sport Psychology and the American Psychological Association (APA) Society for Sport, Exercise and Performance Psychology (Division 47). Erika has coauthored a book chapter on supervision for applied sport psychology consultants in training and has presented at both national and international conferences. In 2016, she received the APA Division 47 Master's Thesis Award for her research exploring self-talk and competitive performance among collegiate gymnasts. During her first year of doctoral study, she was granted a Provost Fellowship based on her scholarship and presently serves as an instructor and success coach for students at the university.

Judy L. Van Raalte, PhD, is professor of psychology at Springfield College, is certified consultant, Association for Applied Sport Psychology, and is listed in the US Olympic

Committee Sport Psychology Registry. Dr. Van Raalte has presented at conferences in 18 countries and published over 100 articles in peer-reviewed journals. Dr. Van Raalte served as president of the American Psychological Association's Division of Exercise and Sport Psychology (Division 47) and as the vice president of the International Society of Sport Psychology. She is a fellow of the American Psychological Association and the Association for Applied Sport Psychology.

Introduction

Sexual orientation and gender minority health has been a topic of interest for health researchers for decades. Sexual orientation minorities are persons whose sexual behaviors or attractions are not exclusively heterosexual. The term LGB (meaning lesbian, gay, and bisexual; the order of letters may vary) has often been used to describe such persons, but there is increasing recognition that this term does not capture a full range of potential manifestations of human sexual expression. For example, some individuals may engage in sexual behaviors with individuals of the same gender exclusively, or with both men and women, yet identify as heterosexual. *Sexual orientation minority* is used as a broad term, to include persons with non-heterosexual behaviors, attractions, and identities. However, it is important to note that differences exist within this group, including differences in health disparities. *Gender minorities* are persons for whom a gender assigned at birth does not align with a felt sense of gender identity. A commonly used term for individuals in this group is transgender (in contrast to cisgender, or persons for whom gender assigned at birth and felt sense of gender identity match), though the more broad term of gender minority may also include other gender identities that persons may identify as, including non-binary gender identities. Again, it is important to note that differences exist within the gender minorities group (e.g., between persons who are transitioning from female to male or from male to female and also among persons who desire different degrees of transition). Further, although sexual orientation minority persons and gender minority persons share many of the same concerns, they also have many differences between the groups that are relevant to health (Donatone & Rachlin, 2013; Moradi, Mohr, Worthington, & Fassinger, 2009).

The Context of Sexual Minority Health Disparities

Research on health disparities among sexual orientation and gender minority persons, until relatively recently, has tended to focus on non-heterosexual and non-cisgender identities as themselves reflective of pathology. That is, the locus of health disparities was often placed within sexual orientation and gender minority individuals themselves. In recent decades, awareness has shifted away from viewing sexual orientation and gender minority persons as intrinsically pathologized to understanding the social context of living as a sexual orientation or gender minority individual. In light of this, research has increasingly turned toward understanding person–environment interactions and the ways in which one's circumstances may exacerbate typical stressors or present unique stressors for sexual orientation and gender minority persons. The leading theory of the influence of social structures on the well-being of sexual orientation and gender minority persons is the *minority stress model* (Meyer, 1995, 2003).

The minority stress model describes the ways in which psychological distress is perpetrated by unique, chronic, and socially based stressors for sexual orientation and gender minority persons. It was initially developed to describe how heterosexism, or behavior that grants preferential treatment to heterosexual people, reinforces the idea that heterosexuality is preferred or more highly valued over minority sexual orientations. Heterosexism is also associated with homophobia or biphobia, which includes a variety of negative attitudes (e.g., anger, fear, discomfort, resentment, or disgust) that an individual may have toward sexual minority persons. Heterosexism or homo/biphobia may include behaviors such as discrimination against sexual orientation minority persons, for example, in employment or housing. Indeed, in much of the world and including in many parts of the United States, sexual orientation and gender minority persons may face hiring or promotion discrimination, in some cases without legal recourse for such discrimination. Heterosexism may also include experiences of violence inflicted upon an individual due to actual or perceived status as a sexual orientation or gender minority. Such experiences of violence can begin early, such as in school bullying, and persist into adulthood, such as in experiences of workplace harassment. Heterosexism and homo/biphobia may also be experienced at a social level. For example, laws may be passed that uniquely impact the well-being of sexual and gender minority persons. Experiences of violence may also take on a range of manifestations but may include experiences such as being assaulted. Consistent exposure to homophobic or biphobic messages can lead to internalization of those messages, meaning that sexual orientation minority persons may feel similar feelings of fear, anger, discomfort, resentment, or disgust for themselves and other sexual orientation or gender minority persons. Although initially developed to understand the experiences of sexual orientation minorities, the model was quickly applied to gender minority populations and proved useful in research on the health of gender minorities (Bockting, Miner, Swinburne Romine, Hamilton, & Coleman, 2013).

The minority stress model conceptualizes these and related experiences of stress as aspects of minority stress. Stress in general is a chronic engagement of taxing coping mechanisms to the extent that the individual does not have the capacity to endure further, leading to mental health and medical concerns. Social stress in particular describes the effect that social environmental events and conditions, above and beyond personal events, can have a deleterious effect on individuals. The minority stress model further emphasizes that the specific stressors faced by sexual orientation and gender minority persons are unique, chronic, and socially based. The stresses are unique, because they are based upon actual or perceived sexual orientation identity. That is, they are not experienced by persons who are, or who are perceived to be, heterosexual or cisgender. The stressors are chronic because they are not reflective of merely random and isolated events, but rather reflect a pervasive negative social attitude that promotes their reoccurrence across time, location, and context. Relatedly, the stressors are socially based because they are based in dominant social views within a society, which are socially constructed and maintained. It is important to note that the minority stress model emphasizes ways in which multiple minority identities can serve as both protective and risk factors for behaviors and experiences related to health disparities. For example, sources of stress and health concerns may differ significantly between gay men and lesbian women, or for sexual orientation and gender minority people of color compared with White sexual orientation and gender minority individuals. Indeed, the minority stress model has been applied several times to understand the experiences of ethnically and racially diverse populations since its conception in 1995 (Meyer, 1995).

The minority stress framework has been instrumental in helping to understand health disparities within their context. Numerous health disparities exist for sexual orientation and gender minority populations. Such disparities are known to begin early, being demonstrated even among adolescents who identify as sexual orientation and gender minorities. Sexual orientation and gender minority youth report higher levels of emotional distress and depressive symptoms than their heterosexual and cisgender counterparts. These symptoms are also associated with elevated levels of suicidal ideation and suicide attempts, as well as self-harm behaviors. Further, these disparities have been replicated across multiple countries, across racial/ethnic groups, and across genders. Transgender youth appear to be at specific and elevated risk for self-harm (McConnell, Birkett, & Mustanski, 2015; Peterson, Matthews, Copps-Smith, & Conard, 2017). Among adults, these health disparities persist and are linked to other negative outcomes for sexual orientation and gender minority individuals.

In minority stress theory, stresses are differentiated based on whether they arise from outside or within an individual. Outside stresses include circumstances in the environment. Such circumstances speak to the intersectional interactions of multiple minority statuses in considering minority stress. One clear example of circumstances in the environment is poverty. Poverty would impact factors such as access to basic needs such as healthcare, access to food (i.e., in a food desert), access to transportation, or safe housing. Unfortunately, limited empirical research has been conducted on the intersection of sexual orientation and gender minority identity and poverty, from within the minority stress framework. Nevertheless, sexual orientation and gender minority persons, especially adolescents, face levels of poverty and homelessness far higher than their heterosexual and cisgender peers (Keuroghlian, Shtasel, & Bassuk, 2014). Other circumstances in the environment may also depend on the specific circumstances of the individuals involved; for example, in considering a same-sex couple who wish to adopt, specific state laws regarding same-sex adoption may be an especially relevant circumstance in the environment. Such laws may ebb and flow in their relevance to individuals; for example, if a same-sex couple has adopted a child in a state in which adoption laws were being called into question, they may worry about the status of their legal rights as adoptive parents. Similarly, such stresses may arise of sexual orientation or gender minority persons when the legality of same-sex marriage is called into question. In prior research with sexual orientation minority persons, in states in which constitutional amendments to define marriage as between a man and a woman were on the ballot, sexual orientation minority persons reported higher exposure to negative media, higher negative affect, and higher levels of distress compared with persons in states where such laws were not on the ballot (Fingerhut, Riggle, & Rostosky, 2011). Myriad other circumstances in the environment may ultimately impact the well-being of sexual orientation and gender minority persons, including persons with multiple minority statuses or other relevant personal characteristics.

Circumstances in the environment are inextricably tied to minority statuses. There are innumerable personal characteristics that a minority of persons may possess, but do not represent socially stigmatized identities (e.g., having green eyes or completely attached earlobes). Minority stress theory focuses on stresses that arise due to social influence, and thus categories of stigmatized identities are socially defined and may intersect. For example, recent research has explored ways in which sexual orientation and gender or race may intersect. Such investigations have indicated that there may be some pervasive mental health issues that cut across different groups when faced with minority stress (e.g., psychological distress or depression, substance use) but also some specific concerns that may be especially relevant to specific groups. For example, obesity, obesogenic behaviors, and resultant health conditions (e.g., cardiovascular disease) appear to be a specific concern relevant to lesbian and bisexual women, use of club drugs or anabolic steroids may be relevant to gay and bisexual men, and risk behaviors for HIV or other sexually transmitted infections (STIs) may be relevant to men who have sex with men. Thus, specific minority identities, and the interactions among identities, may impact both which circumstances in the environment are relevant and potential outcomes of minority stress processes.

Minority Identity

Because minority stress theory focuses on socially defined identities, a concept similar to minority status is minority identity and its characteristics. Individuals may differ in the extent to which their identities align with the categories into which researchers or others may desire to put them. For example, the term “men who have sex with men” was coined, in part, to capture the experiences of men who have sex with men but who may not identify as gay or bisexual. Minority identity itself is closely tied to the characteristics of minority identity, such as prominence of that identity or integration of that identity into everyday life. Such processes have implications for the health of sexual orientation and gender minority populations. For example, among men who have sex with men, the desire to be perceived by others as heterosexual has been associated with decreased likelihood of asking for an HIV test when visiting a doctor (Parent, Torrey, & Michaels, 2012). Other investigations have linked integration of sexual minority identity with lower internalized heterosexism and lower psychological distress. At the same time, outness has also been associated with more experiences of heterosexism, which may exacerbate minority stress processes. In addition, outness has not always clearly been linked to health variables, with some studies finding no relationship between outness and instances of domestic violence among lesbian and bisexual women (Balsam & Szymanski, 2005; Velez, Moradi, & Brewster, 2013). Thus, the relationships among outness or other variables related to identity salience are not straightforward. Indeed, it is possible that in many circumstances, not being out may have some costs to personal well-being but may have substantial benefits as well, for example, if coming out meant a risk for being physically assaulted by family members or kicked out of one’s home.

Minority identity is also associated with stress processes. In minority stress theory, these processes are conceptualized as distal (arising directly from the behaviors of others, such as harassment or discrimination) or proximal (arising directly from within oneself, such as expectations of rejection or internalized homophobia). These proximal and distal stressors have been reliably associated with myriad health concerns for sexual orientation and gender minority persons (Meyer, 2003).

Finally, the minority stress model posits that coping and social support may moderate health outcomes for sexual orientation and gender minority persons. Notably, however, research has not always supported the posited roles of these variables. Some work has supported links between aspects of coping, such as spiritual coping, as a buffer between minority stressors and mental health outcome variables, such as substance use. Other work has demonstrated that emotional regulation mediates the relationship between minority status and depression and anxiety among sexual orientation minority adolescents (but also that sexual orientation minority adolescents demonstrate lower levels of emotional regulation than their heterosexual peers). However, other recent work has called into question the utility of concepts such as "coping" or "resilience" among minority persons who may face social or institutional discrimination, insomuch as those terms may refer to returns to baselines of emotional or cognitive content following experiences of minority stress. By conceptualizing such returns to baseline following experiences of harassment, discrimination, or violence, the impetus for change is placed on an individual experiencing such harassment, discrimination, or violence to deal with the implications of those experiences, rather than emphasizing the need for change in the social or institutional power structures that allow or even encourage those experiences. Experiences of posttraumatic growth, transformative coping, or personal growth following minority stress may be fruitful areas to explore and may lead to a more clear understanding of the relationship between minority stresses and adaptive responses (Meyer, 2015). Regarding social support, a number of studies have supported social support as a buffer of the relationship between experiences of minority stress and negative outcomes. At the same time, involvement with the LGBT community is not always synonymous with social support and has indeed, in some cases, been linked with negative health outcomes for sexual orientation and gender minority persons. For example, more often attending clubs and parties has been linked to increased body image concerns and substance use among gay and bisexual men (Mattison, Ross, Wolfson, & Franklin, 2001).

Minority Stressors and Health Disparities

Experiences of bullying appear to be ubiquitous among sexual orientation and gender minority youth, with nearly all reporting some level of bullying or harassment. More severe forms of bullying including persistent bullying, threats of violence, or actual violence, are also common. Some of these instances of violence can result in physical harm, and sexual orientation and gender minority youth report that often these instances are either not reported to school officials or law enforcement, and if they are, that nothing is done about the behavior. Both harassment and violence are known to persist into adulthood, with sexual orientation and gender minority youth reporting workplace harassment and discrimination in housing or employment. Some disparities appear to be particularly relevant for specific groups within the sexual and gender minority umbrella. In particular, transgender persons may be especially vulnerable to experiences of violence (Berlan, Corliss, Field, Goodman, & Austin, 2010; Kim & Leventhal, 2011). As well, sexual orientation and gender minority persons who are sex workers are also at elevated risk for exposure to violence, again especially including transgender persons and especially male-to-female transgender persons (Nemoto, Bödeker, & Iwamoto, 2011).

Use of substances is also elevated among sexual orientation and gender minority persons, and this finding has been replicated in several countries. Rates of use of all substances are elevated among gender and sexual orientation minority adolescents, though rates of hard drugs and club drugs are markedly elevated, and rates of smoking tobacco are also markedly higher among sexual orientation and gender minority adolescents compared with their cisgender counterparts. This elevation is occurring concurrently with marked drops in smoking behaviors in the general population. Regarding substance use in general, among adolescents, girls appear to have somewhat higher risk for substances than boys, and bisexual adolescents appear to be at somewhat greater risk than gay/lesbian adolescents. Gay and bisexual adolescent boys also appear to be at specific risk for use of anabolic–androgenic steroids. Among adults, rates of substance use remain elevated, including use of tobacco, alcohol, steroids, recreational drugs, and club drugs. Use of such substances may be related to attempts to cope with stresses such as discrimination and violence but also potentially linked to aspects of community engagement. For example, use of illicit substances is common in clubs and circuit parties (large dance parties). As well, use of steroids may facilitate development of a highly muscular body, which facilitates access to a larger number of potential sexual partners (and, potentially, increases risk for exposure to STIs). Among female-to-male transgender persons, use of steroids may also facilitate development of a highly masculinized physique, potentially increasing "passing" as male and decreasing risks associated with being perceived as transgender (Guss, Williams, Reisner, Austin, & Katz-Wise, 2017; Halkitis, Moeller, & DeRaleau, 2008; Lee, Matthews, McCullen, & Melvin, 2014; Marshal et al., 2008).

Sexual risk behaviors are also relevant to sexual orientation and gender minority individuals. Most research on sexual health behaviors has focused on boys and men and potential contraction or spread of STIs. Within this domain, health disparities have been found to emerge early. Adolescent gay and bisexual boys report greater risky sexual behaviors than their heterosexual counterparts, with some studies finding bisexual adolescent boys to be at particular risk. These risks persist into adulthood for gay and bisexual men and appear to be exacerbated by use of substances and engaging in sex while intoxicated. Most research in this domain focuses on risk for HIV infection, and HIV rates remain elevated among gay and bisexual men. Although use of pre-exposure prophylaxis (PrEP) (i.e., medication taken to drastically lower the risk of HIV infection should exposure occur) is increasingly common among men who have sex with men, use of PrEP does not protect individuals from other STIs, and rates of STIs among men who have sex with men on PrEP remain elevated (Rosario et al., 2013; Scott & Klausner, 2016).

Obesity is also a concern among sexual orientation and gender minority persons. This disparity appears to be most prevalent among lesbian and bisexual women and appears to arise relatively early in life as adolescent girls who identify as lesbian and bisexual report higher rates of obesity compared with heterosexual peers. Obesity, and engagement in obesogenic behaviors, may interact with other stressors such as unemployment or underemployment, further complicating health status. However, obesity is not markedly elevated among gay and bisexual men or among transgender persons. The precise cause of specific health disparities among sexual orientation minority women is not known. Indeed, predictors of overweight status and obesity among sexual orientation minority women and heterosexual women are similar (Bowen, Balsam, & Ender, 2008; Yancey, Cochran, Corliss, & Mays, 2003).

Gender minority persons may also face specific health concerns. Some, though not all, transgender persons may seek to undertake aspects of gender transition. Gender transition may involve numerous surgical and nonsurgical procedures. Gender transition processes may be social and legal changes, such as legal adoption of a new name; nonmedical alterations of physical appearance, such as changes in hair style, body hair management, or clothing choices; medical and not surgical, such as use of exogenous hormones; and medical and surgical.

Medical and surgical changes also take on a range of manifestations, including breast reductions or breast implants, alterations to facial bone structure, and genital reconfiguration. Importantly, not all transgender persons wish to undergo all aspects of gender transition. Research supports that completing desired aspects of gender transition is associated with improvements in mental health and well-being. However, numerous barriers exist to transition processes: primarily, the cost of the procedures and access to competent care providers. Due to these barriers, some gender minority individuals may seek to undergo transition processes outside of professional medical supervision. Such processes may include unsupervised use of illicit hormones or injection with silicone that may result in infection (Murad et al., 2010; Sanchez, Sanchez, & Danoff, 2009; Wilson, Rapues, Jin, & Raymond, 2014).

Discussion

Sexual orientation and gender minority persons face a range of health disparities. The study of health disparities within this population has moved beyond views of sexual orientation and gender minority status as intrinsically pathological toward a contextual understanding of social and cultural origins of health disparities within this population. To this end, the minority stress model has been instrumental in framing our understanding of unique, chronic, and socially based stresses that may contribute to health disparities among sexual orientation and gender minority populations. Still, many disparities exist across health behaviors including substance use, obesity, and sexual risk behaviors, and many other disparities affect specific groups within the umbrella of sexual orientation and gender minority, and many opportunities exist for system- and individual-level intervention and future research.

It is imperative to understand how public policy related to health impacts the well-being of sexual orientation and gender minority populations. Within minority stress theory, such a focus would aim to reduce the institutional or structural supports for distal causes of health disparities for sexual orientation and gender minority individuals. For example, enactment of anti-same-sex marriage laws in the United States (prior to the Supreme Court ruling in favor of marriage quality across the country) has been associated with negative impacts on the mental health and well-being of sexual minority persons (Riggle, Rostosky, & Horn, 2010). Similar research has explored how anti-bullying legislation impacts experiences of bullying among sexual minority youth (Hatzenbuehler, Schwab-Reese, Ranapurwala, Hertz, & Ramirez, 2015), though research indicates that specific implementations of such laws by teachers and in schools may affect their impact (Van Wormer & McKinney, 2003). It is important to explore ways in which public policy can be used to reduce health disparities, including ways in which individuals who work in the front lines of implementing such policy may be empowered to better advocate for sexual orientation and gender minority persons.

The minority stress model also emphasizes the importance of examining proximal, or within-person, stressors related to health disparities. Such stressors may include expectations of rejection, internalized stigma, and concealment of sexual orientation (Meyer, 1995). Despite the large body of research on minority stress, very limited empirical research on the treatment of stress among sexual orientation and gender minority populations has been undertaken. Although some treatment guidelines for sexual orientation and gender minority populations have been developed (Pachankis, Hatzenbuehler, Rendina, Safren, & Parsons, 2015), there have been very few trials of interventions that specifically address constellations of minority stress. Studies that have been conducted have tended to be relatively low quality (e.g., including no-treatment wait list groups as controls, having small sample sizes, and having relatively homogeneous samples). It is important to extend extant work on minority stress beyond theoretical investigations of relations among constructs, which have generally been well established in the literature, and integrate these constructs with empirically supported interventions to provide quality, patient-centered care to sexual orientation and gender minority individuals.

Author Biographies

Dr. Mike C. Parent earned his PhD in Counseling Psychology from the University of Florida in 2013. He is now an assistant professor in counseling psychology and counselor education at the University of Texas at Austin. His program of research focuses on gender, sexuality, and behavioral health, as well as professional issues in psychology. He is the author of more than 40 peer-reviewed publications and has received numerous awards for his research and mentorship of students.

Teresa Gobble completed her BS in Psychology at the University of Central Florida. She is a doctoral student in the Counseling Psychology Program at the University of Texas–Austin. Her research focus includes examining risk factors for suicide in sexual and gender minority populations.

Ethics Issues in the Integration of Complementary, Alternative, and Integrative Health Techniques into Psychological Treatment

Jeffrey E. Barnett

College of Arts and Sciences, Loyola University Maryland, Baltimore, MD, USA

Complementary, alternative, and integrative health techniques are widely used in America today, and their use has increased significantly in recent years. With the wide range of complementary and alternative medicine (CAM) practices currently being used in the United States, it is quite reasonable to assume that many psychologists will come in contact with patients who either are presently using one or more CAM techniques or who may benefit from the use of CAM interventions in addition to any mental health treatment to be provided. In fact, many individuals who value psychotherapy and seek it out are likely to also value and utilize CAM as well (Knaudt, Connor, Weisler, Churchill, & Davidson, 1999). Elkins, Marcus, Rajab, and Durgam (2005) found that 64% of psychotherapy clients they surveyed reported also using at least one CAM modality. Further, many psychotherapy patients may ask for or be open to the use of various CAM treatments.

These circumstances may create both opportunities and ethics challenges for psychologists. Relevant ethics issues to be addressed include clinical competence, informed consent, boundaries and multiple relationships, consultation and cooperation with other health professionals, advertising and public statements, integrating CAM techniques with psychological treatment, and making appropriate and effective referrals.

First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

Clinical Competence

Psychologists are required to provide only those services for which they possess the necessary education, training, and supervised clinical experience to ensure that patients are not harmed and hopefully that patients are provided with the highest possible quality of care (American Psychological Association [APA], 2010). Clinical competence has been defined by Epstein and Hundert (2002) as "the habitual and judicious use of communication, knowledge, technical skills, clinical reasoning, emotions, values, and reflection in daily practice for the benefit of the individual and community served" (p. 226). In essence, the competent psychologist will possess the knowledge, skills, attitudes, and values necessary, and will implement them effectively, to provide care that maximally benefits each patient (Haas & Malouf, 2005).

Possessing the competence necessary to ensure that patients receive appropriate treatment is consistent with the aspirational general principles of the APA Ethics Code (APA, 2010) to include beneficence (doing good and providing benefit to patients), non-maleficence (avoiding harm to patients), and fidelity (fulfilling our obligations to our patients). It also is important to note that competence is not a static phenomenon; our knowledge and skills may degrade over time, and there will continually be new developments that may render our knowledge and skills obsolete. Thus, consistent with Standard 2.01, Boundaries of Competence (APA, 2010), psychologists "undertake relevant education, training, supervised experience, consultation or study" on an ongoing basis to ensure they maintain their competence and clinical effectiveness (p. 5).

With the great prevalence of CAM in our society today and with the significant percentage of the population that engages in the use of at least one CAM modality, an argument can be made that every practicing psychologist should possess at least general knowledge of CAM and its most widely used modalities to be considered competent and compliant with the APA Ethics Code (APA, 2010). This is true not just for those psychologists who may wish to integrate various CAM modalities into their clinical work with patients, but for all psychologists in clinical practice. Psychologists should be familiar with the current research literature on the clinical effectiveness, uses, contraindications, common side effects and interactions with other treatments, and mechanisms of action of the CAM modalities most likely to be used by our patients.

It is possible that many patients who seek out psychological treatment will already be utilizing one or more CAM modalities, often without medical supervision and of their own initiative. For many patients, what may seem like a harmless and "natural" practice may in fact bring with it great potential for harm. Many "natural" supplements may be quite dangerous and bring with them great risk if used inappropriately or in combination with prescription medications (Clauson, Santamarina, & Rutledge, 2008). Psychologists who are knowledgeable about CAM and who ask all their patients about the use of any CAM modalities can apply their knowledge to promote their patients' best interests. This is especially important in light of the finding that upward of 35% of all psychotherapy patients use at least one CAM modality without informing their psychotherapist of this fact (Elkins et al., 2005).

Patients may "self-prescribe" various over-the-counter herbal substances that may interact with prescription medications and other over-the-counter substances they may be using with untoward effects. Knowledgeable psychologists can educate their patients about various CAM modalities and their appropriate uses as well as their relative risks and benefits. These psychologists may also be familiar with common side effects of CAM treatments that may easily be overlooked or misdiagnosed as mental health difficulties by those who are unfamiliar with them. This knowledge can lead the psychologist to provide appropriate treatment to patients and, when indicated, refer these patients to their primary care physician to help ensure that medical conditions and treatments are managed appropriately.

Psychologists may also have patients they evaluate and treat who may benefit from the use of one or more CAM modalities. This form of integrative healthcare may be in many patients' best interest. Examples may include pain patients who may benefit from the use of hypnosis, biofeedback, acupuncture, or massage therapy in addition to ongoing psychotherapy and patients suffering from depression who may also benefit from yoga, meditation, dance movement therapy, aromatherapy, or the integration of spirituality and prayer with their ongoing psychotherapy. Accordingly, psychologists will need to possess two forms of clinical competence to effectively integrate CAM modalities with the psychological treatments they provide.

Psychologists will first need to possess knowledge about the various CAM modalities to know their uses, limitations, risks, and benefits. This will help psychologists know if a particular CAM modality may be potentially helpful for treating a patient's presenting problems. They will also need to complete the training necessary to be a competent practitioner of the CAM modality in question. Some CAM modalities require extensive education and supervised clinical experience as well as certification or licensure for a practitioner to be authorized to use that modality with patients. Examples of this include acupuncture, chiropractic, and massage therapy. Others may require extensive education and training to develop needed competence, but they do not require certification or licensure to practice them (e.g., hypnosis, biofeedback, yoga) but that are available as a means of demonstrating competence to the public. Finally, some forms of CAM, such as progressive muscle relaxation, have been well integrated into psychological practice with many psychologists developing competence in their use in the course of their training as psychologists.

Being a competent professional also means knowing the limits of one's competence. Being able to assess each patient's treatment needs and when not personally possessing needed clinical competence, making referrals to appropriately trained colleagues is in our patients' best interest. By being knowledgeable about the various CAM modalities and the training and expertise needed to practice them competently, we can then make referrals to appropriately trained and experienced professionals to best meet our patients' treatment needs.

Informed Consent

Informed consent involves providing patients with the information necessary so that they may make an informed decision about participating in the professional services being offered. This involves sharing information with patients at the outset of treatment about the treatment being proposed, reasonably available options and alternatives and their relative risks and benefits, and other relevant information that is likely to impact their decision to participate (Standard 10.01, Informed Consent to Therapy, APA, 2010). Thus, as has been highlighted, psychologists must be knowledgeable about widely available and empirically supported treatments for patients' presenting problems. This includes knowledge of CAM and the literature on the effectiveness and limitations of each modality so that this information can be shared with patients so they will have the information necessary to make informed decisions about the options available for their treatment.

Valid informed consent necessitates that patients have information provided to them verbally and in writing that it be presented in a manner that renders it "reasonably understandable" to the patient, and we must actively ensure their understanding of the information being presented to them (APA, 2010, p. 6). Merely providing patients with a document to read and sign or asking them if they have any questions after all the information is shared with them is not sufficient. Further, consent must be given by the patient voluntarily and without any coercion or undue influence. Finally, the patient must be competent to give consent. This means that patients must have the cognitive ability to understand the information shared and they must have the legal right to give consent (e.g., an adult and not a minor).

It is also important to note that informed consent should not be considered a one-time event. Rather, it is an ongoing process that should be updated through open discussion with the patient anytime changes to the course of treatment are recommended or are under consideration. So, anytime a new treatment modality is suggested to the patient, a collaborative discussion should occur so that the patient may make the most informed decision possible about it. This very appropriately may occur after a patient's psychological treatment begins, and one or more CAM modalities are considered as means of assisting the patient to achieve agreed upon treatment goals.

Boundaries and Multiple Relationships

Boundaries provide ground rules and structure for the professional relationship to help ensure that patients are not exploited or harmed. Examples of boundaries that exist include touch, self-disclosure, time, space, location, and gifts (Pope & Keith-Spiegel, 2008). Boundaries may be avoided, crossed, or violated. To avoid a boundary is to never traverse it such as never engaging in touch with a patient, never engaging in any self-disclosure, and never accepting a gift from a patient under any circumstances. A boundary crossing is a clinically relevant and appropriate boundary incursion that is accepted by the patient and motivated by the patient's treatment needs and not the psychologist's personal needs. Examples include extending the time of a treatment session for a patient who is in crisis and holding a treatment session in a patient's home such as for a homebound patient who might otherwise not be able to receive needed treatment. In contrast, a boundary violation holds great potential for the exploitation of, and harm to, the patient, may not be welcomed by the patient, may not be motivated by and relevant to the patient's treatment needs, does not meet prevailing community standards, and violates the ethics code (Smith & Fitzpatrick, 1995).

A multiple relationship constitutes entering into a secondary relationship with a patient in addition to the treatment relationship. This may include social, personal, and business relationships, among others. Inappropriate multiple relationships typically include a conflict of interest and thus are likely to adversely impact the psychologist's objectivity and judgment in decision making. Multiple relationships that do not hold a significant potential for exploitation or harm are acceptable (APA, 2010); however when unsure, consultation with an experienced and trusted colleague is recommended.

When integrating various CAM modalities into ongoing psychological treatment, it is possible to violate boundaries and enter into an inappropriate multiple relationship inadvertently. This may occur when endeavoring to meet the patient's treatment needs while overlooking how the provision of certain psychological and CAM treatments should not be provided by the same individual. For example, a healthcare professional may be a licensed psychologist and a licensed massage therapist. A patient being treated in psychotherapy may also benefit from massage therapy. But for one individual to provide both services to a patient would likely constitute an inappropriate multiple relationship with boundary violations occurring. While the boundary of touch may be appropriately crossed such as with a handshake or perhaps a hug to a grieving patient, to engage in the amount and type of physical contact involved in massage therapy holds great potential to violate the parameters of the psychotherapy relationship and process. While a licensed psychologist who is also a licensed massage therapist may appropriately provide psychotherapy and massage therapy to different patients, to provide both to a patient would be ill advised.

Psychologists should keep in mind that multiple relationships are not mandatory. Each situation is different, and we must consider each patient's treatment needs and the reasonably available options and alternatives for meeting them. While a patient may need a particular treatment service, this does not necessarily mean we are the ones who must provide it. Being knowledgeable of competent and credentialed CAM providers in the local area will be important so that appropriate referrals can be made for needed treatment. Thinking (erroneously) that we are the only ones who can meet a patient's needs can lead to impaired judgment and faulty decision making. Psychologists should also be mindful of conflict of interest situations such as financial motivations that may lead us to provide services to patients when a referral to another professional would be in their best interest. Again, psychologists should be aware of their motivations and keep their patients' best interests in mind.

Consultation and Cooperation With Other Professionals

As has been mentioned, psychologists should work collaboratively with professional colleagues in an effort to meet each patient's treatment needs. When we are not able to meet a patient's treatment needs personally, either due to limits to our clinical competence or the potential for an inappropriate multiple relationship, referrals to appropriately trained colleagues are essential.

The APA Ethics Code (APA, 2010) requires that psychologists avoid multiple relationships and conflicts of interests that may impair their objectivity and judgment. Yet, knowing when one's objectivity and judgment are impaired may be very challenging as individuals in general and health professionals in particular tend to be very ineffective at self-assessing our own abilities accurately (Dunning, Heath, & Suls, 2004). In these situations it is essential that we consult with colleagues who can provide an honest assessment of our judgment, functioning, and decision making. We must be open and honest with these colleagues, neither withholding nor distorting relevant information, to ensure that the consultation can be helpful so that patients receive the most appropriate treatment possible.

Consultation with colleagues is also relevant to finding the most appropriate treatment for patients as well as to ensure we personally are providing patients with optimal treatment. It is recommended that psychologists utilize the expertise of colleagues whenever questions arise about which treatment might be best for a patient or if the psychologist is the most appropriate individual to provide that treatment.

Advertising and Public Statements

While psychologists are entitled to advertise the clinical services they provide so that members of the public will know of and be able to access needed services, it is essential that all advertising be done accurately and without any false or deceptive statements; only factual information may be shared (APA, 2010). When offering CAM services, as well as any psychological services, it is important to not overstate one's credentials or the likely benefits of treatment services offered. As it is stated in Standard 5.01, Avoidance of False or Deceptive Statements, psychologists should not make false or deceptive statements about "their training experience, or competence," "their credentials," "their services," or "the scientific or clinical basis for, or results or degree of success of, their services" (p. 8).

Thus, inappropriate and appropriate ways to advertise, respectively, include:

- Compy Tent, PhD, Licensed Psychologist
  Internationally recognized expert in hypnosis, the number one treatment for pain control.
  versus
- Hum Bul, PhD, ABPP, Licensed Psychologist
  Diplomate in Health Psychology (American Board of Professional Psychology). Practice limited to the treatment of chronic pain.

To list one's relevant earned degrees and other relevant credentials that are based on demonstrating one's clinical competence and providing an objective description of the professional services offered meets the requirements of the APA Ethics Code's standard on advertising and public statements (APA, 2010). In contrast, making statements that reflect opinion instead of providing objective information is less useful to the public and may constitute a deceptive or misleading statement.

Standard 5, Advertising and Other Public Statements, of the APA Ethics Code (APA, 2010) requires that psychologists provide accurate and up-to-date information on all services provided, to include "the scientific or clinical basis for … their services" (p. 8). This necessitates that psychologists maintain knowledge of the relevant literature on the various CAM modalities they utilize in their practices. Also, consistent with Standard 2.04, Bases for Scientific and Professional Judgments, psychologists should only offer services, and use techniques, with sufficient scientific evidence and support for their efficacy and use.

Additionally, the APA Ethics Code (APA, 2010) in Standard 5.05, Testimonials, forbids the use of testimonials from current patients or others who may be vulnerable to our undue influence. Testimonial endorsements involve utilizing statements from patients about the psychologist, the services received, and the outcomes achieved, which are used in the psychologist's advertising such as in an advertisement or on one's website. The use of testimonials should be considered a conflict of interest situation and an inappropriate multiple relationship. The patient who provides a testimonial becomes engaged in a new relationship with the psychologist in addition to the original treatment relationship.

With regard to ethical decision making, one can ask what the motivations are for utilizing a patient's testimonial in one's advertising (the motivation is the promotion of one's practice, not the patient's treatment needs), whose needs are being met by engaging in this action (clearly, the psychologist's needs), and how this action is relevant to the patient's treatment needs and treatment plan (there is no therapeutic benefit from taking this action). Even if the patient suggests providing a testimonial endorsement or if the patient is happy to provide it in response to the psychologist's request, this is a conflict of interest situation that is motivated by the psychologist's needs, which exploits the patient's trust and dependence. It will be very difficult for most patients to refuse such a request by their psychologist and in agreeing the nature of the treatment relationship is changed to the detriment of the patient.

Integrating CAM into Psychological Practice

As is hopefully evident, there are a number of issues and concerns relevant to integrating CAM into one's psychological practice. It is essential that first and foremost, the psychologist is competent to provide the CAM service in question. This will include possessing the necessary education and training but may also involve possessing any needed certification and/or licensure. Before integrating the use of any CAM modalities into one's psychology practice, credentialing processes should be researched. Barnett, Shale, Elkins, and Fisher (2014) provide a list of professional organizations, credentialing agencies and requirements, and their website addresses for each of the 14 most widely used forms of CAM. Education and training requirements may be found on many of these websites. Additionally, one may consult with experienced CAM practitioners about the knowledge, skills, and clinical experience needed to be a competent practitioner of that CAM modality. When licensure or certification is required, all relevant laws should be followed to ensure legal requirements are fulfilled.

Once clinical competence is established and any required certification or licensure is obtained, it is then important to ensure that CAM modalities are applied appropriately. As with any form of treatment, CAM modalities should only be integrated into a patient's treatment after a thorough assessment or evaluation is completed to ensure its relevance to the patient's treatment needs. No one CAM modality can be effective for the treatment of all presenting problems and conditions. Further, CAM modalities should only be applied in areas where credible research has demonstrated their effectiveness. If clear support for the use of a particular CAM modality is not established for a patient's treatment needs, the experimental nature of the treatment must be made clear to the patient as part of the informed consent process (APA, 2010).

Once a patient's treatment needs have been assessed and assuming that the psychologist possesses the needed competence to administer the treatment, one must consider the appropriateness of having both treatments (psychological and CAM) being offered by the same individual. As has been addressed, the administration of some CAM modalities is inconsistent with the psychotherapy relationship. One must consider boundary issues and the potential for adversely impacting the treatment relationship. Examples include integrating acupuncture, chiropractic, and massage therapy with psychotherapy. While one may be credentialed and competent in one or more of these in addition to psychotherapy, the type and amount of physical contact involved can be seen as inconsistent with prevailing professional standards for the psychotherapy relationship and process.

Psychologists integrating CAM modalities into psychological treatment should also be mindful of the risk of shifting professional roles. For example, a psychologist who integrates spirituality and prayer into psychotherapy may provide great benefit to a patient. But being supportive of a patient's personal use of prayer is very different from recommending specific Bible passages to the patient and praying together during psychotherapy sessions. One must be cautious about taking on the role of the clergy and leaving the psychologist role. Barnett and Johnson (2011) provide a decision-making model that can be applied to make such decisions.

When a patient's needs exceed the psychologist's clinical competence or when offering a treatment would risk boundary violations or entering into an inappropriate multiple relationship, referring the patient to a qualified colleague is recommended. Ideally, psychologists will maintain a list of competent CAM practitioners in the local area. Names can be added to or deleted from this list based on interactions with these CAM practitioners, reports from patients on their experiences with them, and from other trusted colleagues. It can be helpful to ask colleagues who they refer patients to as well. Additionally, one can meet CAM practitioners though involvement in local professional organizations and by attending CAM conferences, workshops, and trainings.

Conclusion

Ultimately, it is each patient's welfare and best interests that should guide our decision making. Psychologists should respect patients' beliefs and preferences, be cautious about taking on multiple relationships and avoid conflict of interest situations, continually seek to maintain their clinical competence, and provide patients with needed information (truthfully and without deception or misrepresentation) to assist them to make informed decisions about participation in CAM treatments. When ethical dilemmas arise, the use of a decision-making process that includes self-reflection, consideration of the APA Ethics Code (both the aspirational general principles and the enforceable ethical standards), and consultation with colleagues is recommended to help ensure that patients receive the best care possible and to minimize the risk of exploitation of or harm to them.

Author Biography

Jeffrey E. Barnett, PsyD, ABPP, is a licensed psychologist as well as professor of psychology and associate dean at Loyola University Maryland. He is board certified by the American Board of Professional Psychology in clinical psychology and in clinical child and adolescent psychology, and he is a distinguished practitioner in psychology of the National Academies of Practice.

Alcohol Use Disorder: Long-Term Consequences

Angela K. Stevens, Brittany E. Blanchard, Molin Shi,
and Andrew K. Littlefield

Department of Psychological Sciences, Texas Tech University, Lubbock, TX, USA

Long-Term Negative Health Outcomes from Alcohol Use

In addition to the host of short-term consequences associated with alcohol consumption, chronic use of alcohol, especially chronic misuse, is associated with several detrimental health outcomes. In fact, 25 chronic diseases in the *International Classification of Disease (ICD-10)* are completely attributable to long-term alcohol consumption, and chronic alcohol consumption is a component of more than 200 other diseases in the *ICD-10* (see Shield, Parry, & Rehm, 2014). Notably, alcohol shows a dose–response relation to many chronic diseases, in which the risk of disease onset and death from disease depends on the total volume of alcohol consumed (Shield et al., 2014). Further, between 1990 and 2010, alcohol was the third leading risk factor for global disease burden; however, for individuals between the ages of 15 and 49, it was the top risk factor worldwide (Lim et al., 2013).

Chronic, heavy drinking has been implicated as a risk factor for several deleterious health outcomes, including high blood pressure (Fuchs, Chambless, Whelton, Nieto, & Heiss, 2001), hemorrhagic and ischemic stroke (Rehm et al., 2009), Korsakoff's syndrome (i.e., a chronic memory disorder), and Wernicke's encephalopathy (i.e., alcohol-related dementia; see Pitel, Segobin, Ritz, Eustache, & Beaunieux, 2015). Indeed, alcohol-related Korsakoff's syndrome results from chronic, heavy alcohol consumption and thiamine (vitamin B1) deficiency, which is a consequence of a poor diet characteristic of excessive alcohol use (Pitel et al., 2015). Excessive alcohol consumption is also associated with epilepsy, or a predisposition for epileptic seizures (Shield et al., 2014). Research in this area has revealed a dose–response relation between alcohol consumption and the risk for epilepsy, such that repeated withdrawals from alcohol consumptions by heavy drinkers may increase risk for inducing an

First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

epileptic episode (see Shield et al., 2014 for more details). Other neuropsychiatric conditions associated with chronic alcohol consumption include unipolar depression, Alzheimer's disease, and vascular dementia (Shield et al., 2014).

Because chronic alcohol misuse is also linked to several types of cancers, alcohol is considered a carcinogen. Some of the cancers associated with problematic use include those of the prostate, upper digestive track (e.g., oral cavity, esophagus, and larynx), lower digestive track (e.g., colon, rectum, and liver), and breast (Rehm et al., 2009). Further, chronic alcohol consumption is associated with liver diseases (e.g., liver cirrhosis, alcoholic hepatitis); in 2010, an estimated 493,300 deaths were attributed to alcohol-related cirrhosis of the liver (Rehm, Samokhvalov, & Shield, 2013). Further, a recent meta-analysis found that alcohol consumption increased the risk of developing pancreatitis (though the dose–response relation for acute pancreatitis differed across men and women; see Samokhvalov, Rehm, & Roerecke, 2015). Moreover, chronic alcohol use increases the likelihood of developing diabetes mellitus, a condition commonly caused by pancreatitis (Rehm et al., 2009). Alcohol consumption affects blood pressure, and chronic alcohol misuse is predictive of hypertensive heart disease and ischemic heart disease (Rehm et al., 2009). There is also evidence that chronic alcohol use is associated with infectious diseases such as tuberculosis (World Health Organization [WHO], 2014). Although the biological evidence to support the causal link is lacking, observational research has indicated that alcohol consumption may exacerbate the disease progression of psoriasis, which is a chronic inflammatory autoimmune skin disease (Shield et al., 2014). Thus, chronic, heavy alcohol consumption puts an individual at risk for a myriad of negative physical conditions and diseases.

Detrimental outcomes of alcohol consumption during pregnancy include low birth weight (Rehm et al., 2009) and the development of fetal alcohol spectrum disorders, such as fetal alcohol syndrome (FAS), alcohol-related birth defects, and alcohol-related neurodevelopmental disorders (see Riley, Infante, & Warren, 2011). Specifically, infants with FAS exhibit growth deficiencies, craniofacial abnormalities, and heart defects (Riley et al., 2011). Individuals with FAS experience significant problems in adaptive, academic, and behavioral functioning (Streissguth et al., 2004). More specifically, fetal alcohol effects are associated with lower levels of intelligence, disrupted school experiences, criminal behavior and/or incarceration, inappropriate sexual behavior, and alcohol/drug problems (Streissguth et al., 2004). FAS is the leading preventable (i.e., nongenetic) cause of intellectual development disorder (previously known as mental retardation) and birth defects (O'Leary et al., 2013). In sum, alcohol consumption during pregnancy can lead to debilitating long-term health-related consequences for the offspring.

Potential Health Benefits

Despite the many potential adverse consequences associated with alcohol consumption, empirical evidence suggests that light-to-moderate drinking may provide some health benefits. For example, some data indicated that light-to-moderate drinking yields a reduction in risk for coronary heart disease and stroke (Shield et al., 2014). Further, alcohol use may reduce the risk of type 2 diabetes (Shield et al., 2014) and dementia (Peters, Peters, Warner, Beckett, & Bulpitt, 2008). There is also some evidence that alcohol consumption might lower the risk of certain types of cancers, including renal cell carcinoma, Hodgkin's lymphoma, and non-Hodgkin's lymphoma (see Shield et al., 2014). Despite these findings, the health benefits of moderate alcohol use have recently been called into question (see Chikritzhs et al., 2015), and the benefits may not outweigh the consequences.

Treatment Approaches to Alcohol Use Disorders

Numerous treatment approaches to AUDs are available. Though non-exhaustive, provided below are brief summaries of several relevant, empirically supported treatments for AUDs and related problems.

Brief Interventions

Brief interventions are evidence-based practices designed to motivate individuals to understand, reduce, and/or eliminate alcohol use, usually delivered in a 5- to 20-min session (Center for Substance Abuse Treatment, Substance Abuse and Mental Health Services Administration, 1999). Findings from a meta-analytic review suggest that brief interventions are as efficacious as extended alcohol treatments (Moyer, Finney, Swearingen, & Vergun, 2002). Common brief interventions typically used on college campuses are variants of brief motivational interventions (Murphy et al., 2001), such as the *Brief Alcohol Screening and Intervention for College Students* (BASICS) (Dimeff, Baer, Kivlahan, & Marlatt, 1999). Brief interventions have also demonstrated effectiveness in community mental health and primary care settings (O'Donnell et al., 2014).

Motivational Interviewing (MI)

Motivational interviewing (MI) is a brief, client-centered method used in conjunction with individual therapy that has strong research support for its efficacy in treating individuals with alcohol-related problems (Rollnick, Miller, & Butler, 2008). MI seeks to evoke self-efficacy and motivation while encouraging individuals to use their own reasons for change to resolve ambivalence, reduce resistance, and progress in their readiness to change (Rollnick et al., 2008). Similarly, motivational enhancement therapy, which combines MI techniques and personal feedback, has also been used to promote motivation for positive change in individuals who engage in problematic drinking (Miller, Zweben, DiClemente, & Rychtarik, 1992). Research has demonstrated strong support for the integration and use of MI as part of treatment for substance use disorders, including AUDs (see Lundahl & Burke, 2009).

Cognitive Behavioral Approaches

Numerous cognitive behavioral (CB) interventions to treat alcohol dependence have been developed and empirically tested (see Witkiewitz, Marlatt, & Walker, 2005). The CB approach targets cognitive, affective, and behavioral factors related to problematic drinking. It is hypothesized that deficits in abilities to cope effectively with stress serve to maintain excessive and subsequent drinking (Morgenstern & Longabaugh, 2000). As such, CB interventions typically include standardized, performance-based techniques, such as behavioral rehearsal and modeling, which teach individuals to have a sense of mastery in stressful situations without resorting to alcohol consumption.

Behavioral Couples Therapy (BCT)

Behavioral couples therapy for AUD (ABCT) is the most extensively studied approach of treatment at the couple level and has strong research support. ABCT is an outpatient, conjoint treatment that may be used as an additional component of, or subsequent to, individual therapy for those with AUDs and their partners (Epstein & McCrady, 1998). The underlying assumption posits that alcohol-related problems and intimate relationships are reciprocal and reinforcing of the alcohol use (Powers, Vedel, & Emmelkamp, 2008). A meta-analysis of 12 randomized controlled trials found that ABCT demonstrated a significantly greater effect compared with individual treatment alone for individuals with alcohol use problems in relationships (Powers et al., 2008).

Support Groups

Although support groups such as Alcoholics Anonymous (AA) are commonly utilized in the treatment of AUDs, findings are mixed with regard to effectiveness of AA (Tonigan, Toscova, & Miller, 1996). However, some components of AA are supported by research (e.g. recovering individuals as therapists, peer-led self-help groups; Kownacki & Shadish, 1999). Although AA and 12-step programs may not be effective for individuals with certain traits (e.g., severe mental illness), self-help groups such as these represent a viable option for many individuals who are motivated to maintain abstinence (Montalto, 2016).

Pharmacotherapy

The US Food and Drug Administration (FDA) has approved three pharmacological treatments for AUDs: disulfiram (e.g., Antabuse), oral and extended-release naltrexone (e.g., ReVia, Vivitrol), and acamprosate (e.g., Campral; Mark, Kassed, Vandivort-Warren, Levit, & Kranzler, 2009). Although disulfiram (an aldehyde dehydrogenase inhibitor) is meant to condition an individual to avoid alcohol intake by inducing nausea when individuals consume alcohol, it appears to reduce consumption but often fails to yield abstinence (Garbutt, West, Carey, Lohr, & Crews, 1999). Naltrexone (ReVia, Vivitrol) is an opioid antagonist, which lessens the positively reinforcing effects of alcohol (Petrakis et al., 2005). Studies have demonstrated its relative effectiveness in reducing overall alcohol consumption (Petrakis et al., 2005), as well as rate of relapse (Carmen, Angeles, Ana, & María, 2004). Naltrexone has also been shown to enhance treatment effectiveness when used in conjunction with other treatment modalities, such as psychosocial therapies or coping skills therapy (Jarosz, Miernik, Wachal, Walczak, & Krumpl, 2013). Acamprosate (Campral) is thought to enhance the inhibitory effects of the neurotransmitter gamma-aminobutyric acid (GABA) (Hunt, 1993) and acts primarily as a functional glutamate antagonist. Meta-analytic reviews suggest that acamprosate is also effective as a complementary treatment with different psychosocial interventions in treating alcohol dependence and appears to be as effective as naltrexone (Carmen et al., 2004; Garbutt et al., 1999).

Other Medical Interventions for AUDs and Related Conditions

Detoxification from chronic alcohol consumption is an important first step in treatment and often requires medical supervision, given the potential fatality of alcohol withdrawal symptoms (i.e., delirium tremens; see Kosten & O'Connor, 2003). Benzodiazepines have demonstrated effectiveness for managing seizures and delirium related to detoxification (Kosten & O'Connor, 2003). Further, anticonvulsants (e.g., carbamazepine) and alpha-agonists (e.g., clonidine) appear to decrease severity of withdrawal symptoms, and beta-blockers reduce cravings for alcohol (Kosten & O'Connor, 2003). Indeed, medication to manage withdrawal symptoms can be delivered on a fixed schedule or as needed, though the latter requires more frequent monitoring yet leads to a more rapid detoxification. Without pharmacological intervention withdrawal symptoms are expected to peak within 72 hr after last use, but medications reduce these symptoms within hours of delivery (see Kosten & O'Connor, 2003 for more details).

The cornerstone of treatment for alcoholic liver disease is abstinence, as significant improvement in disease progression can be observed in as little as 3 months. However, nutrition therapy also appears to be effective, given that the severity of malnutrition related to chronic alcohol consumption is correlated with disease severity and negative outcomes (see O'Shea, Dasarathy, & McCullough, 2010). Steroid treatment for alcoholic hepatitis has received the most attention in the extant literature, and there is evidence to suggest that a tapered dose of prednisolone over 2 weeks is most effective; however, studies often exclude individuals at an advanced stage of liver disease, which limits the generalizability of these findings (O'Shea et al., 2010). Notably, alcoholic liver disease is the second most common indicator for a liver transplant; however, given the stigma related to alcoholic liver disease (i.e., a "self-induced" disease), less than 5% of patients with advanced liver disease resulting from chronic alcohol consumption are formally evaluated for candidacy for liver transplantation (O'Shea et al., 2010).

Conclusions

AUDs are among the most commonly experienced psychiatric disorders in the United States, with especially high rates among young adults. Although many individuals who experience AUDs during adolescence and young adulthood will subsequently recover, underage alcohol use is more likely to be fatal among young people than all other illegal drugs combined (Grunbaum et al., 2002). In addition to alcohol-related injuries, alcohol consumption has been linked to over 200 health conditions (WHO, 2014). Given that alcohol use is normative and problematic use is common, treatment options to increase treatment involvement and retention rates, such as MI and stepped care approaches, may be especially beneficial (see Littlefield & Sher, 2009). Further, in light of data supporting the so-called prevention paradox (i.e., most alcohol-related harm in a given population arises within drinkers that are "low risk"; see Rossow & Romelsjo, 2006) and the health perils of acute intoxication regardless of disorder status, preventing alcohol-related health problems through prevention policy efforts, should also be considered in addition to treatments aimed at individuals with AUDs (see Gruenewald, 2011).

Author Biographies

Angela K. Stevens is currently a PhD student in clinical psychology at Texas Tech University in the Department of Psychological Sciences. Broadly, her research interests include individual differences in adult problematic substance use.

Brittany E. Blanchard is currently a PhD student in clinical psychology at Texas Tech University in the Department of Psychological Sciences. Her research examines individual differences in alcohol and substance use, including use of protective behavioral strategies.

Molin Shi is currently a PhD student in clinical psychology at Texas Tech University in the Department of Psychological Sciences. Her research focuses on the influences and consequences of substance-related behaviors, with an emphasis on the familial, social, and acculturative impact of substance use in minority subgroups.

Andrew K. Littlefield is currently an assistant professor at Texas Tech University in the Department of Psychological Sciences. He obtained his predoctoral training in clinical psychology at the University of Missouri and completed his clinical internship at the University of Mississippi Medical Center. Dr. Littlefield's research focuses on addictive behaviors.

Body image is a complex, multidimensional construct that includes a number of interrelated facets (e.g., Yagil et al., 2015). As such, a wide range of assessments have been developed to measure these domains. Such measures differ in methodology, specificity and content, and in their targeted populations. It is therefore important to consider the targeted patient or sample, the specific nature of presenting body image issues, and the psychometric properties of measures when selecting a body image assessment. Although a comprehensive list and description of body image measures is beyond the scope of this chapter, below we briefly review and describe a variety of measures that differ in the characteristics noted above.

Methodology

While the majority of body image assessments are self-report measures, subscales related to body image are included in three widely used structured interviews for eating disorders: the Eating Disorder Examination (Fairburn & Cooper, 1993), the Structured Interview for Anorexia and Bulimic Disorders (Fichter, Herpertz, Quadflieg, & Herpertz-Dahlmann, 1998), and the Interview for Diagnosis of Eating Disorders (Kutlesic, Williamson, Gleaves, Barbin, & Murphy-Eberenz, 1998). Similarly, self-report measures of global eating psychopathology include subscales that assess overvaluation of shape and weight or body dissatisfaction (e.g., Eating Disorder Examination Questionnaire, Fairburn & Beglin, 1994; Eating Disorder Inventory, Garner, 2004).

The Wiley Encyclopedia of Health Psychology: Volume 3: Clinical Health Psychology and Behavioral Medicine,
First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

Although many self-report questionnaires use items scored in a Likert-type or multiple-choice format, figural or schematic measures can also provide an index of self-discrepancy related to body image. Figure rating scales require respondents to compare their current figure with an array of figures that differ in body size; the discrepancy between one's current and ideal size provides an index of body dissatisfaction (e.g., Thomson & Gray, 1995; Williamson, Davis, Bennett, Goreczny, & Gleaves, 1989). More recently, the somatomorphic matrix was developed to assess satisfaction based on dimensions of body fat and muscularity (Gruber, Pope, Borowiecki, & Cohane, 2000) and is thought to be relevant to both males and females. In addition, in vivo methods have been applied to the measurement of body image, particularly with respect to perceptual domains (e.g., Video Distortion Method, Probst, Vandereycken, Van Coppenolle, & Pieters, 1995; Digital Photography Mirror-Based Technique; Shafran & Fairburn, 2002).

Content

Measures of body image also range in content and specificity and have previously been categorized based on cognitive, affective, subjective, behavioral, perceptual, and sociocultural focus (Thompson, Roehrig, Cafri, & Heinberg, 2005), although many instruments assess multiple domains. Cognitive assessments evaluate individuals' attitudes and beliefs about the importance of physical appearance (i.e., overvaluation of shape and weight) and the extent to which they experience appearance-related cognitions (e.g., Appearance Schemas Inventory, Cash & Labarge, 1996; Beliefs about Appearance Scale, Spangler & Stice, 2001). Affective and subjective measures generally assess emotional states that accompany body dissatisfaction (e.g., Situational Inventory of Body Image Dysphoria, Cash, 1994) or individuals' degree of satisfaction or concern with their body image, which may be global (e.g., Body Shape Questionnaire; Cooper, Taylor, Cooper, & Fairburn, 1987) or specific (e.g., Body Parts Satisfaction Scale; Petrie, Tripp, & Harvey, 2002). In turn, behavioral indices measure common manifestations of body dissatisfaction, such as body avoidance (e.g., Body Image Avoidance Questionnaire; Rosen, Srebnick, Saltzberg, & Wendt, 1991) or body checking (e.g., Body Checking Questionnaire; Reas, Whisenhunt, Netemeyer, & Williamson, 2002). Further, measures of perceptual components of body image (e.g., signal detection methods) provide an index of body size distortion, which is a core feature of body dysmorphic disorder and has also been observed in eating disorders.

Other measures evaluate sociocultural and interpersonal factors that have been thought to contribute to body image dissatisfaction and the internalization of thin ideals (e.g., Sociocultural Attitudes Towards Appearance Scale; Thompson, Van den Berg, Roehrig, Guarda, & Heinberg, 2004; Ideal Body Internalization Scale; Stice and Agras, 1998; Physical Appearance Related Teasing Scale; Thompson, Fabian, Moulton, Dunn, & Altabe, 1991).

Specific Populations

While body image concerns have been documented in a variety of medical and psychiatric populations, the majority of assessment measures have been developed and validated using adult Caucasian females. Thus, there remains a limited number of assessment measures for which psychometric properties have been evaluated in other samples (e.g., males, children, minority populations). Nevertheless, some advances have been made in the development of measures that specifically assess muscular body ideals that are particularly common among males (e.g., Drive for Muscularity Scale; McCreary & Sasse, 2000; Muscle Appearance Satisfaction Scale; Mayville, Williamson, White, Netemeyer, & Drab, 2002) and developmentally appropriate measures for children and adolescents (e.g., Cragun, DeBate, Ata, & Thompson, 2013; Veron-Guidry & Williamson, 1996).

Given that body image is not a static construct and may change in response to medical status, some measures have been developed to address body image concerns that may be particularly relevant among individuals with specific health problems, such as cancer (Hopwood, Fletcher, Lee, & Al Ghazal, 2001; Kopel, Eiser, Cool, & Carter, 1998), inflammatory bowel disease (McDermott et al., 2014), and conditions associated with disfigurement (Jewett et al., 2015; Lawrence et al., 1998). While the number of body image assessments for specific medical conditions remains limited, it has been recommended that health providers consider conducting routine screenings of body image concerns, as doing so may (a) initiate conversations about issues that patients may not otherwise voice openly, (b) identify patients currently experiencing or who are at risk for the negative sequelae of body dissatisfaction, and (c) provide insight into possible predictors of health outcomes (Pruzinsky, 2004). Thus, further development of condition-specific measures, as well as the use of standardized screening processes in healthcare settings, has promising clinical utility. These efforts may offer more precise and idiographic measures of condition-specific body image concerns, which could serve to inform subsequent prevention and intervention.

Conclusions

There are a large number of existing assessments, including many that are freely available for use in research and clinical contexts that may be used to measure various aspects of body image. Brief assessments of overall body image (e.g., eight-item Body Shape Questionnaire; Pook, Tuschen-Caffier, & Brähler, 2008) and assessments developed for individuals with specific health conditions may be of greatest utility in clinical health settings. In sum, the use of accurate methods to assess and detect body image concerns is necessary to provide health professionals with opportunities to address such concerns and ameliorate risk for the development of related psychopathology.

Author Biographies

Kathryn E. Smith, PhD, is a T32 postdoctoral research fellow at the Neuropsychiatric Research Institute. She received her BA in psychology from Macalester College and her PhD in clinical psychology from Kent State University. Her primary interests include emotion regulation and co-occurring psychopathology in eating disorders and obesity.

Tyler B. Mason, PhD, is an assistant professor in the Department of Preventative Medicine at the University of Southern California. He received his PhD in applied psychological science in 2015 and BS in psychology in 2010 from Old Dominion University. His primary research interests include etiology and treatment of binge eating and obesity.

Jason M. Lavender, PhD, is an assistant research scientist in the Department of Psychiatry at the University of California, San Diego. He completed his undergraduate education at Duke University and his PhD in clinical psychology at the University at Albany, SUNY. His research addresses emotion, neurocognition, and personality in eating disorders.

Stephen A. Wonderlich, PhD, is the Chester Fritz distinguished professor and associate chairperson in the Department of Psychiatry and Behavioral Science at the University of North Dakota, chair of Eating Disorders and codirector of the Eating Disorder and Weight Management Center at Sanford, and president and scientific director of the Neuropsychiatric Research Institute.

Anxiety and Skin Disease

Laura J. Dixon and Sara M. Witcraft

Department of Psychology, University of Mississippi, Oxford, MS, USA

Skin represents the largest organ of the human body, and collectively, skin (dermatology) diseases are among the most widespread illnesses in the world. Skin disease affects all ages and encompasses many conditions, including eczema, psoriasis, acne, alopecia, hyperhidrosis, urticaria (hives), fungal skin diseases, cellulitis, viral warts, skin cancer, and rosacea. Given that dermatology is seldom linked to fatality, the impact of skin disease is often underestimated. However, skin diseases represent the fourth leading global cause of nonfatal burden and are associated with significant psychosocial impairment and high rates of psychological comorbidity (Dalgard et al., 2015; Hay et al., 2014). Perhaps unsurprisingly, given the well-known link between the mind and skin, many skin diseases have a psychological component. Albeit simplified, skin and psychological reactions are posited to be connected through multifaceted responses from the psychoneuroimmunological systems. Psychodermatology addresses this skin–mind connection, and although it is a relatively new subfield, psychodermatology has received increased attention over the past two decades.

Psychodermatological (psychocutaneous) disorders have been classified into three categories—psychophysiologic disorders, primary psychiatric disorders, and secondary psychiatric disorders (Koo & Lee, 2003). Psychophysiologic disorders characterize skin conditions (e.g., acne, eczema) that may be triggered or worsened by psychological factors, such as stress and anxiety. In primary psychiatric disorders, psychopathology contributes to the manifestation of skin symptoms. Examples of primary psychiatric disorders include trichotillomania and delusions of parasitosis. Lastly, individuals affected by secondary psychiatric disorders experience emotional problems as a result of the disfigurement and impairment associated with skin disease. For instance, an individual with vitiligo or alopecia areata may experience depression or social anxiety symptoms due to their visible skin symptoms.

Psychological conditions are catalogued by the Diagnostic and Statistical Manual of Mental Health Disorders (DSM) (American Psychiatric Association [APA], 2013). Of the mental health disorders, anxiety represents one of the most common mental health problems among dermatology patients (Dalgard et al., 2015; Picardi, Amerio, et al., 2004). Anxiety is an

The Wiley Encyclopedia of Health Psychology: Volume 3: Clinical Health Psychology and Behavioral Medicine, First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

adaptive component of the normal human experience, but it becomes maladaptive when it is persistent, distressing, pervasive, and interferes with everyday life. According to recent studies, as many as 52–70% of dermatology patients report moderate to severe clinical anxiety symptoms (Gascón et al., 2012; Rasoulian, Ebrahimi, Zare, & Taherifar, 2010), and the prevalence rate of anxiety disorders ranges between 15 and 17% in dermatology patients (Dalgard et al., 2015; Picardi, Abeni, et al., 2004). Furthermore, studies have found significantly higher anxiety symptoms in dermatology samples compared with controls (Fleming et al., 2017; Pärna, Aluoja, & Kingo, 2015). In addition to worsening symptoms of skin disease, anxiety symptoms have been associated with a number of adverse outcomes for dermatology patients, such as the use of poor coping strategies, low quality of life, loss of life meaning, and poor social functioning (Leibovici et al., 2010; Mazzotti et al., 2012). While it is possible that anxiety symptoms may be separate and unrelated to skin symptoms, it is likely that in many cases, these anxiety symptoms may operate within the framework of psychodermatological disorders. In particular, anxiety may be integral in psychophysiologic disorders, with the cognitive, emotional, and physiological symptoms of anxiety exacerbating or triggering skin symptoms, or to secondary psychiatric disorders, such as an individual experiencing social or health anxiety symptoms in response to their dermatological condition.

Though anxiety refers to a broad syndrome, the most recent editions of the DSM have recognized different types of clinical anxiety including social anxiety disorder (SAD), generalized anxiety disorder (GAD), health anxiety, posttraumatic stress disorder, obsessive–compulsive disorder (OCD), and panic disorder/agoraphobia. Given the high prevalence rates and costs of clinical anxiety in dermatology patients, it is worthwhile to further explore these disorders in relation to skin disease.

Social Anxiety Disorder (Social Phobia)

The primary feature of SAD (formally known as social phobia) is the fear of being judged, rejected, or negatively evaluated in social situations (APA, 2013). Individuals with SAD experience anxiety in situations or in anticipation of a wide range of situations where they perceive that they may act, speak, or appear foolish, silly, stupid, or incompetent in front of others. SAD is one of the most prevalent and costly mental disorders, affecting 7.4% of the US population each year (Kessler, Petukhova, Sampson, Zaslavsky, & Wittchen, 2012). Given the visible nature of skin conditions and potential disfigurement, dermatology patients may be highly susceptible to social anxiety and fear of negative evaluation. Indeed, 33.4% of dermatology outpatients reported clinically significant social anxiety (Montgomery, Norman, Messenger, & Thompson, 2016), and dermatology patients report significantly greater social anxiety symptoms compared with healthy adults (Salman, Kurt, Topcuoglu, & Demircay, 2016). In addition, symptoms of SAD, such as blushing, sweating, and trembling, overlap with various skin diseases. For instance, Davidson, Foa, Connor, and Churchill (2002) found that 24.8–32.3% of individuals with SAD met criteria for hyperhidrosis (excessive sweating).

Social anxiety symptoms may contribute to positive feedback loop among individuals with certain skin diseases, such as rosacea, eczema, acne, or hyperhidrosis. For instance, anxiety in social situations may trigger or aggravate skin symptoms, and then an individual becomes anxious or embarrassed about experiencing visible symptoms, which further exacerbates skin symptoms. Conversely, in long-term skin conditions like vitiligo, the skin changes over time, and situational social anxiety may not have a strong impact on the course of the disease. Nevertheless, individuals with vitiligo may experience embarrassment, shame, and social anxiety due to the visible distortions of their skin. Studies have found that social anxiety symptoms are associated with greater impairment and disability among patients with hyperhidrosis (Lessa Lda et al., 2014), vitiligo (Salman et al., 2016), psoriasis (Schneider, Heuft, & Hockmann, 2013), and acne (Salman et al., 2016). Despite the clear connections between SAD and skin disease, there is remarkably limited research in this area. Further research examining prevalence rates, mechanisms, and treatments for social anxiety among dermatology patients is warranted as this work could improve the identification and treatment of SAD and ultimately, prevent long-term personal and societal costs of this mental disorder.

Generalized Anxiety Disorder

GAD is characterized by persistent, uncontrollable, excessive worry across multiple domains (e.g., health, finances, daily routine; APA, 2013). Individuals with GAD may worry about their health symptoms, but as compared with health anxiety (see below), they also experience pathological worry in other areas in their life. GAD is a relatively common anxiety disorder, presenting in 6.2% of the general population (Kessler et al., 2012). Yet, higher rates of GAD have been observed in dermatology samples. For instance, Woodruff, Higgins, Du Vivier, and Wessely (1997) examined medical records of dermatology patients referred to a psychiatrist and found that 24.8% met criteria for mild GAD and 8.7% met criteria for severe GAD. Although the psychology–dermatology literature is composed of many studies examining "general anxiety" or broadly defined symptoms of distress and anxiety, fewer studies have specifically examined the GAD syndrome. In particular, research in this area has primarily focused on the role of GAD and pathological worry in psoriasis. One study demonstrated excessive worry symptoms were evidenced by 38% of patients with psoriasis, while 25% of the entire sample reported symptom levels consistent with a clinical diagnosis of GAD (Fortune, Richards, Main, & Griffiths, 2000). Beyond the high prevalence rates of GAD in psoriasis, pathological worry has been associated with greater burden of physiological and psychological symptoms. Pathological worry has been found to negatively affect the body and, specifically, has been associated with slower clearance of psoriasis symptoms (Fortune, Richards, Kirby, et al., 2003). Finally, in addition to direct associations with disease symptoms, GAD symptoms have been linked to worse illness-related beliefs, greater disability, and worse coping strategies in psoriasis patients (Fortune et al., 2000; Fortune, Richards, Corrin, et al., 2003). Given the common occurrence of GAD in the general population coupled with the findings revealed by the psoriasis literature, additional research examining GAD and pathological worry in other skin diseases is necessary.

Health Anxiety

Health anxiety, also known as illness anxiety disorder and hypochondriasis, is a preoccupation having or acquiring a serious illness. These concerns are accompanied by either avoidance of medical visits altogether or, at the other extreme, excessive medical visits and tests despite being told that there is nothing physically wrong (APA, 2013). A recent epidemiological study revealed the lifetime prevalence rate of illness anxiety disorder was 5.7% (Sunderland, Newby, & Andrews, 2013). Unfortunately, health anxiety is often unidentified in medical settings, and medical providers may ineffectively, albeit unintentionally, respond to patients' anxieties about their health problems by offering reassurance and conducting unnecessary medical tests (Tyrer, Eilenberg, Fink, Hedman, & Tyrer, 2016). Very few studies have investigated health anxiety in dermatology patients, and to obtain more information about this phenomena, Long and Elpern (2017) conducted a study examining health anxiety in dermatology outpatients. They found that 31% of dermatology patients reported that they worried "a lot" about a health problem, 17% reported that they worried the problem was more serious than a doctor described, and a total of 46% expressed some degree health anxiety. The findings from this study suggest that health anxiety is particularly relevant for dermatology patients, and given these staggering numbers, further research is needed to explicate health anxiety in dermatology samples.

Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) is characterized by anxiety and distress following a potentially life-threatening event such as a car wreck, natural disaster, or a physical or sexual assault. Further, the anxiety is associated with recurrent, involuntary, and distressing memories of the trauma; attempts to avoid cues that remind the individual of the trauma and physiological arousal (e.g., hypervigilance, exaggerated startle reaction, panic symptoms); and increased negative mood and cognitions (APA, 2013). Despite the fact that many individuals will experience at least one potentially traumatic event in their lifetime, PTSD has a relatively low lifetime prevalence rate of 8.0% in the general population (Kessler et al., 2012). Interestingly, skin disease has been found to be higher among individuals with PTSD compared with those without PTSD. A recent review of co-occurring PTSD and dermatology suggested that skin conditions are common among individuals with PTSD due to the increased autonomic and sympathetic arousal, which activates skin symptoms (e.g., sweating; Gupta, Jarosz, & Gupta, 2017). Notably, in a large case–control trial, patients commonly reported psoriasis, alopecia, skin allergies, and other skin diseases, and individuals with PTSD (versus without PTSD) were twice as likely to have dermatology conditions (Britvić et al., 2015).

Obsessive–Compulsive Disorder

OCD is composed of two components—(a) uncontrollable, unwanted, recurrent thoughts that cause distress (obsessions) and (b) mental acts or ritualistic behaviors that are instigated by obsessions and are conducted to reduce anxiety (compulsions; APA, 2013). OCD is a chronic, though relatively rare, disorder, with a lifetime prevalence rate of 2.7% (Kessler et al., 2012). Nevertheless, the prevalence of OCD in dermatology patients is much higher, with studies finding that between 9.1 and 24.7% of patients with skin disease meet criteria for OCD (Demet et al., 2005; Sheikhmoonesi, Hajheidari, Masoudzadeh, Mohammadpour, & Mozaffari, 2014). Interestingly, whereas most of the empirical work examining anxiety disorders has been conducted within specific dermatology conditions (e.g., psoriasis), studies investigating OCD have done so with an unselected dermatological sample. OCD symptoms can interact with skin symptoms in several ways, and within OCD, obsessions or compulsions may relate to or be in response to skin symptoms. The most common obsessions reported by dermatology patients include somatic obsessions, pathological doubt, and contamination (Demet et al., 2005; Ebrahimi, Salehi, & Tafti, 2007). These obsessions may interfere with management of skin symptoms (e.g., doubt about taking medication) and may increase distress about the status of skin symptoms (e.g., intrusive thoughts about the severity of a skin lesion or breakout). The most common compulsions reported by dermatology patients include washing and checking (Demet et al., 2005). Chronic washing behaviors may lead to dry or raw skin and even abrasions, which may directly worsen skin symptoms and contribute to excoriation and skin picking. Similarly, though the study did not specify the type of checking behaviors, repeated checking of skin symptoms may result in decreased memory confidence and greater reactivity to perceived changes in skin status. Given the focus on skin and somatic symptoms, these individuals often present to dermatology or primary care clinics rather than seeking psychological or psychiatric services.

Panic and Agoraphobia

A panic attack is a sudden surge of anxiety and distress that peaks within 10 min and includes at least four of the following symptoms: palpitations/pounding heart, sweating, trembling or shaking, sensations of shortness of breath or smothering, feeling of choking, chest pain or discomfort, feeling dizzy or faint, nausea or abdominal distress, derealization/depersonalization, fear of losing control or going crazy, numbness or tingling sensations, and chills or hot flashes. Panic attacks may be cued by a specific event or environment (e.g., stressful event, needles, crowded area) or may occur "out of the blue" and for no apparent reason. Epidemiological work has estimated that 28.3% of individuals experience one panic attack at some point in their life (Kessler et al., 2006). Although panic attacks are not inherently tied to pathology, individuals who worry about having another panic attack or change their life to avoid having a panic attack may meet criteria for panic disorder. In addition, individuals with other anxiety disorders may experience panic attacks when they come in contact with a feared situation (e.g., social situations in SAD) and individuals with agoraphobia fear situations (e.g., public transportation, being in a crowd) because they are afraid they may not be able to escape or get help if they develop panic-like symptoms (APA, 2013). There is little literature exploring panic attacks, panic disorder, and agoraphobia in dermatology patients. One existing study found that patients with chronic skin conditions experienced significantly greater panic and agoraphobia symptoms than individuals in the control group (Pärna et al., 2015). Future research is required to understand panic and agoraphobia in dermatology. For instance, the avoidance and physiological symptoms characteristic of these disorders may amplify impairment and skin symptoms for individuals with skin disease. Moreover, it is likely that symptoms of these disorders may co-occur with other anxiety-related disorders as is commonly observed in the general population.

Future Directions

As the empirical literature of and clinical services for psychodermatology continue to evolve, anxiety disorders represent an important area for further development. Although anxiety disorders are common and known to contribute to worse outcomes in skin disease, there is a significant unmet need for treatment for individuals with co-occurring dermatological and anxiety conditions, as well as large gaps in the empirical literature. Regarding clinical services, psychiatric symptoms are often unrecognized in dermatology patients (Picardi, Abeni, et al., 2004), and even fewer patients receive psychotherapeutic interventions in routine dermatology care (Fritzsche et al., 2001). Several studies have shown promising outcomes for the inclusion of psychosocial treatments in standard dermatology care, and in particular, adjunctive cognitive behavioral treatments have been found to reduce the severity of dermatological conditions, enhance quality of life, and decrease anxiety symptoms (Lavda, Webb, & Thompson, 2012). With regard to research, studies investigating the prevalence rates and risk factors for the different anxiety disorders across skin disease would be beneficial for improving the awareness and identification of anxiety disorders in routine care. Moreover, investigating mechanisms contributing to the interaction between anxiety and skin symptoms would enhance the understanding of psychodermatology processes and has the potential to inform the development of effective interventions to prevent and reduce anxiety in dermatology patients.

Insomnia

Todd A. Smitherman and Daniel G. Rogers

Department of Psychology, University of Mississippi, Oxford, MS, USA

Diagnosis and Epidemiology

Insomnia is sleep disorder broadly characterized by dissatisfaction with sleep amount or quality as manifested by recurrent difficulty initiating or maintaining sleep and causing significant distress or daytime impairment (e.g., fatigue, difficulty concentrating, irritability) (Morin & Benca, 2012; Rybarczyk, Lund, Garroway, & Mack, 2013). Sleep maintenance difficulties include waking frequently during sleep or being unable to quickly return back to sleep after waking. Both the International Classification of Sleep Disorders—Third Edition (ICSD-3) (American Academy of Sleep Medicine, 2014) and the Diagnostic and Statistical Manual of Mental Disorders—Fifth Edition (DSM-5) (American Psychiatric Association, 2013) also require that sleep difficulties occur despite ample opportunity for sleep, have a frequency of at least 3 days/week for at least 3 months, and are not attributable to another medical or mental disorder. In research settings, regularly obtaining <6 hr sleep per night and being awake for >30 min while trying to fall or stay asleep are commonly employed as diagnostic thresholds.

Prevalence and Impact

Insomnia is one of the most common medical complaints in primary care settings. Over 30% of adults report at least one insomnia-related sleep complaint, 10–15% report daytime impairment resulting from poor sleep, and 6–10% of adults have symptoms that meet formal diagnostic criteria for insomnia (Morin & Jarrin, 2013). Without intervention, 40–60% of individuals with chronic insomnia report similar symptoms a year later (Pillai, Roth, & Drake, 2015).

Complaints of poor sleep are more common in women than men (Zhang & Wing, 2006) and among older adults (Morphy, Dunn, Lewis, Boardman, & Croft, 2007). Older adults experience more fragmented sleep and earlier awakening, awaken to external stimuli more easily, and are more prone to disruptions of normal sleep than young adults (Fetveit, 2009).

The Wiley Encyclopedia of Health Psychology: Volume 3: Clinical Health Psychology and Behavioral Medicine,
First Edition. General Editor: Lee M. Cohen. Volume Editors: C. Steven Richards and Lee M. Cohen.

Older adults also are more likely to experience comorbid medical conditions or disturbed sleep as a side effect of medication, which obfuscates the role of normal aging in sleep impairment (Vitiello, 2006).

Insomnia is associated with worsened cognitive functioning, particularly deficits in working memory, episodic memory, and executive functioning (Fortier-Brochu, Beaulieu-Bonneau, Ivers, & Morin, 2012). Insomnia results in tens of billions of dollars of lost productivity in the United States annually, mostly as a result of impaired work performance (Kessler et al., 2011), as well as significant direct and indirect costs to individuals (Daley, Morin, LeBlanc, Grégoire, & Savard, 2009).

Changes in Conceptualization of Insomnia

The most recent editions of the DSM and ICSD eliminated nonrestorative sleep as a symptom of insomnia (termed "insomnia disorder" in DSM-5 and "chronic insomnia" in ICSD-3) as this symptom is often poorly defined and not specific to insomnia. Classification task forces collaborated to ensure similar diagnostic criteria, including frequency and duration of insomnia, across diagnostic manuals. Epidemiological studies adhering to these updated criteria are needed.

Previous editions of insomnia diagnostic manuals made distinctions between "primary" and "secondary" insomnia, the latter of which referred to insomnia comorbid with another medical or psychiatric disorder. This distinction proved problematic in several ways: (a) limited understanding of mechanistic pathways prevents conclusions about the direction of causality, (b) use of the term "secondary insomnia" may contribute to potential for inadequate treatment, and (c) regardless of terminology, various insomnia presentations share numerous behavioral and cognitive characteristics and similar treatment approaches (NIH, 2005). As such, recent nosologies have eliminated this distinction.

Risk Factors and Comorbidities

Onset of insomnia is often conceptualized from a diathesis–stress perspective, in which inherited predisposing factors interact with precipitating events to disrupt biological processes involved in sleep. The sleep–wake cycle is largely determined by circadian and homeostatic processes, the former being regulated by external light cycles and the latter as a function of a sleep drive that increases the longer an individual remains awake. Diatheses involved in insomnia include genetically transmitted factors that predispose one to physiological hyperarousal throughout the day and night (e.g., family history of sleep disorders, negative affectivity, high susceptibility to stress; Riemann et al., 2010; Vgontzas et al., 2001).

Precipitating events among susceptible individuals include a broad range of medical, environmental, and psychological factors. Medical conditions such as chronic pain, heart disease, chronic obstructive pulmonary disease (COPD), and movement disorders can interfere with sleep onset or maintenance (Smith & Haythornthwaite, 2004). Environmental factors include those in the immediate sleep environment (e.g., excessive light, noise, uncomfortable ambient temperature) and more distal external variables (e.g., life stressors such as a new job or deadlines, changes in an individual's sleep schedule such as from jet lag). Psychological factors encompass comorbid psychiatric disorders and both behaviors and cognitions that contribute to disturbed sleep. Individuals with insomnia are up to five times more likely than those without insomnia to experience symptoms of anxiety and depression, both of which disrupt normal sleep patterns (Pearson, Johnson, & Nahin, 2006). This relationship appears bidirectional in nature, such that insomnia may develop before or after the psychiatric disorder. Use of various substances can also interfere with sleep (Roth et al., 2006): nicotine and caffeine can delay sleep onset, and alcohol can disrupt sleep maintenance and quality. Sleep disturbance may also result from use or withdrawal of controlled substances such as alcohol, anxiolytics, opioids, sedatives, and stimulants.

Beyond their role in the onset of acute episodes of insomnia, psychological factors operate also to maintain insomnia, such that an individual's response to difficulty sleeping may inadvertently perpetuate dysregulated sleep and contribute to development of chronic insomnia (Perlis, Giles, Mendelson, Bootzin, & Wyatt, 1997). Individuals experiencing insomnia often begin to worry about their ability to sleep and the functional consequences of too little sleep, and this preoccupation with sleep contributes to physiological arousal that interferes with sleep. Similarly, compensatory behavioral responses are generally designed to increase opportunity for sleep (e.g., remaining in bed if unable to sleep, sleeping in on weekends, utilizing daytime napping) but inadvertently maintain insomnia by conditioning the individual to be awake at night while attempting to sleep. Ultimately, chronification of insomnia thus often occurs through repeated pairing of cognitive and cortical arousal with sleep-related stimuli.

Assessment

Assessment of insomnia focuses principally on gathering information about sleep-related behaviors and cognitions, symptoms and functional impairment, and perpetuating factors that may maintain insomnia. In most cases, gathering this information via interview and daily sleep diaries is sufficient for making the diagnosis and developing a treatment plan.

Clinical Interview

Existing structured diagnostic interviews for insomnia are few in number, not validated using recent insomnia diagnostic criteria, and time consuming, and thus infrequently used outside of research settings or sleep clinics. The clinical interview focuses principally on gathering detailed information about one's sleep history and screening for the aforementioned comorbid conditions. In addition to querying specific diagnostic criteria and functional impairment, detailed information is gathered about the history of the sleep problem (onset, course, duration), typical sleep–wake pattern, and perpetuating factors. The latter includes identifying behaviors (e.g., daytime napping, staying in bed when unable to sleep, non-sleep activities while in bed), cognitions (e.g., preoccupation with sleep, catastrophizing about the effects of poor sleep), and medications/substances that condition physiological arousal when attempting to sleep.

Daily Sleep Diaries

Self-monitoring via use of daily sleep diaries (logs) is invaluable for quantifying one's sleep schedule at baseline and throughout treatment. At a minimum, sleep diaries should solicit information pertaining to time in bed (TiB), time out of bed, time to fall asleep (sleep latency [SL]), total sleep time (TST), and time spent napping. Some diaries include entries for bedtime, wake time after sleep onset (WASO), medication/alcohol consumption, lights on/off times, and ratings of sleep quality. From these self-monitoring data, sleep efficiency (SE) is calculated (average TST/average TiB × 100), representing the percentage of time in bed that one is asleep. Patients are instructed to complete entries shortly after awakening each morning, and a minimum of 2 weeks of self-monitoring is recommended for each assessment period.

Other Means of Assessment

In most cases a thorough clinical interview and daily sleep diaries provide ample data to inform diagnosis and treatment, but other methods of assessment may be used to supplement the interview and diaries.

Questionnaires

The most widely researched sleep questionnaire is the Pittsburgh Sleep Quality Index (PSQI) (Buysse, Reynolds, Monk, Berman, & Kupfer, 1998), which inquires about one's sleep pattern over the last month and solicits Likert-type ratings of various sleep disturbances. Items are aggregated into 7 component scores and then into a total score that ranges from 0 to 21; scores >5 are indicative of poor sleep quality. However, scoring the PSQI can be difficult, and, as it is not specific to insomnia, elevated scores can reflect difficulties stemming from other sleep disorders.

The Insomnia Severity Index (ISI) (Morin, Belleville, Bélanger, & Ivers, 2011) is the most widely used questionnaire specific to insomnia. This seven-item Likert-type measure quantifies severity of insomnia as a function of symptoms and impairment experienced over the last month. Total scores range from 0 to 28, with higher scores indicative of greater insomnia. The ISI is sensitive to treatment effects and can be utilized to identify insomnia in population samples.

Polysomnography

Polysomnography involves overnight recording of physiological variables during sleep (respiration, electrical activity of the brain) and is usually conducted in a sleep clinic. This form of assessment is not indicated in the overwhelming majority of insomnia presentations. Polysomnography is useful when there is strong reason to suspect breathing (sleep apnea) or movement disorders (e.g., restless leg syndrome) as the cause of poor sleep or when standard treatments fail without a clear reason (Schutte-Rodin, Broch, Buysse, Dorsey, & Sateia, 2008).

Actigraphy

Actigraphs are ambulatory digital monitoring devices that are worn on the wrist and quantify sleep as a function of movement (via accelerometry) and ambient light. Actigraphy is often used to supplement data from sleep diaries, as the former provides more objective data, or as an alternative to overnight polysomnography (Morganthaler et al., 2007). Several companies produce actigraphs and use proprietary computer algorithms to derive sleep–wake variables.

Treatment

Psychological Interventions

Cognitive behavioral therapy for insomnia (CBT-I) is grounded in principles of learning theory and seeks to modify behaviors and cognitions that inadvertently perpetuate conditioned arousal. CBT-I is a multicomponent intervention that includes some combination of stimulus control, sleep restriction, sleep hygiene education, relaxation training, and cognitive therapy. Stimulus control and sleep restriction appear to be the most potent components of

CBT-I (Schutte-Rodin et al., 2008). Stimulus control involves techniques to reassociate the bedroom with sleep using classical and operant conditioning principles. These include instructions in using the bed only for sleep and sexual activity (e.g., eliminating other activities in bed such as eating or watching TV), eliminating daytime naps, and getting out of bed if unable to fall asleep within 20–30 min. Sleep restriction focuses on consolidating one's sleep by restricting one's TiB to the actual time spent sleeping and then gradually increasing TiB as SE reaches 85% or higher as indexed by daily sleep diaries.

Sleep hygiene is a psychoeducational intervention focused on general habits that promote sleep (e.g., limiting caffeine/alcohol, keeping a comfortable sleep environment and consistent sleep–wake schedule) but is not an efficacious monotherapy (Edinger et al., 2009; Schutte-Rodin et al., 2008). Relaxation training endeavors to reduce contributing physiological arousal and is often used for those who have difficulty relaxing at bedtime or in place of sleep restriction for individuals who have bipolar disorder, in whom sleep restriction is contraindicated due to risk of inducing mania. Finally, cognitive therapy techniques may be included to address dysfunctional cognitions that perpetuate insomnia, such as chronic worries that prevent sleep or unrealistic expectations about sleep.

CBT-I is the most frequently researched and well-established psychological intervention for insomnia. The most recent comprehensive review of its efficacy in adults was provided in a meta-analysis conducted by the Agency for Healthcare Research and Quality (AHRQ) (Brasure et al., 2015). Eighteen randomized controlled trials provided data for pooled outcomes regarding CBT-I versus passive control interventions (e.g., attention control, treatment as usual, wait list, sham control) among the general adult population. Most studies utilized individual CBT-I, though some included alternative modes of delivery (e.g., group or phone administration). On average, CBT-I was associated with a tripled rate of remission (61 vs. 18% for control); substantially greater reductions on both the PSQI and ISI; and superior improvements in SL, TST, WASO, SE, and sleep quality. Many treatment gains appeared to be maintained for months after cessation of treatment. CBT-I also produced favorable outcomes versus control treatments among older adults and among those with comorbid pain conditions, though the evidence was of lower quality as there were fewer trials pertinent to these specific groups.

Other recent meta-analytic reviews have reached similar conclusions regarding the short- and long-term efficacy of CBT-I for insomnia, including insomnia comorbid with other medical and psychiatric conditions (Geiger-Brown et al., 2015; Trauer, Qian, Doyle, Rajaratnam, & Cunnington, 2015; Wu, Appleman, Salazar, & Ong, 2015). Advances in treatment delivery and information technology have facilitated efforts to condense CBT-I into as few as two to four treatment sessions so that it can be more easily integrated into routine medical practice settings (Edinger et al., 2009; Edinger & Sampson, 2003), as well as delivered via the Internet to enhance access and utilization (Zachariae, Lyby, Ritterband, & O'Toole, 2016).

There is insufficient evidence for complementary and alternative medicine approaches (e.g., acupuncture, homeopathy, valerian root) to suitably assess their efficacy for treatment of insomnia (Brasure et al., 2015).

Pharmacotherapy

Pharmacological therapies for insomnia can be broadly delineated into over-the-counter (OTC) medications, prescription medications approved by the Food and Drug Administration (FDA) for treatment of insomnia, and prescription medications with sedating properties that are used "off-label." In general, the following medications have shown efficacy for short-term treatment of insomnia, though few studies on long-term efficacy or safety exist.

OTC medications

Common OTC medications for insomnia include antihistamines (e.g., hydroxyzine, diphenhydramine, doxylamine succinate) and exogenous melatonin. Antihistamines are frequently used for insomnia despite limited evidence of efficacy, rapid development of tolerance with daily usage, and risk of rebound insomnia following discontinuation. Melatonin has been increasingly used to aid sleep since sedative properties were discovered in the 1970s. Melatonin has demonstrated significant effects in reducing sleep onset latency and increasing TST and sleep quality compared with placebo across several studies (Ferracioli-Oda, Qawasmi, & Bloch, 2013). However, the clinical significance of these effects appears modest at best, with sleep onset latency and TST improved by less than 10 min on average as compared with placebo.

Prescription medications approved for insomnia

The most common medications approved for the treatment of insomnia are benzodiazepine (e.g., estazolam) and non-benzodiazepine hypnotics (e.g., zolpidem [Ambien], eszopiclone [Lunesta]), the latter of which have the strongest evidence among adults in the general population. Both classes of agents are GABA agonists, though the non-benzodiazepines appear to have more selective action at the GABA_A receptor and perhaps better safety profiles. Non-benzodiazepines have been shown to reduce SL and WASO and to increase SE and sleep quality (Becker & Somiah, 2015; Buscemi et al., 2007). Evidence for benzodiazepines is less robust as a function of trial design limitations and significant improvements evidenced only in sleep onset latency (Brasure et al., 2015). The efficacy of hypnotic agents has been called into question relative to risks associated with both short-term and long-term usage. Short-term side effects include drowsiness and fatigue, cognitive impairment, and motor problems, which can be particularly relevant among older adults (Glass, Lancôt, Herrmann, Sproule & Busto, 2005). Long-term use is associated with risk for dependence, misuse, and rebound insomnia, as well as higher rates of dementia and fractures in observational studies (Brasure et al., 2015).

Other approved medications include the melatonin receptor agonists (MRA) (e.g., ramelteon), orexin receptor antagonists (ORA) (e.g., suvorexant), and tricyclic antidepressants (TCA) (e.g., doxepin). Ramelteon does not appear to produce clinically meaningful sleep improvements, similar to conclusions reached regarding exogenous melatonin (Brasure, Fuchs, & Macdonal, 2016). Both ORAs and TCAs have demonstrated efficacy in improving sleep time and reducing WASO, though evidence for TCAs is weaker (Brasure et al., 2015).

Prescription medications not approved for insomnia

In addition to FDA-approved medications for insomnia, several antidepressants (e.g., trazodone, mirtazapine), anticonvulsants (e.g., tiagabine, pregabalin), and antipsychotics have sedating properties and thus are commonly prescribed. In general, the evidence for off-label use of these medications is insufficient as compared with the aforementioned approved prescription medications, and risk of adverse events is high. As such, these agents are recommended only when insomnia is comorbid with another condition for which they are indicated (Buysse, John Rush, & Reynolds, 2017).

CBT-I Versus Pharmacotherapy for Insomnia

The AHRQ review concluded that there was insufficient evidence to directly compare CBT-I and pharmacotherapy but noted that CBT-I carries considerably less risk for adverse effects and physical harm (Brasure et al., 2015). Accordingly, the American College of Physicians’ most recent clinical practice guideline recommended CBT-I as the frontline treatment for adults with insomnia, with medication as a secondary option for those who do not respond to an initial trial of CBT-I (Qaseem, Kansagara, Forciea, Cooke, & Denberg, 2016). As pharmacotherapy is only recommended for short-term use, most drug trials have been only 4–6 weeks in duration, and thus serious long-term adverse effects directly associated with use of pharmacological agents for sleep remain largely unknown.

Foreword

Until the 1970s, there were no books, journals, or university courses on health psychology. Although the field's intellectual roots stretch back to the beginnings of psychology more than a century ago, its formal emergence depended on a convergence of influences (Friedman & Silver, 2007), including psychosomatic medicine, social-psychological and socio-anthropological perspectives on medicine, epidemiology, and medical and clinical psychology. Today, health psychology is a principal area of significant social science research and practice, with vital implications for the health and well-being of individuals and societies. Understanding the explosive trajectory of health psychology is useful to appreciating the strengths of the field and to approaching this new encyclopedia, the *Wiley Encyclopedia of Health Psychology.*

What is the nature of health? That is, what does it mean to be healthy? The way that this question is answered affects the behaviors, treatments, and resource allocations of individuals, families, health practitioners, governments, and societies. For example, if it is thought that you are healthy unless and until you contract a disease or suffer an injury, then attention and resources are primarily allocated toward "fixing" the problem through medications or surgical repairs. This is the traditional biomedical model of disease (sometimes called the "disease model"). Indeed, in the United States, the overwhelming allocation of attention and resources is to physicians (doing treatments) and to pharmaceuticals (prescription drugs and their development). In contrast, health psychology developed around a much broader and more interdisciplinary approach to health, one that is often termed the biopsychosocial model.

The biopsychosocial model (a term first formally proposed by George Engel in 1968) brings together core elements of staying healthy and recovering well from injury or disease (Stone et al., 1987). Each individual—due to a combination of biological influences and psychosocial experiences—is more or less likely to thrive. Some of this variation is due to genetics and early life development; some depends on the availability and appropriate applications of medical treatments; some involves nutrition and physical activity; some depends on preparations for, perceptions of, and reactions to life's challenges; and some involves exposure to or seeking out of healthier or unhealthier environments, both physically and socially. When presented in this way, it might seem obvious that health should certainly be viewed in this broader interdisciplinary way. However, by misdirecting its vast expenditures on health care, the United States gives its residents mediocre health at high cost (Kaplan, 2019). To approach these matters in a thorough manner, this encyclopedia includes four volumes, with Volume 1 focusing on the biological bases of health and health behavior, Volume 2 concentrating on the social bases, Volume 3 centering around the psychological and clinical aspects, and Volume 4 focused more broadly on crosscutting and applied matters.

Key parts of health depend on biological characteristics and how they interact with our experiences and environments. So, for example, in Volume 1, there are articles on injury to the brain, alcohol effects on the brain, nutrition, drug abuse, psychophysiology, and the tools and key findings of neuroscience. Note that even individuals with the same genes (identical twins) can and do have different health and recovery outcomes, and the articles delve into such complexities of health. Of course humans are also social creatures, and people's growth, development, and health behaviors take place in social contexts. So, in Volume 2, there are articles on such fundamental matters as social support, coping, spirituality, emotion, discrimination, communication, psychosocial stress, and bereavement.

Because our approaches to and conceptions of health are heavily influenced by society's institutions and structures revolving around medical care, much of health psychology derives from or intersects with clinical psychology and applied behavioral medicine. Volume 3 covers such clinical topics as psycho-oncology, depression, drug abuse, chronic disease, eating disorders, and the psychosocial aspects of coronary heart disease. Finally and importantly, there are a number of special and cross-cutting matters that are considered in Volume 4, ranging from relevant laws and regulations to telehealth and health disparities. Taken together, the articles triangulate on what it truly means to be healthy.

What are the most promising directions for the future that emerge from a broad and deep approach to health? That is, to where do these encyclopedia articles point? One key clue arises from a unique opportunity to enhance, extend, and analyze the classic Terman study of children who were followed and studied throughout their lives (Friedman & Martin, 2012). These studies revealed that there are lifelong trajectories to health, thriving, and longevity. Although anyone can encounter bad luck, a number of basic patterns emerged that are more likely to lead to good health. That is, for some individuals, certain earlier life characteristics and circumstances help propel them on *pathways* of healthier and healthier behaviors, reactions, relationships, and experiences, while others instead face a series of contingent stumbling blocks. There are multipart but nonrandom pathways across time linking personalities, health behaviors, social groups, education, work environments, and health and longevity. The present encyclopedia necessarily is a compendium of summaries of the relevant elements of health and thriving, but one that would and can profitably be used as a base to synthesize the long-term interdependent aspects of health.

In sum, this encyclopedia is distinctive in its explicit embrace of the biopsychosocial approach to health, not through lip service or hand-waving but rather through highly detailed and extensive consideration of the many dozens of topics crucial to this core interdisciplinary understanding.

Preface

The field of health psychology is a specialty area that draws on how biology, psychology, behavior, and social factors influence health and illness. Despite the fact that the formal recognition of the field is only about a half of a century old, it has established itself as a major scientific and clinical discipline. The primary reason for this is that there have been a number of significant advances in psychological, medical, and physiological research that have changed the way we think about health, wellness, and illness. However, this is only the tip of the iceberg.

We have the field of health psychology to thank for much of the progress seen across our current healthcare system. Let me provide some examples that illustrate the diversity of these important contributions. Starting with a broad public health perspective, health psychologists have been involved in how our communities are planned and how urban development has a significant and direct impact on our health behaviors. That is, if we live close to where we work, play, and shop, we are more likely to walk or bike to our destination rather than drive or take public transportation. Focusing on a smaller, but no less important, source of data, health psychologists are involved in using information obtained from our genes to help counsel individuals to make good, well-informed health decisions that could have an impact on the individual immediately or in the future. Being well-informed can direct a person toward the best possible path toward wellness, whether it be measures aimed at prevention, further monitoring, or intervention.

Of course, there are many other contributions. For instance, data indicates that several of the leading causes of death in our society can be prevented or delayed (e.g., heart disease, respiratory disease, cerebrovascular disease, and diabetes) via active participation in psychological interventions. Knowing that we can improve health status by changing our behaviors seems like an easy "fix," but we know that behavior change is tough. As such, it is not surprising that health psychologists have been involved in trying to improve upon treatment success by examining patient compliance. When we better understand what motivates and discourages people from engaging in treatment or pro-health behaviors, we can improve upon compliance and help individuals adopt more healthy lifestyles. Health psychologists have also played a role in shaping healthcare policy via identifying evidence-based treatments. This work has direct effects on how individuals receive healthcare as well as what treatments are available/reimbursable by insurance companies. Finally, there are also factors beyond medical care to consider (e.g., economic, educational) that can lead to differential health outcomes. Thus, health psychologists likewise examine ways to reduce health disparities, ensuring that the public and government officials are made aware of the impact of the social determinants of health.

I could go on and on, however, examples like this illustrate the significant impact this broad and exciting field has had (and will continue to have) on our understanding of health and wellness. Given the constantly changing nature of the field, it is not possible to be all inclusive; however, the aim of these four volumes is to provide readers an up-to-date overview of the field. Each entry is written to stand alone for those who wish to learn about a specific topic, and if the reader is left wanting more, suggested readings are provided to expand one's knowledge. Volume I, *Biological Bases of Health Behavior,* includes entries that cover topics in the broad areas of neuroscience and biopsychology relevant to health behavior. General topics include degenerative and developmental conditions, emerging methodologies available in clinical research, functional anatomy and imaging, and gene × environment interactions. Volume II, *Social Bases of Health Behavior,* addresses topics related to theories and concepts derived from social psychology. Specifically, topics related to the self, social cognition, social perception, attitudes and attitude change, perception, framing, and pro-health behaviors are included. Volume III, *Clinical Health Psychology and Behavioral Medicine,* covers the applied aspects of the field of health psychology including practical topics that clinical health psychologists face in the workplace, behavioral aspects of medical conditions, the impact of unhealthy behaviors, and issues related to the comorbidity of psychiatric disorders and chronic health concerns. Finally, Volume IV, *Special Issues in Health Psychology,* contains a wide array of topics that are worthy of special consideration in the field. Philosophical and conceptual issues are discussed, along with new approaches in delivering treatment and matters to consider when working with diverse and protected populations.

It is my sincere hope that the *Wiley Encyclopedia of Health Psychology* will serve as a comprehensive resource for academic and applied psychologists, other health care professionals interested in the relationship of psychological and physical well-being, and students across the health professions. I would very much like to thank and acknowledge all those who have made this work possible including Michelle McFadden, the Wiley editorial and production teams, the volume editors, and of course all of the authors who contributed their outstanding work.

Lee M. Cohen, PhD

Preface Volume 4: Special Issues in Health Psychology

Special issues, by definition, are an evolving target, especially in a topic area as fluid and diverse as health psychology. When we began this volume some three summers ago (June 2016), a cursory overview of peer-reviewed journal articles in health psychology journals reveals multiple topics: assessment techniques, education of providers, populations and subpopulations, new and evolving diseases, new treatments, environmental changes, systemic changes, and of course the repackaging of older, more established interventions to any of the preceding "special issues." Where health psychology seeks to understand the role of behavior and perhaps cognition and behavior in the health of individuals, groups, nations, and humanity writ large, a volume of special issues could range from the molecular to the near universal.

In the present volume, we assembled 26 entries, each drafted by content experts in the special issue addressed. Every effort was made to ensure that each entry is evidence-based yet accessible to the most junior student of health psychology. The goal of this volume is to address at least a bit of each category foreseeably concerning health psychologists in the first two decades of the twenty-first century. To that end, we have three entries on assessment, two entries regarding education of providers, three entries on subpopulations, three entries on new or evolving diseases, six entries on treatments, and eight entries on environmental and systemic/cultural change. No doubt, as we go to press, newer and potentially more expansive knowledge will come to the fore, and each of our authors will wish that they had more time or more space to tell us about the latest information relevant to the health of humanity. To the wishful rewriters, I imagine that another opportunity will present itself.

In the meantime, I am indebted to the many authors that took time from busy schedules to draft the entries contained herein. Even for the fortunate few that write as easily as they breathe, these chapters are a labor of love. To synthesize one's lifework and academic passion to a few cogent paragraphs of use to the novice and the expert alike is no small feat. I am also indebted to Ms. Alexia Maness, whose Herculean effort involved mastering multiple software changes while wrangling time zones and mixed messages across continents. Without her consistent good cheer, we would not have a volume for which to write a preface!

A resounding thank you to all.

Suzy Bird Gulliver

Editor-in-Chief Acknowledgments

I would like to publicly recognize and thank my family, Michelle, Ross, Rachel, and Becca for being supportive of my work life while also providing me with a family life beyond my wildest dreams. I love you all very much. I would also like to note my great appreciation and thanks to the faculty and staff of the Doctoral Training Program in Clinical Psychology at Oklahoma State University for providing me with an opportunity to expand my education and for providing extraordinary training. In particular, I would like to thank my late mentor Dr. Frank L. Collins Jr., Dr. Larry Mullins, Dr. John Chaney, and Patricia Diaz Alexander. Further, I am grateful to the University of Mississippi and Texas Tech University (and the colleagues and students I have had the privilege to work alongside) for affording me excellent working environments and the support to do the work I am honored to be a part of. Finally, I would like to recognize and thank the volume editors for their vision and perseverance to this project as well as to each of the contributors for their excellent entries and their dedication to this very important field.

Overview

At the outset, it should be noted that the term *biopsychosocial model* was originally introduced by George Engel (1977, 1980) because he felt that the traditionally embraced biomedical reductionist model in medicine was outdated in light of the newer advances in medicine. He emphasized that modern medicine needed to encompass a more dynamic system approach, which included different levels of organization that included not only factors related to the patient and physician but also other important sociocultural and lifestyle variables in a "systems theory" manner initially introduced in biology by scientists such as Weiss (1969, 1977) and von Bertalanffy (1968, 1969). In terms of the biomedical model, Engel (1980) succinctly noted that: "…The crippling flaw of the model is that it does not include the patient and his attributes as a person, a human being. Yet in everyday works of the physician the prime object of study is a person, and many of the data necessary for hypothesis development and testing are gathered within the framework of an ongoing human relationship and appear in behavioral and psychological forms, namely, how the patient behaves and what he reports about himself and his life. The biomedical model can make provision neither for the person as a whole nor for data of a psychological or social nature, for the reductionism and mind-body dualism in which the model is predicated requires that these must first be reduced to physico-chemical terms before they have any meaning…" (p. 536).

It should also be noted that Minotti, Licciardone, Kearns, and Gatchel (2010) have indicated how osteopathic medicine actually preceded traditional allopathic medicine in embracing the biopsychosocial model approach to patient care. Indeed, one important tenet of osteopathic medicine is that a patient is composed of body, mind, and spirit, and one needs to

First Edition. General Editor: Lee M. Cohen. Volume Editor: Suzy Bird Gulliver.

treat all three of components of the "whole person" in a holistic manner (Seffinger et al., 2011). Such a holistic approach involves the integration of physical structure, function, emotion, and social factors in order to achieve healing and health. "Knowing the whole person" is of paramount importance in the osteopathic approach, as it is in the biopsychosocial model. Thus, as will be reviewed in the next section, physical disorders (such as pain) are the result of the dynamic interaction among physiological (*bio*), psychological (*psycho*), and social (*social*) factors (i.e., *biopsychosocial*) that often perpetuate and may worsen the clinical symptom presentation of patients, as well as accounting for the individual differences across patients.

Unfortunately, this new *biopsychosocial model* conceptualization of illness was not immediately embraced by the general allopathic medical community. This may have been due to the fact that Engel was a psychiatrist, with psychiatry being at the "bottom of the ladder" in terms of medical specialties at that point in time. Fortunately, however, a synergy of events was occurring in the fields of pain medicine and behavioral medicine/health psychology that made the *biopsychosocial model* very attractive for many clinical researchers interested in the assessment of treatment of chronic pain. Below is a brief listing of how this synergy developed:

- Beecher (1959) highlighted the important role that conditioning played in patients' experiences of pain and helped to further advances the idea that the biomedical model of pain was too limited.
- Melzack and Wall (1965) introduced the *gate control theory of pain*, which emphasized the important effects of emotion and cognitive factors in the experience of pain. Subsequently, Melzack and Casey (1968) extended the model further by introducing the *neuromatrix theory of pain*, which again emphasized the need to incorporate cognitive and motivational–affective components in order to better understand pain.
- Loeser (1982) proposed a general model of pain that included four dimensions: physical nociception, the subjective perception of pain due to the nociception, suffering or the emotional responses that are triggered by nociception or some other negative event associated with it (such as fear and anxiety), and pain behaviors, which are things that pain sufferers do, such as avoiding activities of daily living or work because of fear of reinjury or the further exacerbation of pain.
- The pioneering work by Fordyce and colleagues (Fordyce, Fowler, Lehmann, & DeLateur, 1968; Fordyce & Steger, 1979) successfully applied behavioral psychological principles (such as operant conditioning) to the treatment of chronic pain.

Ever since the above contributions to the study of pain, the *biopsychosocial model* has become the most heuristic approach to the assessment, treatment, and prevention of chronic pain (e.g., Gatchel, Peng, Peters, Fuchs & Turk, 2007; Turk & Monarch, 2002), as will be reviewed next.

The Biopsychosocial Model of Chronic Pain

Indeed, the acceptance of the *biopsychosocial model* is increasingly important in order to recognize the comorbidity of chronic pain and other persistent diseases. Fortunately, this model has consistently led to a better understanding of the considerably complex interactive process among components. In the context of pain, the *biopsychosocial model* approaches it as a consequence of the dynamic interaction among biological, psychosocial, and social components. This interaction perpetuates and may even worsen the clinical presentation of pain. Many other clinical researchers have also emphasized the importance of this model (e.g., Feinberg & Brigham, 2013; Gatchel, McGeary, McGeary, & Lippe, 2014; Turk & Monarch, 2002). In addition, Gatchel (2004) examined the amplified measures of emotional suffering and psychopathology that disrupted effective treatment of patients with chronic pain. Furthermore, the degree of pain experienced by a patient depends on genetic factors, prior knowledge of pain, overall psychosocial well-being, and sociocultural variables (Gatchel et al., 2007). This resulting well-balanced *biopsychosocial model* has shown exceptional utility in chronic illness diagnosis and management. Unlike the framework of the biomedical model, the *biopsychosocial model* emphasizes the importance of the human experience of illness, in addition to the laboratory documentation that represents disease potential by providing a framework of a hierarchy that illustrates the interrelationships of a patient's psychosocial environment to their biological systems, as originally suggested by Engel (1980).

As noted above, the traditional biomedical reductionist model has been insufficient in capturing all of the aspects that are needed in order to appropriately diagnose and treat a patient living with chronic pain. Since the designation of 2001–2010 as being the "Decade of Pain Control and Research" by Congress, there have been other initiatives launched to address the growing problem of chronic pain. For example, chronic pain was highlighted as an important area for future research in the Institute of Medicine's report titled "Living Well and Chronic Illness: A Call for Action" (Institute of Medicine, 2012).

This was because chronic pain is becoming the most prevalent illness among Americans today. Nahin (2015) reported that 25.3 million Americans suffer from consistent daily pain, and 23.4 million Americans report "a lot of pain." The Center for Disease Control and the National Center for Health Statistics (2015) also reported that 15.6% of Americans over the age of 18 reported experiencing a consistent severe headache or migraine, 29% reported consistent low back pain, and 14.9% reported consistent neck pain. In addition, pain accounts for approximately 80% of all doctors' visits, with medical treatment and lost productivity due to pain costing approximately $625 billion annually (Gatchel, 2004; Institute of Medicine of the National Academy of Science, 2011).

Although, up until this point, we have been discussing the great utility of the *biopsychosocial model* for effectively evaluating and managing chronic pain, it is also a heuristic approach for dealing with chronic illnesses in general. This is because there is a close comorbidity of mental and physical disorders (Gatchel, 2004). Most chronic illnesses are accompanied by psychosocial factors (such as anxiety, depression, and anger), as well as cognitive distortions (such as fear avoidance, dysfunctional attitudes and beliefs, and distorted expectations). Fortunately, there are now psychometrically sound tests to measure these psychosocial factors (e.g., Gatchel, 2005). In addition, medical technology has advanced over the years to better evaluate possible biological or pathophysiological underpinnings of these illnesses (e.g., with the use of functional magnetic resonance imaging). However, despite the many improvements in technology and the better understanding of biopsychosocial processes, there are still future advances that will need to be made (e.g., Suls, Krantz, & Williams, 2013).

Beyond the Biopsychosocial Model

With growing research in neuroscience and genetics, the significance of a *diathesis–stress component* to the biopsychosocial model must be acknowledged. This new *diathesis–stress biopsychosocial model* places an additional emphasis that predispositional factors interact with stressors such as health problems/illnesses. Once an illness is established, it becomes a stressor in its own right (Gatchel, 2005). Gatchel (2005) also pointed out that Melzack's (1999) *neuromatrix theory* of pain can be viewed as incorporating a *diathesis–stress model* component to it. Such a *diathesis–stress* component, originally promoted by Levi (1974), assumed that individuals are predisposed toward a specific disorder and manifest that disorder when negatively affected by stress. In other words, the degree/complexity of the interaction among biological, psychological, and social factors often depends on certain *diatheses* that people have when exposed to stressors such as an illness (especially if it is chronic in nature). For example, as illustrated in Figure 1, individuals "bring with them" certain diatheses or predispositions, such as certain candidate genes. In the case of chronic pain, examples of such candidate genes are neurotransmitter transporter, serotonin, solute carrier family (5-HTT), catechol-O-methyltransferase (COMT), interleukin 6 (IL-6), and μ-opioid receptor (OPRM). Also, for such candidate genes, the growing field of *epigenetics* has started to elucidate how these genes can be ultimately expressed as behavioral phenotypes (e.g., Belfer & Diatchenko, 2014; Biemont, 2010). Environmental factors, such as stress, can also alter their phenotypic expression and can have long-lasting effects on health and behavior (Hunter, 2012). One mechanism involved in the epigenetics process is the shortening of *telomeres* that help protect chromosomes. If they become too short, or are totally decimated by environmental stress factors, the chromosome becomes more vulnerable to possible mutation (Sibille, Witek-Janusek, Mathews, & Fillingim, 2012).

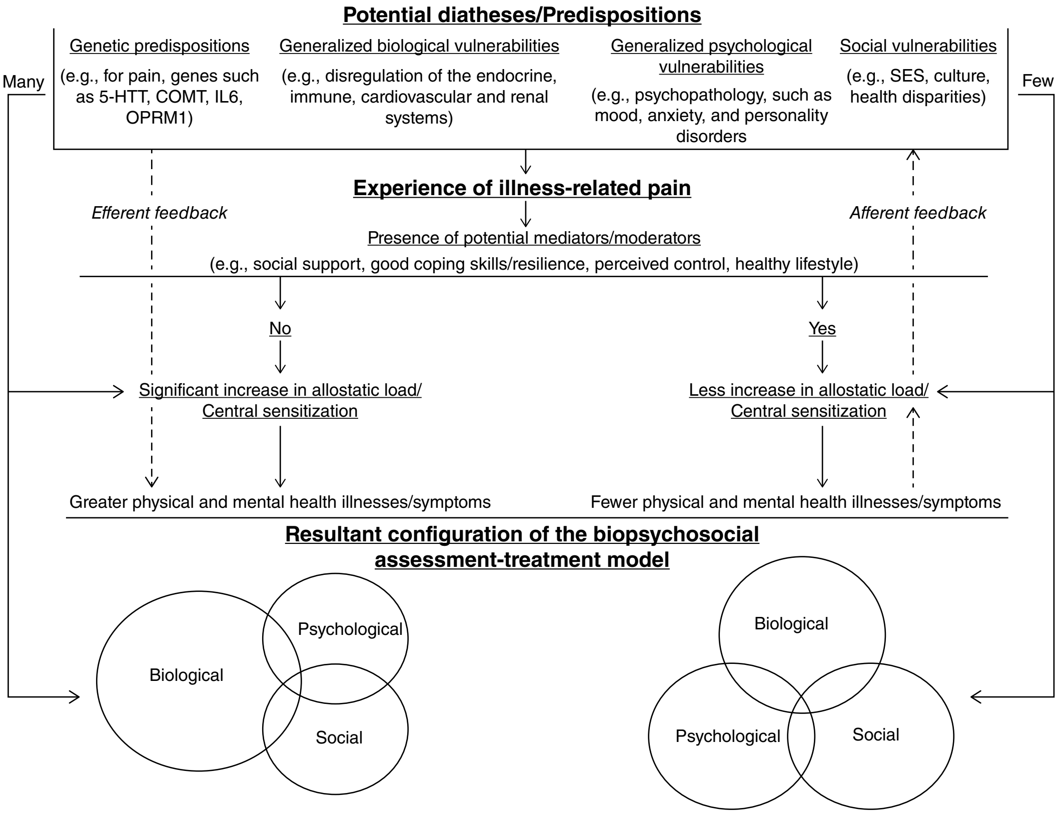

Figure 1 The diathesis–stress biopsychosocial model of chronic illness.

There are additional potential biological factors (e.g., dysregulation of the endocrine, immune, and cardiovascular systems), psychological factors (e.g., psychopathology, such as mood, anxiety, and personality disorders), and social vulnerabilities (e.g., SES, culture and health disparities) that may affect a person's ultimate experience of an illness. In turn, the probability of this illness to become chronic may be lessened by the presence of potential mediators/moderators (such as social support, coping skills, etc.). If mediators or moderators are absent, then they cannot "buffer" the individual from the full impact of the illness. In the event that pain is associated with the illness, *central sensitization* (CS) may result (a term introduced by Yunus, 2007 to refer to an abnormal and intensified experience of pain by mechanisms such as hyperexcitability in the central nervous system). This CS is postulated to underpin central sensitivity syndromes (CSSs) such as fibromyalgia, TMJ disorders, irritable bowel syndrome, and other persistent pain disorders (Adams & Turk, 2015; Mayer et al., 2012; Woolf, 2011; Yunus, 2000). In addition, the lack of effective mediators/moderators may lead to significant increase in the *allostatic load* of the patient (a term originally introduce by McEwen (2000)). Allostatic load refers to the significant decrease in body homeostasis due to the chronic exposure to the stress or trauma of an illness. Neuroendocrine-immune mechanisms, for example, can be negatively affected and result in greater "wear and tear of the body" (thus accelerating the development of diseases such as cardiovascular disorders, as well as psychoneuroendocrinology disorders).

The above will have implications for the mental and physical health status of the patient and may affect the resultant configuration of the biopsychosocial response pattern displayed. This type of configuration, in turn, will determine how complex the assessment–treatment process will need to be for each individual patient. The higher confluence of genetic and biological predispositions may necessitate greater attention to those components of the biopsychosocial interactions (see bottom left configuration in Figure 1). Without doubt, though, a comprehensive interdisciplinary assessment–treatment approach will need to be administered to patients.

Summary and Conclusions

The present chapter provided a comprehensive review of the heuristic value of the *biopsychosocial model* in better understanding health and illness. George Engel (1977, 1980) was the first to introduce the model because of his dissatisfaction of the traditionally embraced biomedical reductionist approach to illnesses that attempted to reduce all illnesses to only physiological/biochemical underpinnings, with the complete exclusion of potentially important psychosocial factors. Unfortunately, this new *biopsychosocial model* was not accepted in the general medical community. However, as we discussed, a synergy of events was occurring in the fields of pain medicine and behavioral medicine/health psychology that made this new model extremely attractive to clinical researchers involved in the assessment and management of chronic pain.

A more detailed discussion of the *biopsychosocial model* of chronic pain was next presented. In doing so, the epidemiology and high costs of this prevalent disorder was presented, as well as the various biopsychosocial components associated with it. It was also noted that the *biopsychosocial model* is generalizable to chronic illnesses in general. Additional advancements in the field, though, are still needed, especially with the development of new technologies that can more reliably evaluate the *bio* component of the model.

Finally, a *diathesis–stress biopsychosocial model* was introduced for an even better understanding of health and illness. The *diathesis–stress* component was originally proposed by Levi (1974). Levi suggested that individuals are predisposed toward specific disorders and will manifest those disorders when negatively affected by stress. In the conceptual model we propose (see Figure 1), it is assumed that patients "bring with them" specific diatheses or predispositions, such as genetic factors, as well as potential biological and psychosocial vulnerabilities that may affect a patient's ultimate expression of an illness. Obviously, the construct validity of this new model will need to be determined by future research efforts.

Author Biographies

Robert J. Gatchel—Robert J. Gatchel, PhD, ABPP, is a professor in the Department of Psychology, College of Science, at the University of Texas at Arlington and a clinical research program consultant at the Eugene McDermott Center for Pain Management at the University of Texas Southwestern Medical Center at Dallas. He is the director of the Center of Excellence for the Study of Health and Chronic Illness at the University of Texas at Arlington, as well as director of Biopsychosocial Research in Osteopathic Research Center at the University of North Texas Health Science Center.

Christopher T. Ray—Ray holds a doctorate degree in movement studies from the University of Georgia and earned both a master's (in human performance and sport studies) and bachelor's degree (in exercise science) from the University of Tennessee, Knoxville. His postdoctoral fellowship work was at the Veterans Administration Medical Center in Atlanta, which included a summer institute in epidemiology and biostatistics at the University of Washington. His research involves kinesiology and geriatric health.

Nancy Kishino—Nancy Kishino, OTR/L, CVE, is the director and founder of West Coast Spine Restoration Center. She is a licensed and registered occupational therapist.

Athena Brindle—Athena attended the University of Texas at Arlington and is now a candidate for a Doctor of Pharmacy at Texas Tech University Health Sciences Center.

Death and Dying

David E. Balk

Department of Health and Nutrition Sciences, Brooklyn College of the City University of New York, Brooklyn, NY, USA

The dying trajectories and principal causes of death in the United States—and in other developed countries, for instance, Canada, Germany, and Japan—have changed dramatically over the past century. Whereas a typical dying trajectory in the early twentieth century was sudden and unexpected death due to a fatal, infectious disease or accident, the process of dying has become principally a lingering, drawn-out trajectory involving a series of chronic, debilitating conditions. The principal causes of death have become heart disease, malignant neoplasms, and circulatory problems.

A major factor that has produced these changes in dying trajectories and causes of death is the triumph of the biomedical model. Other influences have come from advances in the production and protection of food, success in insuring clean water, architectural and engineering triumphs (buildings with better heating and cooling, for instance), and public health campaigns educating communities about healthy and unhealthy behaviors.

The biomedical model became the framework organizing medical school curriculum and defining good medical practices. This model looks for biological and chemical reasons to explain disease. Disease is defined as physical deviations from established norms. The body is seen as a complicated, highly organized set of interrelated physical systems. The fundamental goal is to maintain life, and death is the enemy to resist at all costs.

The triumph of the biomedical model is no doubt due to its success in producing new knowledge and in overcoming previously fatal diseases. In consort with better hygiene and nutrition, the biomedical model helped increase longevity in the United States from an average of 47 years of age in 1910 to a lifespan exceeding 78 years today; whereas in the early twentieth century over 53% of all deaths in the United States occurred to persons 14 years of age and younger, the conquering of infectious diseases has made childhood mortality very uncommon.

As a conceptual framework the biomedical model became the paradigm for medical education and medical practice. The biomedical model has gained widespread cultural acceptance in developed countries. On the whole, most persons in developed countries in the

twenty-first century view life, health, disease, and death from within the assumptive world of the biomedical model.

A clear upshot of the success of the biomedical model is that American society now has large numbers of individuals living significantly beyond their 60s and developing the many infirmities endemic to aging bodies and minds. Concomitant with many progressive infirmities is the presence of functional limitation, such as difficulty walking, stooping, or swallowing. Of the nearly 328 million persons in the United States, 14% (nearly 46 million) have both chronic, debilitating conditions and functional limitations, and this 14% accrues over 56% of all healthcare costs incurred in the United States. These figures will only increase as the aging population continues to grow. In many cases, these persons form a new societal phenomenon, the "frail elderly," persons living into their 80s and 90s. In other eras these frail elderly would have died without the life-prolonging technologies used today. And what is of considerable concern is when life-prolonging technologies produce a continuation of life bereft of quality. Increasing apprehension has emerged over medical interventions to keep persons alive but helpless, incontinent, lacking dignity, connected to all sorts of instruments, and in pain.

Faced with the strong possibility that heroic efforts will be exerted to keep people alive despite their preference to die rather than remain helpless and very possibly in pain, various kinds of written directives have been devised to enable individuals to decline such efforts ahead of time. These written documents are termed advance directives.

An advance directive is a legal document that permits competent adults to state their preferences prior to a medical emergency or some other life-threatening situation. There are four forms of such directives: do not resuscitate orders (DNR), living wills, healthcare power of attorney (HCPOA), and physician orders for life-sustaining treatment (POLST).

DNRs are medical orders explicitly stating that the patient has rejected use of cardiopulmonary resuscitation should he (she) go into cardiac arrest. DNRs are written for medical staff to follow, are placed prominently in the patient's chart, and denote the explicit preferences of the patient (or of the patient's surrogate holding HCPOA).

Living wills provide the means for mentally competent adults to express preferences regarding the use of specified medical interventions should the person's wishes be otherwise impossible to determine; an example would be if the person is in a coma. This type of advance directive is grounded in the right of mentally competent adults to refuse medical treatment. Living wills have gained legal status in each state of the United States and in the District of Columbia. However, specific provisions may differ from state to state regarding what a living will must contain to be legal.

Healthcare power of attorney, sometimes called durable power of attorney or healthcare proxy, offers an alternative to a living will. With HCPOA an individual empowers someone else to make healthcare decisions for the individual if the person is incapable to make such decisions.

POLST is an advance directive a person writes in collaboration with her (his) physician. The POLST makes individual preferences into actionable medical orders signed by the physician and the patient. Reviews of compliance indicate POLSTs are followed more consistently than living wills.

Attitudes toward use of advance directives vary considerably across different ethnic and racial groups in the United States, and these group differences underscore the communication challenges facing health psychologists working with persons from diverse backgrounds. When examining these group differences, it is prudent to recall that individual differences within a group can be as varied as differences between groups.

Advance directives are grounded in respect for the autonomy of the individual and in belief that promoting individual autonomy is a preferred value. Various ethnic groups place greater importance on familial support and guidance than on individual autonomy, and paternalistic decision making is the norm.

Advance care planning is observed more commonly in the United States among European Americans than among African, Hispanic, and Asian American groups. As examples, African Americans on the whole are much less likely than European Americans to complete advance directives. A history of discrimination from the majority White culture and documented cases of medical neglect as well as abuse (consider the infamous Tuskegee syphilis study) lead many African Americans to suspect that signing an advance directive gives the medical establishment a blank check to deny them treatment.

Researchers have studied Hispanic beliefs and intentions regarding end-of-life matters less than those of other ethnic minority groups. One common phenomenon that has emerged, however, is that the family holds a place of primacy among Hispanics and that the decisions of an elderly male possess prominence. While individual Hispanics have told researchers they would want care focused on relieving pain if seriously ill, they had not discussed these matters with family members. At the same time, despite never having voiced these views with their family, these respondents also indicated they wanted their families to be involved in end-of-life decision making. It is not difficult to see the challenges facing health psychologists to find ways to cut through the barriers presented by a hesitancy to discuss wishes and yet wanting family members to be involved in end-of-life decision making.

Asian Americans value saving face and regulating emotions, and this desire to avoid shame and to protect loved ones from shame may lead family members to insist that information about a terminal illness be kept from the patient. Research with groups of Asian patients suggests they are less likely than African American or Hispanic patients to want to learn the life expectancy facing them. The family, particularly a male figure, holds importance when critical decisions are to be made.

The realities that many persons die in a lingering, pain-filled trajectory filled with intrusive medical procedures—procedures that extend length of life but diminish quality of life—have inspired efforts to allow terminally ill persons to die a good death. The notion of a good death is a difficult concept with differing meanings contingent on the assumptive world(s) dominant in a society. In some societies, such as Japanese and Navajo, an underlying concern is whether the wrong kind of death will expose the living to vengeance from the deceased. In countries debating physician-assisted suicide, fundamentally opposed answers are given to whether consciously chosen self-termination to end unremitting pain offers a good death. In countries wedded to the biomedical model, ethicists and physicians are asking whether the healthcare system carries obligations to foster a good death when persons are nonresponsive to treatment and whether resources need to be rationed differently in end-of-life situations.

In twenty-first century Westernized secular societies a good death refers to the process of dying. The emphasis is on how a person's life ends, not on consequences in an afterlife. Emphasis is on several humanistic factors: to be free of distressing symptoms, to be free of pain, to be conscious, to be with loved ones, to be in familiar surroundings, and to be able to take care of oneself.

Consistent answers are given when persons are asked to identify their wishes regarding dying. They want to die free of pain, surrounded by loved ones, and preferably in familiar surroundings. An overwhelming majority of persons dying from a terminal illness, however, experience distressing symptoms such as nausea and vomiting; feel intense, unremitting pain, helpless, and hopeless; are hooked up to machines; undergo invasive, painful procedures; and are surrounded by strangers in a medical or other institutional setting.

A counterforce to keeping terminally ill persons alive at all costs has been the hospice movement. Inspired by pioneering work in England, American hospice programs began in 1974 and now are present in every state. These programs take a holistic view of human existence. A holistic view is a thread connecting much contemporary thought about and work with persons facing the end of life.

Evaluation evidence has demonstrated noticeable family satisfaction with hospice vis-à-vis other forms of care for the dying. Further, evaluators have found significantly decreased costs for persons in hospice in contrast with matched controls; the decreased costs amounted to over $2,300 a year. However, concerns have been raised over the projected costs to be incurred with the increasing numbers of frail elderly who will develop cancer or other debilitating terminal illnesses.

To receive federal funding, American hospice programs must admit persons only if they are diagnosed as having 6 months or less to live and if they forego curative treatment. Hospice efforts are exerted to prevent and manage all pain so that the individual and his (her) family may experience a good death. The practice and the policy are not to keep the terminally ill person alive at all costs.

The hospice movement has been instrumental in holding forth that a good death is possible. First and foremost, hospice understands that the dying person is primarily a living human being. Second, the patient in hospice care is the terminally ill person and the family. Further, hospice promotes quality of life by focusing on six fundamental dimensions of human existence: the physical, the behavioral, the emotional, the cognitive, the interpersonal, and the spiritual/existential. Uncontrollable, unremitting, agonizing pain prevents persons from dying on their own terms, from dying with dignity, and from attending to the many aspects that make existence worthwhile.

Two useful frameworks on coping with a terminal illness have been proposed (Corr, 1992; Doka, 2013). One framework reviews various holistic tasks facing a dying person, the family, and caregivers; the other looks at changes that occur over time once a diagnosis of terminal illness has been learned.

The holistic tasks address physical, behavioral, cognitive, interpersonal, emotional, and spiritual dimensions of existence. Looking at a few of these tasks, consider that a terminally ill person may need help with such physical and behavioral tasks as washing, getting into and out of bed, using the toilet, swallowing, sleeping, and coping with the all-encompassing issue of excruciating pain that affects all dimensions of being alive. Chemotherapy may impair a person's cognitive capacities. Spiritual tasks center on the virtue of hope and on the viability of the person's assumptive world in the face of death from a terminal illness.

The second framework for coping entails responses of ill individuals, family members, and caregivers over time once a diagnosis is learned. Persons move from a pre-diagnostic phase through treatment and then the possibilities of remission, relapse, recovery, and dying. The holistic tasks mentioned above are carried out within these various phases once the diagnosis is learned.

Adopting a holistic perspective could be interpreted as an act of defiance in the face of the technique-driven biomedical model. Holism's roots in existential phenomenology place it in opposition to a positivistic approach to life and to the allure of techniques over mindfulness. Yet, such an interpretation would be incomplete: attending to the cares and the suffering of a terminally ill person and that person's family may well draw on methods and protocols inherent to best practices in biomedical science; a proper dosage of morphine may be exactly what the person needs. Awareness that humans have devised effective means to ameliorate physical suffering can increase hope. Quality care, yet, also recognizes that the dying person is more than the sum of his (her) physical systems, death is not simply a medical phenomenon, and the person will not be reduced to biological or chemical systems that the biomedical model treats very well. The Institute of Medicine (IOM) took a forceful stand on the place of a good death in medical practice. The IOM wrote (1997, p. 5):

> People should be able to expect and achieve a decent or good death – one that is free from avoidable distress and suffering for patients, families, and caregivers; (one that is) in general accord with patients' and families' wishes; and (one that is) reasonably consistent with clinical, cultural, and ethical standards.

Note the main topics in this IOM statement.

1 Achieving a good death is made a norm of medical practice.
2 There is explicit mention of preventing distress and suffering.
3 The stakeholders include more than the person who is dying. A good death will free patients, family members, and caregivers from distress and suffering.
4 The wishes of the patient and of the family will be followed.
5 Accepted clinical standards will be followed, as will cultural and ethical standards.

The IOM document was distributed shortly after publication of the SUPPORT study (1995), a very disappointing longitudinal intervention to improve end-of-life care at five teaching hospitals in the United States. The first year of the study focused on gathering data on staff understanding of patients' end-of-life preferences, medical decision making relevant to terminally ill persons, and medical interventions employed with terminally ill persons. The second year of the study provided each hospital a medical expert trained to consult with the medical teams on four objectives:

1 Staff would know terminally ill patients' end-of-life preferences.
2 Nurses and doctors would employ better pain control procedures.
3 Physician–patient communication would improve.
4 Outcomes would be patient oriented.

None of the objectives was achieved. An alarming finding from the SUPPORT study was that in nearly a third of cases physicians did not know their patients' DNR preferences and in at best 50% of the cases spouses were aware of these DNR preferences. It is not unreasonable to surmise that the 1997 IOM study, at least in part, was a direct response to the very disappointing outcomes regarding prospects for quality end-of-life care that the SUPPORT study had disclosed.

Looking back on the SUPPORT objectives, one can readily infer—based on the success of hospice—steps that may be taken within hospitals to accomplish what the SUPPORT intervention set out to do. Efforts to implement more circumscribed pain management systems have met with resistance in some US hospitals, so rosy-colored expectations of easy success to accomplish the SUPPORT objectives are naïve. However, given those qualifiers about resistance to change, there are some objectives to consider. As examples, in order for staff to know the end-of-life preferences of terminally ill persons, education about working with the dying needs to become holistic, not merely biomedical. Further, integrating hospital teams with professionals alert to the social, emotional, and spiritual realities of dying persons would be a means to address the SUPPORT objective of attending to better pain procedures and of improving patient–staff communication.

The 1997 IOM report made several recommendations in order that a good death would become the norm of medical practice. Three of the recommendations focused on (a) expectations about excellent care at the end of life, (b) commitment from all healthcare professionals to gain and use the best practices and knowledge to care for the dying, and (c) education of health psychologists that would give importance to care for the dying. In 2014 the IOM reviewed their recommendations and concluded that gains had been made and gaps remain (Institute of Medicine, 2014):

1. Expectations about excellent care. Among gains have been noticeable increases in the percentage of terminally ill persons who received at least 3 days of hospice care; an ideal would be to increase involvement with hospice to at least 2 months given the evidence of the benefits to the terminally ill person and long-term benefits to the family following the death. In addition, numerous pilot programs implemented to demonstrate quality end-of-life care produced not only new care delivery models but also several pilot programs made hospice care accessible in rural areas previously underserved or not served at all.

   Gaps identified include the lack of palliative care services in at least one-third of US hospitals. While palliative medicine has become a board-certified specialty, accreditation standards for hospitals and nursing homes in the United States do not require the provision of quality palliative care.
2. Commitment from all healthcare professionals to gain and use the best practices and knowledge for caring for the dying. The chief success reported is the significant increase in palliative care teams within hospital and medical centers. Between 2000 and 2012 the number of these teams increased dramatically from 600 to 1,600.
3. Gaps still needing attention include a continuing neglect in preventing and managing pain, particularly for patients nearing death. More attention needs to be paid to what healthcare professionals know about taking care of persons near the end of life.

   Education of healthcare professionals must give importance to caring for the dying. Several training programs are now producing annually about 230 new physicians specializing in palliative medicine. Nursing programs are required to prepare students for end-of-life and palliative care situations. More than 2,000 individuals have been educated via the Education on Palliative and End-of-Life Care Project; graduates work to educate physicians and other healthcare professionals on providing quality palliative care.

   Gaps still needing attention include the sparse attention given end-of-life care and virtual neglect of death and dying in medical school curricula. Further, of the 49 accredited schools of public health, only 3 have even one course on end-of-life policy. Analogous to the two IOM reports calling for radical changes in medical care at the end of life, a monograph recently appeared calling for a public health perspective on the end of life. The authors accept that quality care at the end of life is a public health imperative, and they focus on such issues as healthcare inequalities in this country and on the imperative to establish a public health agenda on policy insuring quality end-of-life care.

Seemingly in tandem with the IOM document on a good death, two nonprofit organizations in New York City sponsored a project to examine what is meant by a good death. These organizations were the Commonwealth Fund, a nonprofit interested in health policy, and the Nathan Cummings Foundation, which is devoted to social justice, democracy, and healthcare.

The authors of the Commonwealth–Cummings project (Emanuel & Emanuel, 1998) accept that multidimensionality marks a good death and that a holistic framework needs to be adopted to examine the multidimensional aspects of dying. Their holistic framework differs slightly with the framework used by hospice. The Commonwealth–Cummings framework focuses on six dimensions to human existence, namely, physical symptoms, psychological symptoms (hospice refers to emotional and cognitive), social relationships and support (hospice refers to the interpersonal dimension), economic demands and caregiving (not addressed in the hospice framework), spiritual/existential beliefs, and hopes and expectations (subsumed in the hospice framework under spiritual/existential).

Cicely Saunders, the founder of the modern hospice movement, coined the term "total pain," an idea based on a holistic understanding of human experience and emphasizing distress in such existential dimensions as the physical, the cognitive, the interpersonal, and the spiritual and including refusal to accept one's terminal condition. As seen directly above, the Commonwealth–Cummings project built on this seminal idea of holism and identified six dimensions that come into play when human pain is considered.

The Commonwealth–Cummings authors refer to "total pain" to depict the suffering that blocks a good death. Suffering is considered to consist of two situations: (a) poor conditions in all, or nearly all, of the six holistic dimensions or (b) an overwhelmingly bad experience in two of the dimensions.

The suffering in each dimension is examined:

1 Physical suffering has been studied extensively. By the end of the twentieth century, reliable, valid pain assessment tools were available. Physical suffering also includes such distressing symptoms as fatigue, insomnia, vomiting, and nausea. Pain management experts estimate that in 95% of cases, opioid or adjuvant drugs produce pain relief; however, these experts also estimate that pain remains poorly treated in 20–70% of dying patients. Further, around 5% of cases of physical pain do not respond to drug treatment, and other approaches are tried including acupuncture, hypnosis, and yoga.

2 Psychological symptoms include both cognitions and emotions. The symptoms may include depression, anxiety, and irritability. Some medical staff discount the importance of alleviating psychological symptoms because (a) the staff are not skilled in treating them and/or (b) the staff consider these psychological reactions a normal part of dying. One can see the importance of a multidisciplinary team, as in hospice, to ensure that at the end of life a person's psychological suffering is attended to. Various evidence-based practices are available to assist in alleviating psychological symptoms.

3 Maintaining social relationships is a key adaptive task when coping with life crises. Maintaining links with others not only provides important outlets for emotions but also sources of information, solace, and acceptance. Much more work is needed to determine the kinds of social support dying patients rely on and whether support external to the family helps the person who is dying.

4 The reality of economic demands and caregiver needs at the end of life is a welcome addition to this holistic framework. There are sufficient research data to conclude that caring for a dying loved one imposes significant burdens on families. There can be staggering losses in income; the demands of the disease may induce physical and psychological fatigue. There is a link between severe physical and psychological pain in a patient at the end of life and increases in the caregiving needs that impose economic burdens that leave the family less capable of coping following the death. The concerns over caregiver burnout and complicated grief following the death are well documented. A note of hope has emerged

regarding caregiver needs when caring for a loved one at the end of life: empirical data indicate that early entrance to hospice—2 months or more prior to the death—proves beneficial for family members when later grieving the death.

5 Spiritual/existential beliefs form the category denoting how people find meaning, purpose, and value in their lives. Spirituality is integral to being human whether or not a person is religious. Hospice has recognized the central place of spirituality in the life of a dying person and in the lives of others left to grieve someone's death. Meaning making is at the core of prominent models to explain human responses to bereavement. Persons greatly at risk during times of crisis are those overwhelmed by the conclusion that nothing matters. It is difficult to overestimate the profound difficulty a person experiences when what gave her (his) life meaning has been disclosed to be without substance. One can see this scenario playing out when a death due to a terminal illness—for instance, a young child's—so challenges a parent's assumptive world that drifting into unrelenting, chronic grief becomes the only alternative.

6 Some scholars subsume hopes and expectations under the notion of spiritual/existential beliefs. Further, it is well understood that trauma from major life issues can so truncate a person's hopes and expectations that for all practical purposes the person has no future. For the Commonwealth–Cummings project authors, hope and expectations are a bit more prosaic than the points of view mentioned directly above. Persons at the end of life will remain alive until certain anticipated events have taken place; examples would be anniversaries, birthdays, graduations, and the return of a soldier from a war zone. A concern is that terminally ill patients tend to overestimate their life expectancy and therefore tend to put off advance care planning with family members and physicians.

Medical training should make achieving a good death the standard of care. Such training needs to start with making physicians and medical students comfortable with caring for persons who are dying and competent in caring for the terminally ill. This sort of curriculum objective would mean relaxing the intent of the biomedical model to keep terminally ill patients alive at all costs for as long as possible.

Medical training focused on thanatology could start by educating medical doctors how to talk to persons about dying, just as they are taught to talk with someone about an illness. Some aspects of talking to patients about dying would be how to deliver bad news, talking about spiritual concerns, and giving solace and consolation.

Around the same time as the Commonwealth–Cummings project, authors writing in *The Journal of the American Medical Association* (*JAMA*) gathered information from physicians, terminally ill patients, family members, and other stakeholders about achieving a good death. Karen Steinhauser et al. (2000) conducted a mixed-methods study using focus group interviews and a national survey to identify what people consider preferable at the end of life. The numerous focus groups were composed of physicians, nurses, hospice volunteers, chaplains, and terminally ill patients. The surveys were sent to a comparable list of individuals; out of 2,000 surveys mailed, 1,462 were returned, a phenomenal response rate of 73.1%.

Three main findings were reported:

1 The respondents overwhelmingly agreed on the general importance of being prepared for the end of life and of knowing one's family is prepared. Examples of such advance preparation included completing funeral arrangements and of having a sense when death was likely to occur. All respondents agreed that having time to prepare gives a greater chance for patients, family members, and medical caregivers to experience a good death.

2 Respondents wanted to know the treatment options for and the preferences of the dying person. Family members said it helped immensely to know what the dying person wanted to happen if he (she) were unconscious and unable to make wishes known. For instance, does the person want DNR orders carried out? There are obvious implications in this second finding for the functioning of healthcare proxies.
3 Dying persons wanted time to say goodbye to important persons in their lives. They wanted the chance to complete unfinished business. They wanted the opportunity to talk about the meaning of death with someone willing to listen attentively to their fears about dying. In this third set of findings, there were some stark differences between seriously ill persons and physicians. For instance, being mentally aware, at peace with God, and not a burden on one's family were endorsed by nearly all seriously ill persons, but by less than two-thirds of physicians. The differences in what patients and physicians consider attributes of a good death offer topics for medical education sensitizing physicians about end-of-life communication. Some of the differences may stem from patients' lack of experience with palliative care, such as the overwhelming majority wishing to be mentally aware up to the end; some end-stage cancer pain is so excruciating that only heavy dosages of morphine, which basically keep the person asleep, can alleviate the pain. It seems unlikely that physicians will consider it good use of their time to converse with the patient about being at peace with God or to spend time praying with patients. These topics are typically seen as the province of chaplains and thus the presence of ministers on hospice teams.

While there were some notable differences uncovered between patients and physicians over characteristics seen as important for a good death, another set of findings showed broad across-the-board agreement on the ranking of nine attributes linked to achieving a good death. In these findings, the three sets of respondents (patients, family members, and physicians) agreed on the importance of being free from pain, being at peace with God, and of the family being present at the end. Patients and family members placed more importance than physicians on being mentally aware. Physicians gave more importance than patients or family members to whether life was meaningful and whether conflicts had been resolved. Dying at home was ranked last by all the respondents.

Legalization of physician-assisted suicide has occurred in a handful of European countries (the Netherlands, Belgium, and Switzerland, in particular; it has been expressly rejected in Great Britain). Seen as serious issues not to be taken lightly, assisted suicide laws have been written with strict guidelines to govern against abuse; and these guidelines have set the template followed in other places. These guidelines specify age requirements and corroborated diagnoses by licensed physicians; requests must be given voluntarily over time and are not to be prompted by suggestions from the physician. The person must be judged to be acting free of any psychiatric or emotional duress. In order to ensure assisted suicides will not be forced by financial circumstances, Belgium makes palliative care available regardless of ability to pay.

Physician-assisted suicide was legalized in the state of Oregon in the late 1990s, and since then the states of Washington, California, Colorado, and Vermont have adopted protocols with guidelines quite similar to the ones specified in Oregon. In these states, a person must have a corroborated diagnosis of a terminal illness with less than 6 months to live, and the person must be able to ingest the lethal overdose on his (her) own. A New Mexico judge in 2014 ruled that assisted suicide was a matter between physicians and patients, but that ruling was overturned. The Montana Supreme Court ruled that nothing in that state's constitution prohibited assisted suicide. A voter referendum to adopt physician-assisted suicide was rejected in the state of Massachusetts.

The typical assumption is that a terminally ill person's primary motive for selecting assisted suicide is to avoid pain. While such a motive is present in many cases, other intents have been identified: fears about the future and fears of being a burden on others, loss of independence, lack of dignity, and decreasing ability to engage in activities making life meaningful. Typical life conditions people wish to end with assisted suicide include various forms of cancer, amyotrophic lateral sclerosis, early-onset Alzheimer's or some other dementia, and complete paralysis. Belgium and the Netherlands leave open the possibility for a person who is not terminally ill to make use of assisted suicide if in a permanently hopeless situation such as complete paralysis.

The Role of Regulation in Health Behavior (Listed in System as "Federal/State Regulation (FDA)")

David B. Portnoy

US Food and Drug Administration, Silver Spring, MD, USA

Regulation Defined

Regulation includes those activities by a government that allows it to intervene in the private domain. Regulations, or implementation of laws, constitute a "binding legal norm…that intends to shape the conduct of individual and firms" (Orbach, 2013, p. 25). Thus, regulations can be defined as a series of rules established by a government to effect change among both individuals and firms in the private and public sectors. Whereas legislation establishes the authority for government actions and can be enforced by the courts, regulations refer to the much more specific rules developed by the governing body to implement those laws. Despite this distinction, many actions by governments, whether they occur through legislation or rule-making, are often considered part of regulations.

The commonality between these and other definitions of regulation is that they all identify the source of action as a government (or components thereof) and the recipient or intended target of those actions as individuals and organizations in the private sector. However, beyond that broad definition, the meaning of regulation is subject to much variability, the greatest source of which derives from the level of the action. Regulation can occur at federal, state/territory, county, and many other levels of government. Level-specific differences in purview, jurisdiction, and power result in different types of regulations; for example, the regulations issued by a city council may greatly differ from those issued by a federal government. However, this power disparity does not mean that regulations at different levels must be distinct in their focus or that federal regulations are always "stronger" than local ones. For example, federal agencies may not have the authority to regulate specifically local issues and vice versa, although federal regulations may sometimes preempt those at lower levels of government.

Regulation in Context

Ecological models of health behavior recognize that health behaviors are influenced not only by individual factors but also by the larger context in which those behaviors occur and in which the individual lives. These models are most effective when they are organized around a specific health behavior, have multiple levels, and recognize influences across these levels, that is, interventions at one level can affect other levels as well. However, certain frameworks seek to focus on multiple related risk factors concurrently that are intertwined at the community level. Although the specific levels may change from model to model, they generally start at the most proximal (individual) level, progress to the community level that can include workplaces or a place-based focus, and end with the outermost (i.e., national) level. That outermost level is sometimes referred to as public policy, policy environment, or community/policy. Regardless of the terminology, the most distal level of influence on health behavior is that of the law, public policy, and other large-scale factors that influence health through the other levels. Interventions at this level are intended to affect entire populations, as compared with interventions that focus solely on individuals or specific groups of individuals. Despite this, interventions at this level are by definition broader and thus must work in concert with local regulations, interventions at the individual level, and within the defined social and cultural context. One such review of tobacco control programs noted that comprehensive programs, such as those that include multiple levels of intervention, reduce tobacco use (Community Preventive Services Task Force, 2014). These types of models have received support and endorsement in guiding strategic plans for public health, such as the US Department of Health and Human Services' Healthy People 2020 and others.

Support for the Role of Regulation in Health

Regulation as a strategy to improve health, both at individual and population levels, has received wide support. The Institute of Medicine report on ensuring the health of the public in the twenty first century (2003) notes that federal, state, local, and tribal governments all play a role in identifying those in need of support and intervention and providing necessary services. The report notes that federal governments can intervene in six main areas, the first of which is policy making; decisions on policy optimally result from "…creation and use of an evidence base, informed by social values, so that public decision makers can shape legislation, regulations, and programs" (2003, p. 113). This emphasizes the need for strong regulatory science (as discussed below) to inform, support, and implement policy.

Dr. Thomas Frieden, director of the US Centers for Disease Prevention and Control (CDC) from 2009 to 2017, also notes the many ways in which regulation can contribute to improved public health outcomes. He identifies three main areas in which the government can protect public health and safety (Frieden, 2013). First, the government can require the provision of truthful information, such as nutrition information or calorie counts on menus, in order to empower individuals to make better health decisions; similarly, government-mandated warnings serve to inform the public about health risks and in certain cases to counter industry efforts to suppress or undermine science, such as the tobacco industry's history or disputing the science on the harms of smoking and of secondhand smoke (Samet & Burke, 2001). Second, the government can take action to prevent harm caused by others; examples include laws and regulations to reduce drunk driving, occupational hazards, and the inclusion of harmful ingredients in foods (e.g., recent local bans on trans fats and their removal from FDA's list of foods that are "generally recognized as safe"). These specific examples represent regulation, some of which have been accompanied by industry self-regulation prior to enforcement as well as public education. The effectiveness of industry self-regulation varies widely from industry to industry, but self-regulation is often ineffective for public health benefit (Sharma, Teret, & Brownell, 2010). Such self-regulation is often an attempt forestall stronger and more enforceable local, state, and federal regulations. Finally, Dr. Frieden notes that the government can take actions to encourage healthy behaviors or create obstacles to harmful choices, such as zoning regulations that promote physical activity or that limit community density of retailers of harmful products such as alcohol or tobacco. He notes that a critical but often overlooked aspect of how people respond to such actions is "the degree to which individual actions are influenced by marketing, promotion, and other external factors," a ripe area for research and intervention by health psychologists.

Perhaps the most sweeping regulation that supports changes in health behavior and subsequent population health is the Patient Protection and Affordable Care Act. This Act spawned a wide-ranging series of regulations, many of which focused on encouraging the use of preventive services (e.g., screening and immunizations), employer incentives for employee health promotion, nutrition labeling at chain restaurants, and other activities. In support of the Act, "the health of the individual is almost inseparable from the health of the larger community. And the health of each community and territory determines the overall health status of the Nation" (Koh, 2010, p. 1656).

Examples

A diverse and ever-growing list of health topics can be addressed through regulation. Many regulations focus on information, warnings, and public education about health risks and informed health decision making or promoting health promotion services. Two examples of this form of regulation are the provision of nutrition information on food products and (more recently) on restaurant menus and the provision of health warnings on tobacco products. As in most health-related regulation, the industry, rather than the target audience, is being regulated, but the focus of the impact is on the public.

Nutrition labeling began in the United States with a White House recommendation, which resulted in FDA issuing a final rule in 1973. These regulations were revised to allow health claims about foods and were again updated in the Nutrition Labeling and Education Act (NLEA) of 1990, which mandated nutritional labeling on most foods in the now-familiar nutrition facts panel (Institute of Medicine, 2010); an additional update occurred in 1993. At each step in this process, policy makers, scientists, and the public provided significant input regarding the benefits of such labeling as well as optimal labeling formats and content, which further illustrates that regulation is a constantly evolving process. More recent changes made include revising the format of the nutrition facts panel, changing the content of the nutrients, including "added sugars," and other changes (US Food and Drug Administration, 2016, https://www.federalregister.gov/documents/2016/12/30/2016-31597/food-labeling-nutrition-labeling-of-standard-menu-items-in-restaurants-and-similar-retail-food). In recent years, many states and localities have begun to require calorie counts and other forms of nutrition information to be displayed on restaurant menus. In 2014, FDA issued a final rule requiring such information be listed on chain restaurant menus and menu boards, with the following stated purpose: "To help make nutrition information for these foods available to consumers in a direct, accessible, and consistent manner to enable consumers to make informed and healthful dietary choices" (US Food and Drug Administration, 2014). Both menu and package labeling have been the subject of a wide variety of studies of the basic theory behind, potential impacts of, and best practices for labeling (e.g., Andrews, Burton, & Kees, 2011; Roberto & Kawachi, 2014).

The Family Smoking Prevention and Tobacco Control Act (FSPTCA) required that FDA publish a list of the harmful and potentially harmful constituents of tobacco and tobacco smoke "in a format that is understandable and not misleading to a lay person." However, beyond requiring that FDA conduct periodic consumer research to ensure that the list is "understandable and not misleading," Congress provided no further instructions as to the purpose of this list, unlike the rule on food menu labeling, which is explicit in its attempt to make nutrition information accessible for consumers. However, some intent regarding public health protection can be inferred given that the overall focus of the FSPTCA is to protect public health and that evidence that consumers were misled about the health impact of "light" and "low tar" cigarettes was cited in support of the law.

What Is Regulatory Science and How Can Health Psychology Contribute?

Regulations may be directly required or authorized by statute. In some cases, scientific support may be needed to help justify a particular regulation. This is especially true for regulations that seek to influence health through behavior. However, the science used to support regulation may differ from what is traditionally found in the published literature. For example, regulatory science focuses on "ensuring that scientifically valid techniques, tools, and models are available to evaluate products and, subsequently, to inform regulatory actions that promote optimal health outcomes" (Ashley, Backinger, van Bemmel, & Neveleff, 2014, p. 1046). Thus, not all published literature may be specific enough to inform regulation. For example, if a new technique is published, it may move the science forward and may be innovative, but it is unlikely that a new and unvalidated tool would be used to support a regulation, assuming that other more accepted methods are available. Regulatory agencies generally rely upon scientific data to base their actions, as illustrated by the current public debate over the potential benefits or harms of electronic cigarettes.

Considerable efforts are being made to increase the regulatory science that is being conducted. The science used to support regulation may need to be more focused than typical scientific research and in general must focus on areas for which regulatory actions may be possible. For example, a study that examines the psychological mechanism underlying why youth post on social media about their use of tanning beds may be interesting, may advance scientific knowledge, and may inform the design of interventions. Although this type of study may inform the need for a regulation, it would be unlikely to directly inform the regulation itself. In other words, mechanistic or basic psychological research is critically important to advance the science, to allow for development of interventions, and for many other reasons; however it is unlikely to be useful in direct support of regulation unless it can be tied directly to a specific regulatory activity. It may, however, have relevance for advocacy and spur other research on the topic. For example, basic psychological research on judgment and decision biases, health literacy, and presentation format could be used to support regulations on restriction of potentially false or misleading claims made in an advertisement for a prescription drug (e.g., Aikin, O'Donoghue, Swasy, & Sullivan, 2011).

For health psychology research to be maximally useful in regulatory science, it should minimally fulfill the following criteria. First, the research should address a topic of interest to a regulatory agency; agencies typically announce topics of interest or solicit comments on agency websites, in notices in the *Federal Register*, or in similar official methods of public notice. Second, the research should be tailored to the appropriate study populations to ensure that study findings can be directly applied to the potential regulation. For example, a study conducted in women over age 65 may be less relevant if the regulation of interest focuses on women of reproductive age. Third, the stricter the sampling using, the more controlled the methodology and analytical controls, and ensuring a sufficient sample size will increase the likelihood that the research findings will be useful to help support regulatory actions and that conclusions will withstand challenges. In addition, reporting study details and results using one of the many reporting guidelines is helpful to ensure a full description of the study is provided. Complementing quantitative data, strong qualitative data can be useful to info to help explain "why" and "how" of certain issues. Fourth, interpretation of results should not extend beyond what the data portray; interpretations should not generalize beyond what is possible with the study design or suggest that cross-sectional associations are causal. All of these misinterpretations and statistical errors, which are common in published research in psychology and many other fields (e.g., Ioannidis, Munafo, Fusar-Poli, Nosek, & David, 2014), will weaken the potential usefulness of the study. Lastly, any conflicts of interest should be clearly disclosed. Research studies that adhere to these criteria are more likely to be used by an agency to inform regulation.

Researchers can provide study findings to regulators in a number of ways so that the agency may officially consider these findings in its rulemaking. Researchers may directly submit their research along with a lay explanation directly to local and state agencies, some of which may have processes for submission of public comments; other agencies may accept such findings without public notice. For federal regulation, public comment solicitations are generally announced in the *Federal Register*, and comments can be submitted online (www.regulations.gov). Public comments summarizing research findings can also be provided at in-person public meetings. Even without such outreach efforts by researchers, high-quality regulatory science research published in peer-reviewed journals is often referenced and used by agencies in designing and implementing regulations.

Summary

Regulations are actions taken by a government to implement laws. In the context of health, regulations can focus on individuals, industries, or larger organizations. Seen through the lens of ecological models of health behavior, regulations can influence health behavior changes through multiple pathways, interacting with interventions at the individual and community levels as well as state and local laws. Regulations related to health can be informed by strong and specific regulatory science.

Author Biography

Dr. David B. Portnoy is a Social Science Branch Chief in the Office of Science at the US Food and Drug Administration Center for Tobacco Products. Dr. Portnoy received his MA and PhD in Social Psychology from the University of Connecticut, MPH from the Johns Hopkins Bloomberg School of Public Health, and postdoctoral training in cancer prevention and control at the National Cancer Institute. His research interests focus on risk perception and communication and the interplay between basic social psychological processes and health behaviors. At FDA, he conducts research on consumer perceptions of tobacco products and health warnings, reviews industry submissions, and works to develop the science base for regulations and health communication efforts. He has published on the topics of tobacco regulatory science, consumer perceptions of tobacco products, factors affecting tobacco use, and the effects of risk and worry on health behaviors.

Funding for Health Psychology Research

Robert T. Croyle

National Cancer Institute, Bethesda, MD, USA

Funders of Health Psychology Research

Both the public and private sectors provide funding for health psychology research. As the largest funder of health psychology research, the federal government plays an essential role in maintaining and enhancing the vitality of the field. Although several federal agencies provide funding, the largest source is the National Institutes of Health (NIH). Other agencies within the Department of Health and Human Services also play a significant role, including the Centers for Disease Control and Prevention and the Substance Abuse and Mental Health Services Administration. Because the latter two agencies are focused on support for program services, their research funding tends to focus on the evaluation of those services as well as public health surveillance to determine the scope and distribution of diseases and disease risk factors.

The NIH contains 27 institutes and centers. Because the governance structure delegates substantial autonomy and authority to the institutes, support for health psychology research can vary substantially. Institute directors are authorized to make final funding selections in most cases and therefore have a substantial impact on funding priorities and allocations. Health psychologists employed by the institutes can and have made a substantial contribution in ensuring that grant applicants in the field receive a fair review and appropriate consideration in funding decisions. Nevertheless, the selection of a new institute director can have a significant impact on that institute's support for health psychology.

In recent years, the NIH Office of the Director has played a larger role in funding and coordinating research across the agency. The NIH Common Fund, which is overseen by the NIH Director, supports trans-NIH initiatives, although individual grants are managed within the institutes.

The Wiley Encyclopedia of Health Psychology: Volume 4: Special Issues in Health Psychology,
First Edition. General Editor: Lee M. Cohen. Volume Editor: Suzy Bird Gulliver.

In 1993, Congress established the Office of Behavioral and Social Sciences Research (OBSSR) at NIH. This action reflected the growing recognition of the role of behavior in health as well as the need for better coordination of related programs across the agency. Notably, four of the five directors of the office to date are health psychologists. From an operational perspective, this means that a health psychologist has been a member of the agency's leadership team ever since, and this has afforded the field as a whole with greater opportunities to shape the priorities of the agency.

Two other federal departments that have long histories of health psychology research funding are the Department of Defense and the Department of Veterans Affairs. Both departments also support clinician scientist training and have housed many of the most influential health psychologists in the United States.

The nonprofit sector has also played a key role in funding for health psychology research. The Robert Wood Johnson Foundation, the American Cancer Society, and the American Heart Association are among the many organizations that have provided support. Because these organizations operate outside of the constraints of the federal government bureaucracy, they can often rely on more nimble or rapid funding processes. Foundations have proven to be an essential source of support for applied and policy-related work, especially that focused on underserved and stigmatized populations. For example, in the areas of tobacco control and obesity, foundations supported much of the seminal work detailing the role of industry in product marketing and regulatory policy, including strategies for targeting ethnic minority populations. The Robert Wood Johnson Foundation has provided significant leadership in forging collaborations between scientists, health officials, and community organizations to facilitate the dissemination of evidence into clinical and public health practice.

The role of prominent individual philanthropists has been less significant in health psychology than in other fields. Large individual donations to universities and cancer centers, for example, have rarely targeted work focused on health behavior.

Clinical trials supported by industry have supported health psychologists in a wide variety of research domains but often in a secondary role. Not surprisingly, the scientific role of health psychologists in industry-supported drug trials has often focused on the issues of recruitment, adherence, and retention. As more trials incorporated measures of quality of life and other psychosocial constructs as secondary endpoints, opportunities for health psychologists have expanded. Industry-funded trials continue to provide important contributions to the research literature in a variety of behavioral medicine domains, such as smoking cessation, weight loss, diabetes and pain management, and cancer treatment symptom management. The contemporary interest in patient-reported outcomes and comorbidities among both industry and regulatory agencies such as the Food and Drug Administration are likely to further strengthen support for health psychology research within the context of clinical trials.

The Role of Special Initiatives

Special funding initiatives from both government and nonprofit sector organizations have played an important role in the development of health psychology. Although most have not been focused on health psychology per se, health psychology investigators have utilized a wide variety of special funding opportunity announcements to build the field, scale up research, and accelerate progress in research methods. The growth in funding for interdisciplinary research concerning common health problems has enabled health psychologist to expand their participation on large-scale research consortia, clinical trials, centers of excellence, and cohort studies.

Several special initiatives supported by the NIH have been led and coordinated by the OBSSR. Initiatives especially relevant to health psychology include the Behavior Change Consortium (co-funded by the American Heart Association and the Robert Wood Johnson Foundation), launched in 1999, and a follow-on initiative, the Health Maintenance Consortium.

Individual or subsets of NIH institutes also have led important efforts. The National Cancer Institute (NCI), for example, funded a series of transdisciplinary team science research centers in which health psychologists played key roles as principal investigators, project leaders, and co-investigators. The first in the series, the Transdisciplinary Tobacco Use Research Centers, was co-funded by the National Institute on Drug Abuse, the Robert Wood Johnson Foundation, and the National Institute on Alcohol Abuse and Alcoholism. This initiative was followed by similar efforts that supported the Centers for Population Health and Health Disparities, the Centers of Excellence in Cancer Communication Research, and the Transdisciplinary Research on Energetics and Cancer Centers. More recently, the National Heart, Lung, and Blood Institute, in collaboration with NCI, the National Institute of Diabetes and Digestive and Kidney Diseases, the National Institute of Child Health and Human Development, and OBSSR, funded the Obesity-Related Behavioral Intervention Trials (ORBIT) initiative. ORBIT focused on the translation of findings from basic research on human behavior into more effective clinical, community, and population interventions to reduce obesity.

The NIH Common Fund has supported the Science of Behavior Change initiative, which focuses on the initiation, personalization, and maintenance of behavior change. The utilization of central NIH funds for this effort is a further reflection of the progress that health psychology has made within the NIH leadership community, given that Common Fund topic ideas compete with all areas of biomedical science. Interestingly, the growing interest in and recognition of the importance of behavioral risk factors has also influenced priority setting within mechanistically oriented biomedical research. The NIH recently launched a Common Fund initiative titled Molecular Transducers of Physical Activity in Humans.

At the NIH, high-priority initiatives are solicited via requests for applications (RFAs), published in the NIH Guide for Grants and Contracts, which are developed by program staff and reviewed by institute advisory boards prior to their release. Unlike Program Announcements, which also are used by institutes to communicate their research priorities to the scientific community, RFAs are associated with funds that are set aside specifically to support grants submitted in response to the announcement. Applications are reviewed by ad hoc panels that are established specifically for the initiative. Grants awarded using RFA-associated funds often are the basis for a research network or consortium. In many cases, the consortium is convened on a regular basis to enable work in progress to be shared among the funded investigators. This structure also allows the funder to monitor progress more closely and ensure that roadblocks are addressed in a timely fashion.

Two of the signature efforts led by the foundation sector are the Healthy Eating Research and Active Living Research initiatives, both supported by the Robert Wood Johnson Foundation. The foundation has also supported interdisciplinary population science research training efforts that have helped integrate health psychologists into other fields and settings. One such effort, the Health and Society Scholars Program, supported institutional postdoctoral fellowship grants, which were complemented with an annual national meeting of program participants. Given the individual- and group-level focus of traditional clinical health psychology training programs, special initiatives such as this one have helped to strengthen the ability of health psychologists to participate fully in population-level research and programs.

Challenges and Opportunities in Health Psychology Research Funding

Support for health psychology research now seems firmly established among major research funders. The challenge to sustained support will lie in the productivity and impact of research supported to date and in the future. The growing visibility of health psychology research findings among policy makers and the public should facilitate ongoing support. Compelling findings from highly relevant research such as the Diabetes Prevention Program are perhaps the most essential ingredient for success. The growing importance of cost-effectiveness analyses needs to be recognized among investigators and funders alike.

Most funders do not target their support to specific disciplines like health psychology. Rather, funding tends to be focused on broad research questions, diseases, or public health problems. As a subdiscipline of behavioral science, health psychology is often painted with the same brush as other social and behavioral sciences. Therefore, it is not surprising that as funders like the NIH have expanded support for social and behavioral science, so too have they expanded support for health psychology research. Because so many of today's medical and public health challenges relate to behavior, broadly defined, it has been easier to make the case for support among the leaders of funding agencies and organizations. Within the political realm, however, the assignment of moral blame to victims of disease continues to be a challenge for advocates of health psychology research funding.

Another challenge to adequate research funding is the paucity of health psychologists in leadership positions within the key funding organizations. The relative status of psychology to medicine within academia and government is exacerbated by the underrepresentation of psychologists among leadership. Health psychologists are needed to serve in funding organizations and in advocacy roles before elected officials who allocate appropriations at the national and local levels.

Finally, the ability and willingness of health psychologists to participate in and contribute to large-scale transdisciplinary team science will predict to a large extent the trajectory of funding for health psychology research. Health psychology must be viewed as one of the essential disciplines to be included in broader, integrated efforts to advance knowledge and practice concerning the most significant medical and public health problems of our day. The ability to effectively communicate and integrate our work with other fields is therefore essential. Health psychologists also must embrace rigorous scientific standards, including objective self-criticism, to enable progress and demonstrate the value of funders' investments. As applicants for research funding, health psychologists are most successful when they recognize the limits of their expertise and methods and embrace collaboration with scientists from other disciplines. These are among the grant-writing skills that should be afforded to every young scientist in the field to maximize their likelihood of success.

Author Biography

Robert T. Croyle, PhD, was appointed director of the Division of Cancer Control and Population Sciences (DCCPS) at the National Cancer Institute (NCI) in July 2003. In this role, he is responsible for overseeing a research portfolio and operating budget of nearly half a billion dollars and serves on NCI's Scientific Program Leaders governance group. As a division, DCCPS covers a wide range of scientific domains and disciplines, including epidemiology, behavioral science, surveillance, cancer survivorship, and health services research. He previously served as the division's associate director for the Behavioral Research Program, leading its development and expansion. Before coming to NCI in 1998, he was professor of psychology and a member of the Huntsman Cancer Institute at the University of Utah in Salt Lake City. Prior to that, he was a visiting investigator at the Fred Hutchinson Cancer Research Center in Seattle, visiting assistant professor of psychology at the University of Washington, and assistant professor of psychology at Williams College in Massachusetts.

Dr. Croyle received his PhD in Social Psychology from Princeton University in 1985 and graduated Phi Beta Kappa with a BA in Psychology from the University of Washington in 1978. His research has examined how individuals process, evaluate, and respond to cancer risk information, including tests for inherited mutations in BRCA1 and BRCA2. His research has been published widely in professional journals in behavioral science, public health, and cancer, and he has edited two volumes: *Mental Representation in Health and Illness* (1991) and *Psychosocial Effects of Screening for Disease Prevention and Detection* (1995). He is co-editor of the *Handbook of Cancer Control and Behavioral Science* (2009) and co-author of *Making Data Talk: Communicating Public Health Data to The Public, Policy Makers, and The Press* (2009).

Genetics and Psychology (Health)

Overview

Improved understanding of the genetic basis of human disease and human behavior is rapidly changing the field of health psychology. Recent advances in genetic research and technology are permitting researchers to identify the genetic basis of a wide array of health conditions for the first time. Moreover, improved understanding of the field of epigenetics is rapidly shaping understanding of how environmental factors and behavioral changes can fundamentally alter gene expression. Genetic testing also has great potential to improve assessment, optimize the effectiveness of treatments, reduce side effects, and improve safety; however, it can also reveal vulnerabilities for disease that can be difficult for patients to cope with. As such, it is critical that health psychologists recognize the tremendous impact that genetic and epigenetic findings will likely have on their practice, as well as the field of health psychology more broadly, for the foreseeable future.

Central Dogma of Molecular Biology

All cellular processes begin with the genetic code written in every cell known as deoxyribonucleic acid (DNA), which is composed of four different nucleotides: adenine (A), cytosine (C), guanine (G), and thymine (T). Each is made of a phosphate group, a sugar known as 2′-deoxyribose, and a unique base that gives each nucleotide its identity. These bases pair with one another (A with T and G with C) to form DNA's well-known double

The Wiley Encyclopedia of Health Psychology: Volume 4: Special Issues in Health Psychology,
First Edition. General Editor: Lee M. Cohen. Volume Editor: Suzy Bird Gulliver.

helix structure. These physical characteristics allow DNA to carry out its intended function, which is described by the central dogma of molecular biology. Simply put, the central dogma states that genes specify the sequence of messenger ribonucleic acid (mRNA) molecules, which, in turn, specify the sequence of proteins. Proteins perform a variety of functions in the cell such as regulatory functions, transport of small molecules, support, and catalysis of important reactions that would not normally occur under the conditions seen in a cell. DNA is transcribed to mRNA, the intermediate between DNA and proteins, by DNA-dependent RNA polymerases and other relevant proteins. RNA uses the same subunits as DNA, with slight modification of the sugar from deoxyribose to ribose, as well as using uracil (U) rather than thymine. Much of the RNA transcribed from DNA performs a host of various functions in the cell; however, a small selection of RNA, known as mRNA, is translated into proteins by structures known as ribosomes.

Epigenetics

There are many different levels at which gene expression can be controlled. One of the most heavily studied areas is that of epigenetics, which involve changes to the genome that do not affect the specific sequence of the nucleotides that comprise genes (Weinhold, 2006). One of the levels at which epigenetic marks can be seen is the level of histones and chromatin. The term chromatin describes the nucleoprotein complex that is seen when cells compact the 2–3 m of DNA present in a given cell into its nucleus. This packing begins with the DNA being wrapped around protein complexes known as histones. A segment of DNA that is 146 base pairs (bp) long is wrapped around the histone and is known as the core particle. By adding 20 bp and a linker histone known as H1 creates what is known as the chromatosome. Once the length of DNA is greater than 168 bp long, the structure is known as a nucleosome.

As one can imagine, navigating the chromatin can cause problems when the cell begins to transcribe genes. Histones placed over promoters, sequences on the DNA that allow transcription to initiate, can prevent the transcriptional machinery from recognizing the region and initiating transcription. In addition, histones placed throughout a gene can prevent the machinery from traveling the length of the DNA to read and transcribe the gene. Thus, one level at which regulation of gene expression can occur is at that of the histones. Modifications to the chromatin that cause a change in gene expression fit the definition of epigenetic marks because the changes are caused without changing the sequence of the genes affected. Two of the most common forms of epigenetic modification come in the form of histone acetylation and methylation, which involve the addition of two different small molecules (acetate and methane, respectively) to the lysine and arginine tails found on histones after the histone proteins are translated. These modifications can have significant effects on levels of gene expression of the DNA that interacts with modified histones with the general pattern of methylation decreasing gene expression and acetylation increasing it (Allfrey, Faulkner, & Mirsky, 1964).

DNA can also be methylated at cytosine residues. These methylated cytosines are most often found when they neighbor a guanine in what is known as a CpG dinucleotide (Rose & Klose, 2014). Though the specific nucleotides are being modified, the sequence of the nucleotide bases remains the same. Thus, DNA methylation can also be considered an epigenetic modification. As with histone methylation, increased levels of DNA methylation are associated with decreased levels of gene expression. As a result, DNA methylation also plays an important role in cell differentiation.

Genetic and Epigenetic Analysis Techniques

Researchers employ several different techniques to investigate what DNA looks like, the changes that are made to it, and the effects that it may impose on a person. Numerous research designs and techniques for studying the genetic and epigenetic basis of diseases exist, including candidate gene approaches, genome-wide association studies (GWAS), DNA methylation chips, and DNA sequencing. GWAS and candidate gene approaches are used to identify associations between genes and a disease of interest. Candidate gene studies are theoretically driven studies that aim to examine associations between diseases and specific genes that are hypothesized to potentially play a role in the pathogenesis of the disease under study (e.g., because of the known function of a gene). In contrast, GWAS is an atheoretical approach designed to identify novel genetic associations with a particular disease. This is accomplished by comparing individuals with and without the condition of interest on millions of different locations throughout their genome. While GWAS requires very large sample sizes, it has the potential of identifying novel associations that might not otherwise be identified.

Other genome- and epigenome-wide technologies frequently used by modern-day researchers include DNA sequencing and DNA methylation chips. These techniques enable researchers to quickly identify differences in the order of bases or functional groups that may be added on to DNA. For example, methylation chips are constructed with synthetic DNA designed to fluoresce when it binds to methylated cytosines in the sequence of DNA being examined. As a result, researchers are now able to quickly find the locations of methyl groups within a given sequence of DNA. Still other approaches enable researchers to study both the transcriptomes (i.e., all expressed mRNA molecules) and proteomes (i.e., all expressed proteins). Together, these and other techniques enable modern researchers to systematically study the genetic and epigenetic basis of a wide array of health conditions.

Health Psychology Issues Through a Molecular Genetics Lens

Smoking

Tobacco smoking is a global public health problem, as it represents one of the primary preventable risk factors for a wide array of health conditions, including respiratory diseases, cardiovascular diseases, and cancer (Gao, Jia, Breitling, & Brenner, 2015). Notably, tobacco initiation, regular tobacco use, and nicotine dependence all have a substantial genetic component, with heritability estimates of 75, 80, and 60%, respectively (Maes et al., 2004). More recently, a large number of studies have demonstrated that tobacco smoking is associated with substantial DNA methylation modifications throughout the genome (Gao et al., 2015). Indeed, a recent review on this topic found more than 1,000 smoking-associated CpG sites, the most common of which were cg05575921 (*AHRR*), cg03636183 (*F2RL3*), and cg19859270 (*GPR15*; Gao et al., 2015). There is also increasing awareness that smoking-associated DNA methylation changes may also be a key pathway through which tobacco smoking can lead to smoking-induced diseases (Breitling, 2013; Breitling, Salzmann, Rothenbacher, Burwinkelly, & Brenner, 2012). Epigenetic alterations are also known to play a role in cardiovascular disease. Moreover, methylation levels in *F2RL3*—one of the top three genes associated with smoking-associated methylation changes noted above—have also been associated with higher mortality among patients with stable coronary heart disease (Breitling, 2013; Breitling et al., 2012). Thus, it is possible that epigenetic alterations may be one of the mechanisms through which tobacco smoking—an environmental risk factor with a known genetic component—may lead to increased risk for cardiovascular disease.

Diet

Diet is a behavioral factor that plays an important role in both obesity and cardiovascular disease; however, there is growing evidence that dietary changes, particularly during development, may also affect DNA methylation patterns through biochemical pathways. For example, several nutrients are required for the production of *S*-adenosylmethionine, which is the key methyl donor for DNA, RNA, proteins, and lipids (Glier, Green, & Devlin, 2014). Specifically, both vitamins (folate, riboflavin, vitamin B_{12}, vitamin B_6, choline) and amino acids (methionine, cysteine, serine, glycine) are needed to produce *S*-adenosylmethionine. As a result, imbalances in these nutrients have the potential to impact DNA methylation. While there is growing evidence that DNA changes in nutritional status can lead to methylation changes, this area of research is still in the early stages; however, it is hoped that improved understanding of the association between nutrition and DNA methylation could eventually lead to new biomarkers and new treatments aimed at reversing altered DNA methylation patterns associated with disease (Glier et al., 2014).

Understanding the Overlap Between Physical and Mental Health Conditions

The overlap between physical and mental health conditions has long been of interest to health psychologists. For example, posttraumatic stress disorder (PTSD)—a mental health disorder that has a clear environmental basis (i.e. a traumatic event)—has been linked to a wide range of cardiometabolic conditions, including heart disease, metabolic syndromic, and diabetes (Dedert, Calhoun, Watkins, Sherwood, & Beckham, 2010; Sumner et al., 2017). A variety of behavioral explanations have been posited to account for this association (e.g., poor diet, tobacco smoking, substance use, physical inactivity); however, it is likely that genetic factors also play a significant role in the pathogenesis of PTSD (Duncan et al., 2018). Notably, a novel study recently conducted by Sumner et al. (2017) has provided the first evidence of molecular genetic overlap between PTSD and coronary artery disease using a genome-wide design. This study utilized computational methods that allow researchers to estimate genetic correlations between complex phenotypes using GWAS summary statistics. Through this methodology, Sumner et al. (2017) were able to demonstrate that a variety of cardiometabolic traits were associated with each other. Moreover, they were also able to demonstrate for the first time that the molecular genetic basis of coronary artery disease is significantly correlated with the molecular genetic basis of PTSD ($r = .41$, $p = .01$).

Impact on Assessment and Treatment

Given that the field of genetics is rapidly advancing, it stands to reason that these advancements will continue to have major implications on healthcare for the foreseeable future. One such area will be the domain of personalized medicine, where we see can already see the emergence of this type of approach in relation to the treatment of breast cancer. Specifically, *BRCA1* and *BRCA2* are two genes that are known to be implicated in familial breast cancer. Identification of these genes and their cancer-causing mutations has begun to revolutionize the way in which cancer treatments and screenings are conducted. Already, individuals who are identified as carrying genetic mutations associated with increased risk can undergo additional screenings and/or elect to have preventative mastectomies in order to reduce the risk of breast cancer. *BRCA* mutation type is also being used to guide treatment decisions in patients, as there is evidence that it may influence risk of relapse and that carriers may be particularly likely to benefit from specific treatment approaches (Li et al., 2016; Soenderstrup et al., 2018). Thus, genetic testing has great potential to improve assessment, optimize the effectiveness of treatments, reduce side effects, and improve safety; however, it can also reveal vulnerabilities for disease that can be difficult for patients to cope with. Since the advent of *BRCA1/2* genetic testing, model communication and counseling protocols have been developed to evaluate the behavioral and psychosocial effects of *BRCA1/2* genetic testing on patients (e.g., Botkin et al., 1996; Tercyak, O'Neill, Roter, & McBride, 2012). In general, studies on this topic have found that *BRCA1/2* genetic counseling and testing is not harmful for the majority of individuals who are found to carry risk variants, although individuals with high levels of preexisting anxiety do appear to respond more poorly (Tercyak et al., 2012). More recent interventions have begun to examine the role of patient knowledge, preferences, and values regarding genetic testing; however, it is clear that more work on this important topic is needed and that health psychologists are uniquely positioned to conduct such work (Tercyak et al., 2012).

Future Directions

It is hoped that advances in our understanding of the genetic and epigenetic basis of cancer and other diseases will eventually lead to a plethora of targeted, evidence-based behavioral health interventions for individuals who are identified as being at increased genetic risk; however, as noted by McBride, Birmingham and Kinney (2015), a significant challenge that health psychologists frequently encounter concerns how to effectively convey to patients the joint contributions of both genetic and environmental factors to disease risk. In addition, there is presently a great need for additional research aimed at (a) determining the optimal communication approaches for providers to employ to help their patients to effectively interpret genetic testing results, (b) identifying the most effective means of leveraging provider–patient communication about genetic testing to increase the patients' engagement in risk-reducing health behaviors (e.g., smoking cessation, weight management) and utilization of appropriate healthcare services, and (c) understanding how best to disseminate risk information to family members in order to further support patients' actions to reduce risk (McBride et al., 2015). Health psychologists are uniquely well suited to make significant contributions to each of these important and growing areas of science and practice (Tercyak et al., 2012).

Author Biographies

Dr. Nathan A. Kimbrel is the assistant director of the Genetics Research Laboratory at the Department of Veterans Affairs' Mid-Atlantic Mental Illness Research, Education, and Clinical Center (VA Mid-Atlantic MIRECC). He is also the assistant director for Implementation Science and Program Evaluation for the VA Mid-Atlantic MIRECC Clinical Core as well as an assistant professor in the Department of Psychiatry at the Duke University School of Medicine. His research primarily focuses on psychiatric genetics and the etiology, assessment, and treatment of self-injurious behavior. Christopher Fink is a graduate student in the Department of Physiology at North Carolina State University in Raleigh, NC. He received a BS in Biology from the University of North Carolina in 2016 and has served as a clinical research assistant in the Traumatic Stress Laboratory at the Durham VA Medical Center and the VA Mid-Atlantic MIRECC since 2017.

The Role of Cultural Mistrust in Health Disparities

Brandon L. Carlisle[1] and Carolyn B. Murray[2]

[1]*Department of Psychiatry, University of California, San Diego, CA, USA*
[2]*Psychology, University of California, Riverside, CA, USA*

This entry examines the role *cultural mistrust* plays in health disparities experienced by African Americans, in contrast to Whites. While a multitude of individual and environmental factors contribute to trends in health outcomes, the focus of the present entry is the role of trust and its relationship with healthcare disparities, service utilization, adherence to treatment, and patient satisfaction. There are individual differences in the amount of trust potential patients have in the healthcare system, but it is also the case that variation can be partially explained by accounting for patient race/ethnicity. As a result, researchers have conceptualized mistrust as an important cultural variable when interpreting health trends among racial/ethnic minorities, particularly African Americans.

Health Disparities

Health inequality in the United States is a serious problem, and while there has been some improvement in particular areas, the overall picture is bleak. The health status of racial and ethnic minorities continues to lag far behind that of the majority population (Center for Disease Control and Prevention [CDC], 2013), especially for African Americans. In fact, African Americans have much higher disease and death rates than other racial and ethnic groups in this country (Kawachi, Daniels, & Robinson, 2005). The disparity of life expectancy across ethnic groups remains staggering. The gap between the highest and lowest life expectancies for race–county combinations in the United States is currently over 35 years (Murray et al., 2006). In the case of African Americans, disparities in mortality and life expectancy are predicted to increase (Levine et al., 2001). The overall mortality rate was 31% higher for African Americans than for White Americans. African Americans were 46% more likely to die

First Edition. General Editor: Lee M. Cohen. Volume Editor: Suzy Bird Gulliver.

from a stroke, 32% more likely to die from heart disease, and 23% more likely to die from cancer (CDC, 2013). Even when receiving corrective medical surgery, African American patients are twice as likely as White patients to experience mortality (Nathan, Frederick, Choti, Schulick, & Pawlik, 2008).

Numerous studies have been conducted to identify the cause of health disparities between African Americans and Whites. These studies have identified individual and/or group factors such as obesity, low health literacy (Schwartz, Crossley-May, Vigneau, Brown, & Banerjee, 2003), and lower SES (Mandelblatt, Andrews, Kao, Wallace, & Kerner, 1996), as well as institutional factors, such as health insurance status (Bradley, Given, & Roberts, 2001), patient dumping (Randall, 1993), lack of a primary health provider, less qualified doctors (Bao, Fox, & Escarce, 2007), and other factors that, singly or combined, play a causal role in the creation and persistence of health disparities. However, after controlling for many of these factors, the health disparities across racial groups still remain.

The Role of Cultural Mistrust

The construct of *cultural* mistrust has been defined as a tendency of African Americans to distrust White people, based upon a legacy of direct or vicarious exposure to racism or unfair treatment (Benkert, Peters, Clark, & Keves-Foster, 2006). Terrell and Terrell (1981) first proposed *cultural mistrust* to describe the extent to which African Americans may distrust institutional systems in the United States that are dominated by the White majority; some of the relevant institutions include the education system, politics, business, and interpersonal contexts that may coincide with daily interactions. In addition to these domains, the healthcare system has also been identified as an institution that can elicit cultural mistrust (Benkert et al., 2006).

Understanding why African Americans tend to report greater distrust of the healthcare system requires consideration of a specific historical context within the United States. Often, blame for the disproportionate mistrust of the healthcare system held by African Americans is attributed to the infamous Tuskegee syphilis study. This study, conducted by the US Public Health Service, involved the recruitment of hundreds of African American men in order to document the severity of syphilis and its symptoms when left untreated; the study continued long after penicillin was identified as an effective treatment. For many African Americans, the Tuskegee syphilis study serves as a vivid example of African Americans being deliberately victimized by an institution in the healthcare system (Kennedy, Mathis, & Woods, 2007). However, it is important to note that this case of gross mistreatment is "symbolic for the larger problem of African American distrust of the largely White medical establishment which has evolved in the presence of racial discrimination, racial inequalities in quality of care received, and a previous history of medical research misuse" (Shavers, Lynch, & Burmeister, 2000, p. 571).

Historically, those who now *mistrust* the *dominant group* (Whites) either were once held in captivity (African Americans were *legally* held in chattel slavery), were deprived of their rights to citizenship (Asian Americans), were exploited for their labor and cheated out of their lands (Mexican Americans), or endured genocide and were forced into concentration camps called reservations (Native Americans). While these were governmental policies and practices, often it was medical scientists and practitioners that legitimized and implemented these activities. Specifically, a substantial number of leading American scientists and medical doctors believed in eugenics, a practice they thought would improve the genetic quality of mankind. The US government, along with the medical profession, embarked on two such programs—one known as positive eugenics and the other known as negative eugenics. Positive eugenic strategies involved urging individuals deemed particularly "fit" (Whites—in particular, Nordics and Aryans) to marry and procreate. Negative eugenics, on the other hand, was meant to actively limit, or control, the "genetically inferior" (e.g., those with low intelligence scores, those believed to be mentally deficient, criminal, and people of color—in particular, those of African American heritage). Negative eugenic practices included abortion, sterilization, and castration, among others. Segregation, incarceration, and terror were employed to keep the "genetically inferior" in their place, and physically limit their ability to increase in number, until such time as it would be acceptable to exterminate them.

By the 1950s, 24 states had anti-miscegenation laws that forbid Whites to marry non-Whites (in particular, African Americans). Additionally, in the United States, the government had compulsory sterilization laws; too often, women of color were sterilized without their knowledge. This strategy was used to control the "genetically inferior" populations, which included immigrants, people of color, poor people, unmarried mothers, the disabled, the criminal, the violent, and the mentally ill. As a matter of fact, government-funded sterilization programs existed in 32 states throughout much of the twentieth century. Driven by prejudiced attitudes, which fostered pseudoscience and social control, these programs were the driving force that fostered ill-conceived policies on immigration and segregation.

Today, if healthcare practitioners' treatment of African Americans were to reflect a normal bell curve distribution, one would be led to presume that (a) the overwhelming majority of doctors do their job without consideration of race; (b) some doctors mistreat, or even purposefully harm, African Americans; and (c) some doctors make extreme efforts to make sure that African Americans receive treatment consistent with the "gold standard" of medical care (i.e., prescribe the best diagnostic tests or medical treatments available). Unfortunately, evidence indicates that the medical treatment of African Americans is far from a normal distribution but is instead skewed to the low end of treatment (Smedley, Stith, & Nelson, 2003). The evidence indicates that healthcare professionals exhibit the same levels of implicit bias toward African Americans as the wider population. Correlational evidence indicates that biases are likely to influence care in diagnosis, treatment decisions, and levels of medical care given in some circumstances, and these discrepancies need to be further investigated.

According to Dr. J. Corey Williams (2017), a psychiatrist, it is "no surprise that Blacks do not trust doctors or hospitals" (p. 2). He goes on to say that medical practice discrimination takes many forms, including differential prescription patterns such that African American patients, in contrast to Whites, are less likely to receive better-tolerated or more effective medications. African Americans are also more likely to receive an older treatment protocol, with reduced effectiveness and worse (i.e., more severe or deleterious) side effects, rather than the "gold standard" treatment, which has comparatively superior health effects and fewer or milder side effects. In addition, African Americans who go to emergency rooms often wait longer to see a doctor, are permitted less time spent with a doctor, and receive comparably poorer treatment (Williams, 2017).

This type of unfair and abhorrent treatment of African American patients has been noted on more than a few occasions. For instance, in 2003, the Institute of Medicine issued a report titled "Unequal Treatment" (Smedley et al., 2003) after reviewing over 100 studies concluding that African Americans do not receive the same quality of treatment as Whites, even when insurance status, patient income, and access to care were held constant. Specifically, African Americans received fewer referrals, more incorrect diagnoses, poorer provider–patient communication, and so on. One of the many egregious findings was the significantly higher mortality rate from breast cancer seen in African American women. Despite the lower incidence of breast cancer in African American women and the higher rate of aggressive breast cancer in White women, African American women had a much higher mortality rate even when the number of doctor visits was held constant (Bradley et al., 2001). When searching for a reason for this anomaly, it became clear that physicians employed less aggressive and less appropriate treatment for African American women than for White women (National Cancer Institute, 2003). Discriminatory treatment of African Americans in healthcare is well recognized, yet the literature to a certain extent "blames the victim," namely, African American patients.

In addition to the influence of historical and present abuses, researchers have also investigated modern perceptions of African Americans in order to understand the role of cultural mistrust in health outcomes. In a series of focus groups among African American patients, themes related to medical mistrust emerged when patients reported feeling that their symptoms were discredited and clinicians did not convey respect during their communications (Cuevas, O'Brien, & Saha, 2016). Earlier research had likewise found that racial/ethnic minorities are significantly more likely to report being treated with disrespect during interactions with their healthcare provider (Blanchard & Lurie, 2004). Valid and reliable instruments that specifically measure cultural mistrust can facilitate investigations designed to assess the perceptions of African Americans. Furthermore, tailored measurement can contribute to the identification of correlates and predictors of important health attitudes, behaviors, and, ultimately, health outcomes.

Measuring Cultural Mistrust

The most common measure of cultural mistrust is the Cultural Mistrust Inventory (CMI), which was developed by Terrell and Terrell (1981). The CMI is a 48-item questionnaire assessing the extent to which African American people mistrust White people in societal domains of education (e.g., "If a black student tries, he will get the grade he deserves from a White teacher"), business (e.g., "White storeowners, salesmen, and other White businessmen tend to cheat Blacks whenever they can"), politics and law (e.g., "White politicians will promise Blacks a lot but deliver little"), and interpersonal relations (e.g. "Whites will say one thing and do another").

Researchers have administered the questionnaire in order to determine if responses are significantly associated with attitudes (e.g., perceived discrimination) and behaviors (e.g., treatment adherence) in the healthcare setting. Despite the well-documented utility of the CMI (Whaley, 2001), the questionnaire does not specifically assess mistrust of the healthcare system; this creates a potential limitation when extending research on cultural mistrust to healthcare settings. Decades after Terrell and Terrell (1981), the Group-Based Medical Mistrust Scale (GBMMS) (Thompson, Valdimarsdottir, Winkel, Jandorf, & Redd, 2004) was developed in order to specifically measure the extent to which respondents exhibit race-based medical mistrust. Thompson et al. argued that an instrument specifically designed to measure mistrust in healthcare settings was warranted, because attitudes and behaviors in healthcare settings may present a unique area of concern given the legacy of medical disparities and abuses experienced by racial/ethnic minorities.

The GBMMS is a 12-item measure that assesses suspicion of mainstream healthcare systems (e.g., "People of my ethnic group should be suspicious of modern medicine"), suspicion of healthcare professionals (e.g., "People of my ethnic group cannot trust doctors and healthcare workers"), and perceptions about the treatment provided to individuals that identify with the respondent's racial/ethnic group (e.g., "I have personally been treated poorly or unfairly by doctors or healthcare workers because of my ethnicity"). Previous research has produced evidence demonstrating the validity of the GBMMS, and the measure has been incorporated into several investigations of health attitudes and behaviors exhibited by African Americans (Shelton et al., 2010).

Perception, Utilization, and Adherence

The importance of patient attitudes has been emphasized in research on the perceptions of healthcare providers and patient satisfaction (Hall & Dornan, 1988). Furthermore, researchers have also measured patient attitudes in relation to perceptions about help-seeking and perceived discrimination. Evidence suggests that cultural mistrust can partially explain attitudes reported by African Americans in healthcare settings. In a study of men diagnosed with prostate cancer, African Americans reported greater medical mistrust than Whites, and medical mistrust was negatively associated with physical and emotional well-being (Bustillo et al., 2017). Benkert et al. (2006) collected responses from low-income African Americans across two primary care clinics, and they found that CMI scores were negatively correlated with trust in a patient's primary healthcare provider. Furthermore, CMI scores were also negatively correlated with indicators of patient satisfaction with healthcare.

Previous research has also revealed racial and ethnic differences in use of healthcare services (i.e., frequency, duration; Weinick, Zuvekas, & Cohen, 2000). Consideration of cultural mistrust can improve understanding of behaviors exhibited by African Americans in the healthcare setting. In a study of preventive care utilization among African American women, greater cultural mistrust predicted a significantly lower likelihood of receiving a physical exam in the previous year (Pullen, Perry, & Oser, 2014). Thompson et al. (2004) found that African American and Latina women who reported that their last breast cancer screening was more than 5 years ago, or who reported no previous breast cancer screening, had significantly higher GBMMS scores. In a related study of preventive health behaviors, Shelton et al. (2010) found that higher scores on the GBMMS were negatively associated with favorable attitudes about prostate cancer screening among African American men. A similar pattern emerged in a systematic review of quantitative and qualitative research on cultural mistrust and colorectal screening, wherein African Americans with higher mistrust scores reported lower rates of receiving colorectal screening (Adams, Richmond, Corbie-Smith, & Powell, 2017).

The importance of patients' adherence to treatment, and its relationship to positive health outcomes, is well documented in the literature. Furthermore, poor adherence to medical treatment can contribute to racial/ethnic disparities in health outcomes (McQuaid & Landier, 2018). The influence of cultural mistrust is significant because it can potentially impact a patient's decision to adhere to their medical treatment or follow the recommendations of their physician. For example, in a study of self-care among African Americans diagnosed with type 2 diabetes, greater cultural mistrust was associated with lower adherence to dietary interventions (deGroot et al., 2003). In conclusion, mistrust of the medical profession has been shown to be a major obstacle to African Americans seeking health treatment and properly adhering to health regiments.

Promoting Trust

Cultural mistrust has a deleterious effect on the quality of the relationship between African Americans patients and their physicians. In order to improve the quality and content of their interactions with patients, physicians and medical staff need to understand that cultural mistrust is primarily derived from suspicions at an organizational level, and they must recognize that this mistrust among African Americans is an adaptive defensive strategy stemming both from historical abuses and modern disparities. Cultural competency initiatives have been implemented in systems of physical and mental healthcare. One approach to enhance cultural competency, and to improve patient interactions, is to increase cultural sensitivity and awareness of cultural mistrust so that it can be directly addressed.

Trust can also be fostered through the training and recruitment of racial/ethnic minority care providers. Some African Americans may feel more comfortable in healthcare settings when their provider is African American as well. Doctor–patient race concordance has been associated with an increased likelihood of utilizing health services when needed and a decreased likelihood of delayed help-seeking (LaVeist, Nuru-Jeter, & Jones, 2003). While race concordance does not always produce significant differences in health behaviors, the improved representation of African Americans in healthcare roles can partially address concerns related to cultural mistrust. Based on the existence of several directories that have compiled lists of African American care providers, there appears to be a strong interest in race concordance within segments of the African American population.

Improving trust among African Americans could also involve partnering with the Black church. Among African Americans with strong ties to their community church, disseminating health information in an environment where they feel more comfortable can foster trust. Health campaigns that aim to raise awareness and increase health service utilization can improve outcomes by recognizing the importance of pastors and by allowing them to advise and also play a significant role in the promotion of health behaviors that can potentially mitigate disparities.

Conclusion

Lacking trust in the healthcare system and its providers can influence both service utilization and treatment adherence and thereby influence health outcomes for African Americans. Additionally, differential treatment and disparate outcomes experienced by African Americans could confirm their potential suspicions and consequently exacerbate existing tendencies to lack trust in the healthcare system. Therefore cultural mistrust of healthcare can serve as a predictor of attitudes and behaviors among African Americans, or it can be conceptualized as an outcome that stems from perceived or actual medical mistreatment. These perspectives underscore the importance of examining cultural mistrust and how it may relate to African American health trends. Improving trust among African Americans requires sustained effort on several fronts. Healthcare organizations, providers of care, researchers, and community advocates should give careful consideration to the historical and modern experiences of African Americans in order to inform the development and implementation of interventions. Establishing (or earning) the trust of African Americans will require various methods at individual, situational, and organizational levels, because "just as there are many reasons for the mistrust, there is no one answer that will solve all of the mistrust issues" (Kennedy et al., 2007, p. 60).

Author Biographies

Brandon L. Carlisle, PhD, is a senior mental health researcher in the Department of Psychiatry at the University of California, San Diego. He contributes to research focusing on the evaluation and improvement of behavioral health services provided to children, youth, and families. His research interests include identifying barriers to seeking and receiving care and the importance of cultural competence when providing care to diverse populations.

Carolyn B. Bennett Murray, PhD, is currently a full professor in the Psychology Department at the University of California, Riverside (UCR). She received her PhD from the University of Michigan, Ann Arbor, and has published numerous journal articles and book chapters. Her primary research interest is self-sabotage. A few of her many awards include the Chancellor's Award for Excellence in Undergraduate Research, the Association of Black Psychologists' Distinguished Psychologist Award, and the UCR Distinguished Teaching Award.

Health Disparities

Melissa Ward-Peterson and Eric F. Wagner

Department of Epidemiology, Florida International University, Miami, FL, USA

Introduction

Racial and ethnic minority groups, rural populations, populations with low socioeconomic status (SES), and other marginalized and medically underserved minority populations persistently experience higher than average rates of illness, impairment, and death. For example, diabetes is more than three times as likely to be a cause of death for Native Americans than for other racial/ethnic groups (66.0 per 100,000 population compared with 20.8 per 100,000) (Indian Health Service, 2018). This health disparity, along with others plaguing Native American communities, has contributed to a life expectancy that is 5.5 years shorter than that of the general US population (Indian Health Service, 2018).

These types of disadvantages in health and longevity suffered by minority groups are referred to as **health disparities** (Braveman, 2014). Compared with non-Hispanic Whites, minority racial and ethnic populations experience earlier onset of illness, more severe disease, and poorer quality of care (Williams, Mohammed, Leavell, & Collins, 2010; Williams, Priest, & Anderson, 2016). Minority racial and ethnic populations also experience dramatically lower SES (e.g., income, education, occupation), which is associated with poorer health and reduced longevity (Williams et al., 2010, 2016). However, the relationship between SES and health varies by race. Research has shown as SES levels increase, the health differences between Blacks and Whites become more pronounced, supporting a *diminishing returns hypothesis* for SES vis-à-vis health among minority groups (Farmer & Ferraro, 2005).

Since health disparities adversely affect groups of people who are socially and/or economically disadvantaged, health disparities reflect social injustices. **Health equity** refers to the ideology, motivation, and actions behind correcting these social injustices and eliminating health disparities (Braveman, 2014). A health equity perspective adheres to the human rights principles of nondiscrimination and equality (Braveman, 2014) and presumes that health disparities ultimately are avoidable if the underlying social structures and arrangements creating and maintaining social injustices are addressed (Pearlin, Schieman, Fazio, & Meersman, 2005).

The Wiley Encyclopedia of Health Psychology: Volume 4: Special Issues in Health Psychology,
First Edition. General Editor: Lee M. Cohen. Volume Editor: Suzy Bird Gulliver.

While the alleviation of health problems experienced by minority individuals may be accomplished through the types of direct interventions common in health psychology, the alleviation of health disparities affecting marginalized minority groups can only be accomplished through social change.

Conceptualizations of Health Disparities

There is consensus among health disparities scholars that contextual exposures, a life-course approach, and the consequences of discrimination, intersectionality, and residential segregation must be taken into account in efforts to understand and eliminate health inequities. Each of these key conceptualizations of health disparities is described next.

Contextual exposures refer to the collection of neighborhood, environmental, socioeconomic, and cultural exposures influencing health (Benn & Goldfeld, 2016; Ruiz & Brondolo, 2016; Williams et al., 2016). Minority individuals are disproportionately exposed to toxic social and environmental contexts that reduce health and longevity (Ruiz & Brondolo, 2016). Toxic contextual exposures directly disrupt biological functioning by producing alterations in gene expression, causing tissue and organ damage and dysregulating stress response and recovery systems (Williams et al., 2016). At least in theory, and hopefully in practice, contextual exposures can be changed in ways that improve health and promote health equity and thus are an increasing focus of health disparities research (Benn & Goldfeld, 2016).

A **life-course approach** is essential in efforts to understand and address the drivers of health disparities. Health disparities emerge from exposure to adversity throughout the life course, including before conception, in utero, and throughout infancy, childhood, and adolescence (Williams et al., 2016). A life-course approach takes into account how risks, resources, and demands linked to race, ethnicity, and SES early in life influence health later in life and systematically considers how these factors combine and accumulate with biological factors to affect health outcomes (Braveman, 2014; Williams et al., 2016). Pearlin et al. (2005) point out that health disparities result from differential exposure across the life course to different demands and hardships. For example, exposure to persistent adversity over time produces greater wear and tear on physiological systems, resulting in physiological dysregulation, with consequent health problems; the various terms used by health disparities scholars for this process include *allostatic load*, *weathering*, *cumulative physiological dysregulation*, and *biological risk profile* (Peek et al., 2010). Among marginalized minority and low SES groups, exposure to multiple adversities across time dramatically increases these individuals' allostatic loads (Pearlin et al., 2005). It is well established that higher allostatic loads are associated with increased mortality, morbidity, cognitive decline, and disability (Peek et al., 2010).

A unique contributor to the allostatic load of individuals from marginalized and stigmatized groups is **discrimination**. Discrimination results from the exertion of power by dominant groups to preserve their relative privilege over subordinate groups (Krieger, 2014). Discrimination falls into several categories of justifying ideologies, including racism, sexism, heterosexism, ableism, nativism, ageism, and class bias (Krieger, 2014). There are two overarching types of discrimination: de jure discrimination, which is legally permissible in the societies where it occurs, and de facto discrimination, which is not legally allowed but occurs nonetheless because of social and cultural norms (Krieger, 2014). Some of the most frequently cited examples of de jure discrimination are Jim Crow laws, which legalized discrimination against African Americans in the Southern states from the late nineteenth century through the mid-twentieth century (Krieger, 2014). Although racial discrimination is now prohibited by law, de facto discrimination continues to be a rampant and destructive issue problem for minority groups, due in no small part to the norms de jure discrimination cemented into American society during the Jim Crow era (Krieger, 2014).

Studies have found that experiencing discrimination is associated with victimization, poor sexual functioning, less REM stage (deep) sleep, more abdominal fat, elevated hemoglobin A1c, coronary artery calcification, uterine myomas, breast cancer, healthcare underutilization, poor treatment adherence, and alcohol, tobacco, and drug use problems (Williams et al., 2010). Discrimination represents an abject violation of human rights. The experience of discrimination, and the stereotypes and prejudice that go along with it, may foment negative social psychological processes (e.g., internalized racism, status incongruence, rising expectations), emotional dysregulation, and impaired stress reactivity and recovery that pile onto an already burdensome allostatic load (Farmer & Ferraro, 2005; Ruiz & Brondolo, 2016; Williams et al., 2010).

Discriminatory experiences have long half-lives—the psychic pain inflicted by discrimination includes not only the pain of the discriminatory experience itself but also worrisome thoughts and emotions about when it will happen again and why it keeps happening again and again (Pearlin et al., 2005). Moreover, while discrimination is often overt and obvious, there are more subtle discriminatory attitudes and actions that contribute to health disparities experienced by marginalized minorities. **Microaggressions** are subtle insults and subjective reminders to marginalized groups of their oppressed status in society (Sue, 2010). Similar to overt types of discrimination, experiencing microaggressions erodes self-esteem and self-worth and raises the allostatic burden, further compromising the health and longevity of marginalized minority groups.

Of course, it is unrealistic to assume all individuals belong to only one socially subordinate group that is exposed to discrimination. While a White woman will encounter challenges posed by sexism, a Black woman will encounter the combined challenges posed by sexism and racism. Worse still will be the lived experience of a Black lesbian, whose life will be impacted not only by sexism and racism but also by heterosexism. First proposed in 1989, **intersectionality** is a framework for understanding this phenomenon of compounding disadvantage caused by membership in more than one subordinate group (Crenshaw, 1989). Intersectionality has been extended to describe challenges posed by sexual orientation and class as well (Bowleg, 2012). Intersectionality is a critical perspective to take when seeking to understand the causes and effects of health disparities experienced by individuals with more than one identity (Bowleg, 2012).

Enduring **residential segregation** by race/ethnicity and income is a particularly pathogenic example of systemic discrimination and is considered “the most critical distinctive social exposure” driving health disparities (Williams et al., 2016). As enumerated by Williams et al. (2010), the pathways through which residential segregation adversely affect health include:

1 socioeconomic immobility by limiting access to quality elementary and high school education, preparation for higher education and employment;
2 suboptimal health practices because of conditions created by concentrated poverty;
3 economic hardship and compound stressors for individuals, households, and communities;
4 difficulties and mistrust among neighbors due to weakened community and neighborhood infrastructure;
5 institutional neglect and disinvestment leading to increased exposure to environmental toxins, poor quality housing, and criminal victimization; and
6 limited access to and low quality of healthcare.

Historical and Current Examples of Health Inequities

The following section provides some historical and current examples of health inequities and the factors driving them. While the examples offered here are by no means exhaustive and focus only on the social context of the United States, they offer an important glimpse into the complex realities facing marginalized communities. The examples illustrate how structural social injustices have dire implications for the health of minority groups. Additionally, they underscore the relevance of the life-course and intersectionality perspectives and show just how pernicious health disparities are in our society.

Historical Examples

A life-course approach emphasizes the role longitudinal exposure plays in creating health disparities. Therefore, scholars interested in health equity must be actively engaged in a broad historical perspective on the social conditions that have produced current circumstances. Historical events can impact the health and well-being of those who lived through them and of later generations.

One example can be found in the historical practice of "redlining," in which banks refused to provide home loans in neighborhoods deemed undesirable (Aaronson, Hartley, & Mazumder, 2018). For minority populations, this practice eliminated access to the financial capital needed to purchase homes. Aaronson, Hartley, and Mazumder estimate discriminatory lending practices contributed to up to half of the disparities in Black/African American home ownership between 1950 and 1980. The systematic obstruction of this path to wealth had a cumulative effect on future generations by limiting the assets that were passed from parents to their children and grandchildren.

A second example can be found in the enduring *historical trauma* experienced by Native Americans. Beginning with first contact and continuing through subsequent colonization and the expansion of the United States, indigenous communities have suffered through genocide, dislocation, and other deplorable patterns of violence inflicted upon them by the colonists and their descendants. The cumulative adverse effects of this history are known as "historical trauma," which describes the profoundly negative, long-term, and intergenerational impact of colonization, cultural suppression, and historical oppression on indigenous peoples (Brave Heart, Elkins, Tafoya, Bird, & Salvador, 2012). The manifold health disparities experienced by Native Americans (e.g., significantly greater morbidity and mortality from diabetes, cancer, substance use, obesity, bronchiolitis, and injuries; Indian Health Service, 2018) are at least partially attributable to massive historical trauma imposed across many generations.

Contemporary Examples

A life-course approach is also valuable when examining contemporary examples of health disparities. A child belonging to a minority group is more likely to be born into racial residential segregation and underprivileged communities, a remnant of redlining and Jim Crow-era discriminatory practices. In the United States, Black, Latino, and Native American children disproportionately grow up in neighborhoods with constrained opportunity structures, underresourced schools, compound and unrelenting stress, and toxic social and physical environments (Braveman, 2014; Pearlin et al., 2005; Williams et al., 2010).

Environmental exposures are of critical importance during childhood when cognitive and physical development is vulnerable. Lead exposure, which may occur through poor housing conditions or contaminated water, is an especially nefarious environmental toxin because it causes cognitive deficits that limit children's academic potential, thereby altering their futures (Zhang et al., 2013). Racial/ethnic disparities in lead exposure have persisted for decades; low-income Black and Hispanic children residing in older housing continue to have the highest prevalence of exposure (Jacobs, 2011). The most effective way to address lead exposure is to move into a new residence or neighborhood, but this solution is not feasible for the groups most frequently affected. Despite the known risks of even low levels of lead exposure (Lanphear, Dietrich, Auinger, & Cox, 2000) and evidence supporting the effectiveness of interventions that address these risks (Jacobs, 2011), health disparities due to differences in environmental exposures endure. As a result, environmental justice must remain at the forefront of efforts to achieve health equity.

Disparities continue into late adolescence and young adulthood. For minority men in the United States, incarceration becomes an important determinant of health. Incarceration is a "disorderly transitional" stressful event that creates nonnormative, undesired, involuntary, and often irreversible life changes (Williams et al., 2010). Incarceration is associated with subsequent homelessness, employment and financial difficulties, destabilization of relationships, increased health risks, and other impediments to health and well-being (Iguchi, Bell, Ramchand, & Fain, 2005). In 2016, Black individuals were incarcerated at a rate five times higher than that of White individuals (1,608 per 100,000 people compared with 274 per 100,000), and the number of Black children in juvenile detention far exceeds the number of White children in juvenile detention (Gramlich, 2018; Iguchi et al., 2005). The preceding speaks to the putative influence of incarceration on health disparities and the importance of measuring incarceration in studies of health and longevity differences between Black and White individuals (Williams et al., 2010).

Distinctive health disparities are experienced by minority women. In 2011, among Black and Hispanic women, 64 and 50% of pregnancies were unintended, respectively, compared with 38% of pregnancies among White women (Finer & Zolna, 2016). Once pregnant, Black women can expect drastically increased maternal morbidity and mortality compared with White women (Tucker, Berg, Callaghan, & Hsia, 2007). From 2010 to 2014, Black women died at a rate of 40.0 per 100,000 live births, while White women died at a rate of 10.4 per 100,000 live births (Centers for Disease Control and Prevention [CDC], 2018). Potential mediators such as educational achievement do not seem to improve outcomes for Black mothers; a 2016 study conducted by the New York City Department of Health found the rate of severe maternal morbidity for college-educated Black mothers was still more than twice the rate for White mothers who had not graduated from high school (New York City Department of Health and Mental Hygiene, 2016).

Similar to individuals who are racial/ethnic minorities, individuals who are sexual minorities (LGBTQIA) are also subject to de jure and de facto discrimination throughout their lives. While some states have passed laws that explicitly protect LGBTQIA individuals from employment discrimination and hate crimes, many states have not (Krieger, 2014). In fact, as of 2017, 12 states had passed laws allowing for the denial of services to LGBTQIA individuals, largely based on the strongly held religious beliefs of business owners (Raifman, Moscoe, Austin, Hatzenbuehler, & Galea, 2018). Evidence has shown that LGBTQIA individuals in states with de jure discriminatory practices have higher rates of mental distress than LGBTQIA individuals from states without de jure discrimination (Raifman et al., 2018).

Health Disparities Research Priorities

Health disparities are receiving increasing attention in health psychology. Though it has long been recognized that marginalized minority groups experience large disadvantages in health and longevity, only recently have sophisticated models and associated empirical work on health disparities and their alleviation begun to appear in the literature. As the literature has grown, so has extramural funding opportunities for conducting research explicitly intended to understand and eliminate health disparities. The following section enumerates several current research priorities for future research on decreasing health disparities and promoting health equity.

Health Disparities Research Priorities

1. Develop multivariate, multilevel, transdisciplinary, integrative, life-course models to guide research on contextual exposures, their epigenetic effects, and the onset and course of illness among vulnerable populations (Ruiz & Brondolo, 2016; Williams et al., 2010, 2016).
2. Conduct research focused on modifiable drivers of improved health outcomes among vulnerable populations (Benn & Goldfeld, 2016; Ruiz & Brondolo, 2016).
3. Identify influential contextual exposures and optimal intervention strategies at each specific point of the disease continuum based on research conducted with both healthy and clinical populations (Ruiz & Brondolo, 2016; Williams et al., 2010).
4. Understand resilience and coping in the context of social disadvantage and stress (Ruiz & Brondolo, 2016; Williams et al., 2010).
5. Ascertain the degree to which medical care and genetic factors contribute to racial and SES differences in health (Williams et al., 2010).
6. Explore the intersections of race, ethnicity, SES, sex, gender, immigration status, and other variables alongside experiences of discrimination and health outcomes (Ruiz & Brondolo, 2016; Williams et al., 2010).
7. Estimate the heretofore under-examined contributions of occupational stress, work environment, community violence, and diet to health disparities (Peek et al., 2010; Williams et al., 2010).
8. Attend to the putative influences of acculturation, assimilation, and biological risk on the Hispanic paradox, the health and longevity advantage of foreign-born (vs. US-born) Hispanics (Peek et al., 2010; Williams et al., 2010).

Call to Action

Racial and ethnic minority groups, LGBTQIA groups, rural populations, populations with low SES, and other marginalized and medically underserved minority populations persistently experience earlier onset of illness, more severe disease, poorer quality healthcare, and disproportionate morbidity and mortality from disease. These health disparities are long standing and result from historical and contemporary structural and social injustices such as constrained opportunity structures, under-resourced schools, compound and unrelenting stress, toxic social and physical environments, de jure and de facto discrimination, residential segregation, and the experience of microaggressions. The development and testing of multivariate, multilevel, transdisciplinary, integrative, life-course models of health disparities is urgently needed, especially in regard to modifiable drivers of health outcomes among vulnerable populations. Although additional research is critically important, advocacy, community engagement, and effective communication of findings to decision makers and the lay public are all indispensable and urgent for advancing health equity and eliminating health disparities. While the health risks and health problems experienced by marginalized minority groups may be modifiable on an individual level through behavior change as per conventional health psychology practices, the long-term elimination of health disparities is dependent on social change.

Author Biographies

Melissa Ward-Peterson, PhD, MPH, is a postdoctoral associate in the Community-Based Research Institute at Florida International University in Miami, Florida, where she manages the Research Infrastructure Core for FIU's Research Center in Minority Institutions (FIU-RCMI). A social epidemiologist by training, her research interests include disparities in access to substance abuse treatment and women's health. She has extensive experience in health equity research and program management and has provided technical support for projects sponsored by a number of federal and international agencies, including HRSA, NIH's Fogarty International Center, the US Department of State, the World Health Organization, the World Bank, and UNAIDS.

Eric F. Wagner, PhD, is the director of Florida International University's (FIU) Community-Based Research Institute, a professor in FIU's Stempel College of Public Health & Social Work, the principal investigator of FIU's NIMHD-funded Health Disparities Research Center in a Minority Institute, and a psychologist licensed to practice in Florida (active) and Rhode Island (inactive). His clinical research expertise is addressing substance use and related problems among teenage, young adult, and underrepresented medically underserved populations. His work has been supported by grants from NIAAA, NIDA, NIMHD, HRSA, SAMHSA, the Ware Foundation, the Aetna Foundation, and Consejo Nacional de Ciencia y Tecnología.

Injury, Accident, and Injury Prevention

Kristi Alexander[1] and Riley Cropper[2]

[1]Department of Psychology, University of Central Florida, Orlando, FL, USA
[2]Stanford University Counseling and Psychological Services, Stanford Hospital and Clinics, Stanford, CA, USA

Worldwide, unintentional injuries are one of the greatest threats to the health and well-being of people. Nine percent of all deaths globally are attributable to injuries (World Health Organization [WHO], 2017), and unintentional injury is the leading cause of death for children older than 9 years (Ameratunga & Peden, 2009). In the United States alone, injuries are the leading cause of death for people 1–44 years (Centers for Disease Control and Prevention [CDC], 2018). For every injury death, there are countless more hospitalizations, emergency room visits, and primary care treatments.

Unintentional injuries have been defined in a variety of ways, but for the purposes of this entry, these are unplanned events that result in bodily harm or tissue damage (WHO, 2008). Baker (1992) defined injury as "physical damage that results when a human body is suddenly subjected to energy in amounts that exceed the threshold of physiological tolerance—or else the results of a lack of one or more vital elements such as oxygen." Although what constitutes an "unintentional injury" varies somewhat by who is defining the term, research and policy has typically limited the definition to harm that occurs without intent such as injuries sustained during a motor vehicle accident, poisonings, drownings, falls, and burns (WHO, 2008).

There are some differences, however, in how the public interprets and defines unintentional injuries and accidents. Girasek (2015), in a survey of over 900 adults, found differences between the public's and professionals' interpretation of the word. Specifically, many professionals prefer not to use the term "accident," as they believe it reinforces the common misconception that injuries are not preventable or predictable. However, Girasek found that the term "accident" evoked associations with preventability in 83% of the public surveyed. Although the term "accident" may imply a lack of predictability, the reality is that injuries almost always involve foreseeable high-risk behaviors and are therefore typically predictable and preventable.

The Wiley Encyclopedia of Health Psychology: Volume 4: Special Issues in Health Psychology,
First Edition. General Editor: Lee M. Cohen. Volume Editor: Suzy Bird Gulliver.

Across the globe, unintentional injuries represent the greatest threat to the health and safety of people across all ages. According to the WHO (2017), 9% of all deaths worldwide are attributable to injuries, which is approximately 1.7 times the number of deaths resulting from HIV/AIDS, tuberculosis, and malaria combined. Millions more people, who are not killed, are injured and incur lifelong disabilities as a result of injury. In the United States alone, unintentional injuries were the third leading cause of death in 2016 across all age groups (National Safety Council [NSC], 2018) demonstrating that unintentional injuries do not only affect children and young adults, but individuals across the lifespan.

Although unintentional injuries occur at every age, around the world, young people are differentially impacted. For people between the ages of 15 and 29 years, road traffic injuries are the number one cause of death for both men and women. Younger children are also at high risk to die as result of a traffic injuries and drowning. Furthermore, poverty increases the risk of injury-related death; about 90% of such deaths occur in low- and lower-middle countries (Wegman, 2017). For example, more than two-thirds of all road traffic child deaths occur in underdeveloped communities of Southeast Asia and Africa (WHO, 2008). Additionally, in the United States, there are significant racial and ethnic differences in mortality rates. For example, in comparison to European Americans, the risk of a fire-related death is significantly greater for Native American and African Americans over 55 years (Bishai & Lee, 2010). Lastly, there are robust gender differences, emerging at birth and lasting until old age, resulting in boys and men being significantly more likely to be fatally injured (NSC, 2018).

Across the lifespan, there are predictable patterns both in the United States and the world in the types off unintentional injuries that occur. Many factors contribute to these differences including cognitive and motor skills. Worldwide, suffocation is the leading cause of death in infants younger than 1 year; falls are the most common *nonfatal* injuries treated in the emergency department (WHO, 2008). The risk of fall injury increases dramatically over the first year of life, reflecting the impact of motor skill development on injury risk.

For children 1–4 years, the leading causes of injury death for children across the world are drowning, followed by road traffic injuries (WHO, 2008). Unfortunately, this trend continues throughout childhood, with drowning and traffic injuries remaining the leading causes of injury death for children across the globe.

In the United States, motor vehicle injuries, including both traffic and pedestrian deaths, are the leading cause of death beginning at age 5. With regard to *nonfatal* unintentional injuries, US children are most likely to sustain an injury due to a fall (5- to 9-year-olds) or being struck by or against an object or person (NSC, 2017). School-age children are more likely to be injured when they are playing outside and away from the home, most commonly on the playground, while playing sports, or as a pedestrian.

Road traffic injuries are the leading cause of death across the world for adolescents and young adults (15–29 years; WHO, 2017). It is during this developmental period that the largest gender difference in motor vehicle deaths is realized with boys and men sustaining significantly more than girls and women (WHO, 2017). In addition, serious nonfatal injuries for adolescents and young adults result from being struck by or against an object or person.

For adults worldwide, road traffic injuries drop to the third cause of death after age 30 (WHO, 2017). During this same developmental period, falls are the leading urgent cause of *nonfatal* injury. In the United States, injury is the seventh leading cause of death for older adults (65 years +) (CDC, 2018). Of these injury deaths, falls are the most prevalent cause for Americans 65 or older. In addition to falls, which account for 85% of injury deaths in this age group, older adults are vulnerable to motor vehicle injuries, poisonings, and lacerations (DeGrauw, Annest, Stevens, Xu, & Coronado, 2016).

Older adult pedestrians are especially vulnerable to severe injury or death as a result of a pedestrian–vehicle collision. In the United States, the fatality rate for pedestrians over 65 was higher than the rate for all other adults. In addition, in comparison with children or adults less than 60, adults over 60 had a higher injury severity risk in a full-frontal pedestrian–car collision (Niebuhr, Junge, & Rosén, 2016).

Despite the seemingly random nature of unintentional injuries, there are some psychological and temperamental characteristics that have been repeatedly associated with increased risk for injuries. Sensation seeking, or a desire to experience novel situations, is a temperamental characteristic that has been repeatedly implicated as a risk factor for unintentional injuries across the lifespan (Morrongiello, Sandomierski, & Valla, 2010; Schwebel, 2004). For example, children that demonstrate higher levels of sensation seeking tend to pursue novel situations regardless of the presence of physical risk, which in turn increases their risk for injury (Morrongiello et al., 2010). Similar results have been found with adults; multiple studies examining driving behavior have found an association between sensation seeking and an increased risk for motor vehicle accidents (Graziano et al., 2015; O'Jile, Ryan, Parks-Levy, Betz, & Gouvier, 2004). O'Jile et al. (2004) also found that men scored higher in sensation seeking, which may partially explain why males have higher rates of unintentional injuries across the lifespan.

Another temperamental characteristic that has been linked to increased injury risk is impulsivity, or the tendency to quickly react to novel stimuli (Schwebel, 2004; Stavrinos et al., 2011). Although the exact link between impulsivity and injury risk is unclear, it has been proposed that individuals that are more impulsive may overestimate their physical abilities, as they react quickly to stimuli without thoughtfully considering their ability to complete the task. For example, Thomson and Carlson (2015) found that in combination with other variables, high impulsivity was associated with risky skiing and snowboarding in adults. Further, inhibitory control, or the capacity to suppress behavioral responses, has also been shown to play a role in the relationship between impulsivity and unintentional injury. For example, Stavrinos et al. (2011) found that an individual's ability to inhibit impulsive responses while crossing the street (e.g., darting into the street before assessing safety) significantly impacted his or her risk for pedestrian injury. Thus far, inhibitory control is the only temperamental characteristic that has been shown to reduce an individual's risk for injury, as those who possess this quality are more likely to perceive potential dangers and avoid them, be controlled and cautious, engage in less dangerous behavior, and comply with rules (Schwebel, 2004).

Prevention

Unintentional injuries have a substantial impact around the world, but ultimately, they are largely predictable and preventable (WHO, 2017). In the United States alone, research suggests the over 90% of pediatric injuries could have been prevented if someone had done something to change the circumstances prior the injury (Rimsza, Schackner, Bowen, & Marshall, 2002). Although research over the past few decades has identified those demographic and behavioral characteristics that increase the risks of unintentional injury, the development and evaluation of effective injury prevention programs has lagged (CDC, 2018).

Unintentional injury prevention has proven to be a difficult issue to address worldwide. Globally, prevention has decreased unintentional injury deaths substantially (Ameratunga & Peden, 2009), but the gains have not been equally realized (Vecino-Ortiz, Jafri, & Hyder, 2018). While high-income countries have realized significant improvements in safety and prevention of injury, low- and middle-income countries have not (WHO, 2017). As previously noted, the vast majority of injury-related deaths occur in low- and middle-income countries where safety and prevention efforts appear to have not caught up with the developments that increase risk. Specifically, low- and middle-income countries have 90% of the world's road traffic deaths but only have half of the vehicles in the world (WHO, 2017). Consequently, road traffic deaths have been steadily increasing in India and Cambodia over the past decade and over two-thirds of all *child* road traffic deaths occur in under-resourced countries in Southeast Asia and Africa (WHO, 2017). In the United States, there are also significant racial and ethnic disparities in unintentional injury death rates (Pollack & LaVeist, 2012).

To date, legislatively mandated and environmental prevention strategies have been among the most successful interventions in decreasing specific injuries (Christoffel & Gallagher, 2016). In the United States, laws that mandated the use of child safety seats, smoke detectors, and graduated driver licensing have each been effective in reducing unintentional injuries (Gardner & the Committee on Injury, Violence, and Poison Prevention, 2007). Similarly, in Asia and Europe, helmet laws have significantly reduced motorcyclist deaths (Araujo, Illanes, Chapman, & Rodrigues, 2017), and Australian pool fencing legislation has decreased child drowning deaths (Franklin & Peden, 2017). Environmental interventions, such as child-resistant packaging for prescription and over-the-counter medicines and air bags, have been effective in decreasing injuries, but there is a perception within the field that these types of interventions may have been "exhausted" (Gielen, Sleet, & DiClemente, 2006). This has led to a current focus on behaviorally based prevention strategies such as teaching swimming and water safety to reduce drownings, the use of safety equipment in sports, and teaching motorists to avoid texting while driving (CDC, 2018; WHO, 2017).

Although effective, behaviorally based prevention strategies require action (Sleet & Gielen, 2008). Even when injury prevention interventions are mandated by law, there remains a behavioral component; children need to wear helmets while bicycling, smoke alarms need to be checked, and seat belts need to be buckled. Unfortunately, many factors influence the adoption of injury prevention behaviors. For example, research has found that even when the efficacy of prevention programs for sports injuries is well established, a minority of coaches employ them with their players (Norcross, Johnson, Bovbjerg, Koester, & Hoffman, 2016). Similarly, other research has demonstrated that over 50% of parents of young children fail to use prevention measures to reduce injuries at home, making even the "most effective" strategies largely ineffective in preventing the occurrence of unintentional injuries in children (Tsoumakas, Dousis, Mavridi, Germou, & Matziou, 2009). Thus, understanding factors influencing compliance is key to increasing the effectiveness of prevention strategies.

However, compliance is not the only issue, as unintentional injuries still occur even when interventions are implemented correctly with absolute compliance. Therefore, the current prevention strategies seem to be failing to address some aspect of this problem (Schwebel & Barton, 2006). In an attempt to resolve this issue, researchers have begun to take a greater multidisciplinary focus as they formulate new interventions. For example, prevention strategies that focus on psychology, public health, medicine, and engineering simultaneously in order to address the beliefs and behaviors of the individual and caregiver as well as the environmental characteristics that contribute to increased injury risk (Schwebel & Barton, 2006).

Integrated Primary Care

Sandra B. Morissette[1] and Brian Konecky[2]

[1]Department of Psychology, The University of Texas at San Antonio College of Sciences, San Antonio, TX, USA

[2]Boise VAMC Virtual Integrated Multisite Patient Aligned Care Team Hub, Boise, ID, USA

Integrated primary care involves the delivery of mental and behavioral health services within primary care settings. There are numerous terms for this care delivery system including primary care mental health integration (PCMHI) or integrated primary care behavioral health (IPCBH). Some contend that the term "behavioral health" may be less stigmatizing than "mental health"; therefore, henceforth the term IPCBH is used. This terminology is important for consideration, as a major aim of IPCBH programs is to reduce stigma and other barriers to care (e.g., location, scheduling separate appointments, longer waiting times) by providing behavioral health services directly within the primary care setting. Integrated care, in which the IPCBH provider is part of the primary care treatment team, is distinguished from co-located care (referral within the same medical center) and coordinated care (behavioral health services referred to a separate location). The rationale for integrating mental and behavioral health services within primary care settings is that often primary care providers (PCPs) are the first point of contact for patients to address their mental and behavioral health concerns. Further, failure to detect mental health conditions along with underutilization of mental health services can lead to negative health outcomes for patients and place significant burden on healthcare systems. Thus, by design, the IPCBH provider works closely with the patient's medical provider as an integrated part of the primary care team to improve access and deliver seamless coordination of care for both physical and mental/behavioral health conditions. This seamless coordination of services is perhaps best exemplified by "warm handoffs" in which PCPs introduce patients to an IPCBH provider during a medical visit. This decreases barriers to care, the burden of scheduling, and stigma and also allows for a patient to have a same-day visit with an IPCBH provider when needed. Further, warm handoffs increase communication between all treatment team members and the patient and can occur multi-directionally between PCPs, IPCBH providers, and IPCBH prescribers.

IPCBH models focus on population-based care in which fewer, more specific services are offered to more individuals, in contrast to specialty mental health services in which more intensive treatments are offered to patients with more severe clinical presentations. Generally, IPCBH treatments are designed to be brief (one to six sessions) and are shorter in duration (20–30 min) than typical 50- to 60-min specialty psychotherapy sessions. Patients who are perceived as being able to benefit from such brief interventions, including preventative interventions, are seen within primary care. Should it be determined at any point in treatment that the patient needs a higher level of care or more intensive treatment, the patient is referred to specialty mental health services. However, should the patient need care sooner than the availability of specialty services (e.g., waitlist is too long), the IPCBH provider may opt to engage in watchful waiting to observe the progression of symptoms or begin treatment within primary care and then transfer the patient to specialty services when available. Likewise, if a patient needs specialty mental health services but is not ready for such, the IPCBH provider may work with the individual to increase motivation or basic coping strategies. In this manner, patients are seen at the most appropriate level of care, reserving briefer and more targeted interventions for those within the primary care setting and more intensive treatments for those needing specialty services. This can ease burden on the healthcare system by treating mental and behavioral conditions promptly and allocating resources appropriately. This systemic structure also allows for PCPs to feel confident that their patients' behavioral health needs are being addressed while still being able to maintain their clinic schedules. IPCBH programs have been developed within both pediatric and adult primary care settings.

IPCBH Models of Care

Models of IPCBH have been developed dating back to the 1970s, although they were not widely adopted until decades later. Stemming from a growing demand for behavioral healthcare, numerous models have been developed, but none on the scale and scope of the Veterans Health Administration (VHA), the largest healthcare system in the United States. For that reason, this summary focuses on VHA IPCPH programs, which were implemented within medical centers across the nation using three primary models: Behavioral Health Laboratory (BHL) care management model (Tew, Klaus, & Oslin, 2010), White River Model of Colocated Collaborative Care (Pomerantz et al., 2010), and Translating Initiatives for Depression into Effective Solutions (TIDES). VHA medical centers were required to adopt one of these three models and then adapt them to fit within and meet the unique needs of their primary care context and patients. This has led to multiple variations of the below models being implemented and utilized in varying forms. By doing such, a person's health and well-being can be enhanced by interprofessional collaboration aimed at highlighting and intervening at the intersection between physical health, habits, and emotional health, with same-day access to behavioral health services being the norm.

The BHL is a care management model that was designed to help screen and treat common mental health conditions (depression, anxiety, addictions) in the primary care setting. It is a team-based approach involving the patient, the PCP, a care manager (typically a nurse, social worker, or psychologist), and a supervising psychiatrist. BHL staff provide support to PCPs, who are considered central to treatment planning. In particular, BHL staff assist with a structured patient identification process to determine those in need or at risk. Once a patient is identified, they are invited to complete a BHL initial assessment either in person or by telephone, during which patient education is provided and treatment recommendations are made. Specialized software provides BHL staff with decision support logic, clinical reports, and patient tracking. Recommendations can include care management, prevention and "watchful waiting" (i.e., to determine if symptoms will progress), specialty care services, or no treatment. As needed, BHL staff provide patient-centered services delivered through virtual clinics, telephone assessments, and in-person services. Further, they provide education, behavioral activation (e.g., addressing ambivalence about change and developing an action plan), and assistance with decision making by both patients and providers. Brief evidence-based interventions (e.g., for alcohol misuse, depression/anxiety care management, and monitoring of response to new antidepressants) are also provided as indicated. Throughout this process, care managers work collaboratively with the PCP to attend to the patient's behavioral health needs.

The White River Model of Colocated Collaborative Care is an open-access model in which patients are seen within primary care on a walk-in basis in order to improve access and reduce wait times. Staffing includes a therapist (psychologist or masters level), psychiatrist or advanced practice nurse, and a clerk. Importantly, staff are co-located directly within primary care space in order to facilitate warm handoffs from the PCP or discussion of patient needs. Patients can self-refer for services or be identified through screening processes, their PCP, or specialty providers. Once identified, the clerk gives the patient an electronic touchpad to complete self-report measures to screen for common presenting concerns (e.g., depression, posttraumatic stress disorder, anxiety, and health and well-being) that can inform the focus of the visit. The therapist then conducts a brief assessment to evaluate psychosocial history and the presenting problem and begins discussing treatment options. The psychiatrist or advanced nurse practitioner then conducts a medical evaluation to determine whether any medical conditions are contributing to the behavioral health symptoms, following which a treatment plan is developed and treatment initiated to include psychotherapy, medication, or both. Psychotherapy is delivered in individual and group formats (e.g., psychoeducation or brief cognitive behavioral therapy [CBT]) and is generally brief, although in keeping with the open-access model patients can opt to conduct sessions in coordination with their PCP visits over time. One week following initiation of the treatment plan, a nurse care manager contacts the patient by telephone to follow up to see how the patient is doing.

The TIDES model was developed in response to the need to help the large number of patients struggling with depression in the primary care settings, including suicide risk management. TIDES was developed using evidence-based quality improvement (EBQI) methods. EBQI is a quality improvement approach with the aim of translating research treatments into routine clinical practice. As with the other models, TIDES includes elements demonstrated to be useful in collaborative care models (i.e., care management, support of patient self-care, assessment and follow-up by care managers, collaboration between PCP and non-physician staff, and referral to specialty mental healthcare). A care manager and mental health specialist play key roles in collaboration with the PCP. The care manager is typically a nurse, given the need for this person to be at ease with monitoring antidepressant medications and medical comorbidities. The care manager conducts initial assessments to determine program eligibility, followed by education about depression for all patients, and behavioral activation. Within the medical record, there is a templated program that aids the provider with determining which patients should be referred for care management. The care manager then assists the PCP with management of depression within primary care, including up to six months of follow-up as needed, or referral to specialty mental health. The mental health specialist likewise plays a key role working with patients who have complex conditions, providing supervision to care managers, as well as delivering educational trainings for PCPs.

IPCBH Treatment Interventions

Because of the varied clinical presentations that occur in primary care settings, the IPCBH provider must have knowledge of a wide variety of health conditions and brief interventions. Conditions treated in IPCBH include those in the realms of mental health, lifestyle changes, and medical psychology. Patients presenting problems can include anxiety, posttraumatic stress disorder, depression, adjustment difficulties, role transitions, relationship problems, attention deficit hyperactivity disorder, grief and loss, dementia, bipolar disorder, personality disorders, and thought-related disorders. As described above, patients are triaged to the appropriate level of care dependent on availability and willingness. However, at times a patient with a serious mental illness may receive a brief intervention within an IPCBH setting. Lifestyle changes can include any issues that are getting in the way of a person's health or well-being, often involving smoking cessation, substance misuse, problems with sexual behavior, problem-solving strategies, chronic pain management, insomnia, weight management, or wanting to change behaviors related to interpersonal relationships. Medical conditions frequently addressed include but are not limited to diabetes, heart disease, hypertension, headaches, spinal cord injury, traumatic brain injury, medication adherence, preparation for stressful medical/medication procedures, age-related decline, adjustment to illness, or terminal illness. Patients are helped to consider and work on the relevant cognitive, behavioral, emotional, social, spiritual, and environmental aspects of their health conditions. Most chronic health conditions have a large behavioral contribution, rendering the role of psychological interventions in the prevention and treatment of such critical. Given the nature of the IPCBH model, it is important to remember that most IPCBH interventions are brief and targeted and involve multi-directional communication among the care team. Below, we describe general mental and behavioral health services offered and review the state of the science in behavioral interventions. Notably, although psychotropic medications are often prescribed by PCPs or IPCBH prescribers (e.g., psychiatrist, psychiatric mental health nurse practitioners), a full summary of such prescription practices is beyond the scope of this summary. Generally, IPCBH prescribers provide expert consultation to PCPs regarding medication management or prescribe medications themselves. IPCBH prescribers may see patients for one to six sessions, triaging them back to their PCP when stable or to specialty mental health if brief intervention/stabilization is unlikely.

Mental and behavioral health interventions are typically aimed at providing psychoeducation, helping patients increase motivation to change, setting adaptive goals, increasing psychological flexibility, decreasing maladaptive avoidance patterns, identifying and challenging irrational or unhelpful thinking patterns, making behavioral changes, clarifying values, coping with stress, and improving problem-solving skills. Patients are also often helped to adhere to medical treatments, engage in appropriate self-care strategies, and best utilize their primary care team. The 5A's framework (Hunter, Goodie, Oordt, & Dobmeyer, 2016) is frequently utilized and is a conceptual model where a therapist will *A*ssess, *A*dvise (options for treatment), *A*gree (on goals), *A*ssist (in moving toward goals), and *A*rrange for follow-up. As with most psychotherapy relationships, the core components of empathy, rapport building, alliance, and positive regard are present in IPCBH interventions.

The state of the science for brief interventions being utilized within IPCBH models is in its early stages of development and varies greatly across interventions for differing problems. Several behavioral health interventions have been adapted for use within primary care settings, including depression, anxiety disorders, posttraumatic stress disorder, and health psychology interventions (e.g., chronic pain, sleep, obesity, diabetes, smoking cessation, etc.). Treatments are primarily adapted to fit the briefer models necessary within a primary care context. As these treatments are developed, there is a push to begin empirical validation of their utility based on the current zeitgeist valuing empirically supported treatments. Many treatments that have been or are being adapted for brief models emanate from CBT, acceptance and commitment therapy, solution-focused/problem-solving therapy, and motivational interviewing. These types of interventions are strong candidates for being adapted for IPCBH as they have an established evidence base when implemented in traditional therapy modalities and are well suited to be modified to fit a brief model. Specifically, certain components of larger treatment protocols are efficacious when used in a dismantled approach (e.g., stimulus control or sleep restriction from a full CBT manual for insomnia). When considering the state of the science for brief interventions in primary care, another challenge is that it is not uncommon for providers and the subsequent research evaluating the interventions to have been conducted with people who meet full diagnostic criteria for disorders, which is not necessarily the population IPCBH models are intended to treat. In an extensive literature review, the Center for Integrated Health's White Paper on embedded behavioral health providers in VA IPCBH concluded that the state of the research on co-located collaborative care is primarily quasi-experimental or in the form of observational studies of programs (Beehler et al., 2015). However, interventions targeting tobacco use and alcohol use have a strong evidence base and can be implemented in a manner consistent with primary care clinical practice. The Society of Clinical Psychology's website section of psychological treatments (https://www.div12.org/psychological-treatments/) is a reputable resource that provides information and categorizes the strength of research regarding interventions for specific disorders and currently reflects the state of the research described above. Further research is clearly indicated to foster adoption of IPCBH programs and optimize patient care practices.

In addition to delivering care in person and via telephone, IPCBH interventions are also being delivered via emerging technologies in efforts to decrease barriers to care and reach underserved populations (e.g., those in rural communities). These interventions are typically delivered by what is commonly referred to as clinical video telehealth (CVT). Typically included in CVT encounters are a service provider(s), a service recipient(s), Internet connections of reasonable bandwidth, a software interface that allows for secure connections, and hardware on both ends of the connection to facilitate communication and run the software (e.g., computer, tablet, smartphone, speakers, microphone, webcam technology). Both individual and group sessions can be facilitated and conducted across multiple locations in synchrony. Services can be provided across states lines (theoretically globally) and in a myriad of conglomerations regarding where the provider and recipients are located (e.g., medical center to medical center, medical center to home, home to home, home to medical center). It is worth noting that the legal and ethical aspects of such service delivery are still being established as technology advances.

Within VHA, IPCBH via CVT is being more widely offered in two basic modalities. First, it is being utilized by providers who work traditional IPCBH roles in brick-and-mortar VA settings. These providers typically see veterans in person and then implement CVT as clinically indicated with veterans as needed. Second, Boise VA is rolling out a new telehealth model of healthcare designated as Virtual Integrated Multisite Patient Aligned Care Team (V-IMPACT; for full review see Ambert-Pompey, Konecky, Ahlstrom, & Keefer, 2017). Within V-IMPACT, mental and behavioral health services are implemented through IPCBH. Brief CVT assessment and interventions are provided by psychologists, neuropsychologists, social workers, and psychiatric prescribers (i.e., psychiatrists, psychiatric nurse practitioners) who work in tandem with other staff (e.g., nurse, support assistants, telehealth clinical technician) in distant locations. In this manner, CVT can augment traditional IPCBH practices by facilitating broader outreach and accessibility of behavioral health interventions.

The Beginnings of Neuroimaging

Approximately 30 years ago, one of the first human neuroimaging experiments was published (Petersen, Fox, Posner, Mintun, & Raichle, 1988; Posner, Petersen, Fox, & Raichle, 1988). Researchers used a technique called positron emission tomography (PET) to map locations in the brain that were more active during various language tasks than when the participant was lying still staring at an image of a crosshair. Though revolutionary at the time, these findings represented only a first step in our understanding of how to think about cognition and the human brain by asking a very basic question—"where in the brain do these cognitive processes happen?"

It was not long until the field began to rely less heavily on PET, turning to a technique called functional magnetic resonance imaging (fMRI), which both avoided the need to expose participants to ionizing radiation and promised greater temporal and spatial resolution. In the beginning, fMRI was used much like PET in that participants performed cognitive tasks in a blocked manner, responding to stimuli multiple times over the course of 2 or 3 min. Researchers would then average the signal across that period of time to get an estimate of brain activity. However, not long after, researchers began to wonder if they could estimate brain activity on each separate trial. After all, the assumption that all responses within a block were uniform was surely inaccurate, as participants were certainly responding more quickly during some trials or perhaps answering incorrectly. In 1996 and 1997, two seminal papers (Boynton, Engel, Glover, & Heeger, 1996; Dale & Buckner, 1997) were published that set guidelines for how

First Edition. General Editor: Lee M. Cohen. Volume Editor: Suzy Bird Gulliver.

fMRI could be used to detect activity at the single-trial level. The details that led to this conclusion are beyond the scope of this chapter, but suffice it to say that the field of cognitive neuroscience had now opened up a whole new set of questions, unlocked by analytical advances made in a very short time span.

In 1998, researchers from Harvard (Wagner et al., 1998) and Stanford (Brewer, Zhao, Desmond, Glover, & Gabrieli, 1998) published a pair of studies that asked the question, “can we predict whether or not a word or picture will be remembered in the future, based on brain activity witnessed at an earlier time?” The answer was a resounding yes and led to the proliferation of what are termed event-related fMRI experiments. The discovery of the neural correlates of cognitive events, captured in single trials, has led to a deeper understanding of how attention, learning, memory, emotion, decision making, language, and a whole host of other domains are instantiated in the human brain.

The Advent of Functional Connectivity

Fast-forward another 5–7 years to two papers published in the *Proceedings of the National Academy of Sciences* (PNAS) (Fox et al., 2005; Greicius, Srivastava, Reiss, & Menon, 2004) that would launch what is still today the most widely researched single topic in fMRI—a technique known as resting-state functional connectivity MRI (RSFC). Instead of measuring discrete brain activity time-locked to an event or stimulus, RSFC measures correlations of slow, or low-frequency, brain activity across regions. For some time, neuroscientists were skeptical that this was a useful technique and instead decided that these slow waves of activity were probably just noise. However, researchers became more convinced of the utility of RSFC because the correlations between brain regions appeared to recapitulate known sets of regions that would typically be deployed in a task setting (Power et al., 2011). In other words, regions that co-activate when performing a task also tend to co-fluctuate in the absence of any overt task. RSFC is a particularly powerful technique because it (a) allows for the identification of all major brain systems with one scan, without having to create a large battery of tasks; (b) is thought to represent the statistical history of brain function; (c) enables study of populations that cannot perform complex tasks; and (d) is not confounded by group differences in task performance. Why hadn’t anyone noticed this phenomenon until now? After all, a great deal about sensory and motor brain systems was understood even before PET and fMRI, and interrogation of these regions in these systems was possible. The simple answer is that someone did notice. In 1995, Bharat Biswal and colleagues (Biswal, Yetkin, Haughton, & Hyde, 1995) showed that low-frequency correlations were present in the motor system of human individuals in the absence of an explicit task. The brain maps showed clear representation of the motor systems not just in the cerebral cortex but also in subcortical structures and the cerebellum. So why did it take so long for RSFC research to become so mainstream on the order of 8–10 years after Biswal’s finding? The answer is likely complex and by no means singular. Perhaps the transition from blocked to event-related design had gotten sufficient attention from the field to keep researchers busy enough asking about cognitive tasks. Perhaps it was not until the early twenty-first century that neuroscientists recognized the promise of RSFC for clinical populations. No matter the reason, the notion that an idea or technique that does not get immediately picked up in any scientific domain does not necessarily spell the end for that line of research. Instead, the adoption of techniques and the ability for ideas to take center stage must sometimes wait their turn until they are championed under the right circumstances.

Is Functional Connectivity Modifiable?

In 2009 and 2010, three papers (Lewis, Baldassarre, Committeri, Romani, & Corbetta, 2009; Stevens, Buckner, & Schacter, 2010; Tambini, Ketz, & Davachi, 2010) were published that addressed whether the correlations between brain regions could be changed with an intervening task tapping learning or attentional processes. The underlying assumption drawn from studies showing the one-to-one correspondence between systems discovered with functional connectivity and those discovered during task-evoked studies was that functional connectivity followed Hebbian principles. Instead of the "fire together, wire together" rule put forth by Hebb (Hebb, 1949), the concept as it pertains to RSFC is that regions that co-activate during tasks co-fluctuate at rest. It would stand to reason, then, that researchers should be able to induce stronger correlations by having participants engage in tasks where specific regions are known to co-activate. Indeed, this has now been consistently shown in the literature, with the field moving from proof-of-principle studies to experiments that aim to discover which regions or networks of regions are modified by a task or intervention. This discovery-based approach lends itself to fMRI studies with a high degree of clinical relevance, because scientists can ask about treatment interventions that have demonstrated success and determine potential mechanisms of brain plasticity. For instance, a study by Liston and colleagues (Liston et al., 2014) examined RSFC patterns in the brains of patients with and without depression, treated the depressed patients using repetitive transcranial magnetic stimulation (rTMS), and asked what brain networks were affected. More specifically, which RSFC patterns that were abnormal before treatment with rTMS looked like the patients without a depression diagnosis? The study found that modulation of connectivity with the subgenual cingulate cortex, a region previously implicated in depression, was one potential mechanism by which rTMS may act to alleviate symptoms.

Functional Connectivity and Health Psychology

Interestingly, although the field of health psychology has not adapted behavioral studies to determine whether the modification of specific brain systems underlie things like physical health, within-subject RSFC designs lend themselves well to this topic of study. For instance, a plethora of research has focused on links between exercise, wellness, and brain function (Geda et al., 2010), asking whether exercise can mediate the effect of aging on cognitive impairment. However, current RSFC studies have not manipulated variables like exercise and ask whether increased (or decreased) exercise causes a change in brain organization. Like other studies focusing on psychiatric disorders, mechanisms of action can be elucidated with such a design because of its interventional nature. Instead, the marriage of health psychology and fMRI has existed inside studies that use brain activity at one timepoint to predict health outcomes related to weight gain (Demos, Kelley, & Heatherton, 2011) or the propensity to engage in behaviors that impact physical health, like smoking (Wagner, Dal Cin, Sargent, Kelley, & Heatherton, 2011). The shift from prediction to within-subject intervention would represent a movement toward a less correlative, more causal scientific framework.

Perhaps the biggest contribution of functional connectivity to the field of health psychology is in the realm of chronic pain, as syndromes such as chronic back pain (CBP), fibromyalgia, diabetic neuropathy, and complex regional pain syndrome (CRPS) have been examined (Thorp et al., 2018). Studies of chronic pain have shown consistently that regions of insular cortex are abnormal in patients who deal with a variety of related pain disorders. As such, this brain region, and specifically the extent to which it is functionally connected to other regions that are part of its network in healthy adults, can help to provide a proxy for diagnostics and an understanding of how therapy may modify and strengthen these networks. As we will argue in the next section, the degree to which we can map specific brain regions in the insula onto individual anatomy will determine the degree of precision with which we can make claims and ultimately decide whether a relationship between insula connectivity and pain symptoms can move the field forward to personalized medicine approaches in chronic pain.

How to Make FMRI More Clinically Relevant to Health Psychology

Since its inception, fMRI has held considerable promise as a technique that could revolutionize how we think about and treat psychiatric disorders. However, it is all too clear that little progress has been made in advancing our understanding of how mental health abnormalities translate to brain abnormalities and how that information can inform treatment. A key roadblock toward success may stem from an over-reliance on experiments that ask how two groups differ from one another. Although sampling from large numbers of individuals to determine the average of some brain-based measure is appealing when trying to estimate differences in central tendencies between groups, what often gets lost are idiosyncratic features of data in specific individuals. We know this is the case when, for instance, a group of patients with posttraumatic stress disorder (PTSD) have a wide range of scores on measures that tap different clusters of symptoms. To some degree, this kind of variance may be unavoidable. However, when we map RSFC or activation data onto a group average brain template, as is standard in most fMRI research, neuroscientists also run the risk of distorting *where* differences exist among individuals in an attempt to describe central tendencies of connectivity. In other words, when we add fMRI to the mix, another layer of data must be contorted in order to perform appropriate statistical comparisons in "brain space," but this comes at a significant cost because functional anatomy is highly heterogeneous. So how do we overcome this added layer of distortion? The answer is to collect far more data from the individual patient than the vast majority of the field currently does in order to greatly reduce within subject variance in data like RSFC so that functional data can be mapped to the patient's own anatomy (Gordon et al., 2017, 2018; Laumann et al., 2015; Poldrack et al., 2015). The famous neurophysiologist William T. Newsome once said, "in order to understand brain function, we must respect the integrity of cortical organization." The same can be said in our attempt to understand brain disorders. That is, each individual brain has a specific structural and functional organization that should not be averaged together to arrive at a difference in central tendencies. Instead, in order to make fMRI and human neuroscience clinically relevant, we need to embrace discoveries we make at the individual level, even if at first we do not understand them or we are slogging through data collection because of the increased labor that goes into one participant. This highly sampled individual-based approach provides our best chance of mapping brain to behavior and in the end is likely to guide precision treatments that are tailored to specific patients.

Author Biography

Steven M. Nelson received his bachelor's degree in psychology and mathematics from Winona State University (Winona, MN). We went on to receive his PhD in Neuroscience at Washington University in St. Louis, where he stayed on as a post-doctoral scholar and research scientist.

He is currently the chief of the Neuroimaging Core at the VISN 17 Center of Excellence for Research on Returning War Veterans, where he uses functional MRI to study veterans with post-traumatic stress disorder and traumatic brain injury.

Palliative Care

Mamta Bhatnagar and Robert C. Arnold

Department of Medicine, University of Pittsburgh Medical Center, Pittsburgh, PA, USA

Definition

Palliative care is both a model of care and a specialty focusing on improving quality of life for patients and family with serious illness. It focuses on providing patients with relief from symptoms, pain, and stress of a serious illness—whatever the diagnosis. The goal is to improve quality of life for both the patient and the family. It is appropriate at any age and at any stage of a serious illness. It can be provided at the same time as disease treatment to help people live as well as possible while facing illness (Center to Advance Palliative Care, n.d.).

Psychology and psychologists are an integral part of the palliative care team. During progression of a serious illness, patients and family members have to adjust significantly to the reality of care focused on disease and symptom management without a cure. Psychological concepts such as resilience, coping, grief, anxiety, and depression are thus central to the work of palliative care (Patterson, Croom, Teverovsky, & Arnold, 2014). Psychologists can provide support and psychosocial interventions to assist with anticipatory grief and adjustment reactions, mental disorders, existential and spiritual issues, advance care planning, life review, and unresolved issues that are likely to surface as meaningful concerns (Haley, Larson, Kasl-Godley, Neimeyer, & Kwilosz, 2003).

Models for Palliative Care Delivery and Their Growth in the United States

In the United States much of the growth in specialty palliative care has been in the inpatient setting. This has been fueled by data showing cost avoidance as well as nonrandomized trials that suggest improved patient satisfaction and outcomes (Cassel, Kerr, Pantilat, & Smith, 2010; Morrison et al., 2008, 2011; Norton et al., 2007). The number of hospitals with

The Wiley Encyclopedia of Health Psychology: Volume 4: Special Issues in Health Psychology,
First Edition. General Editor: Lee M. Cohen. Volume Editor: Suzy Bird Gulliver.

palliative care teams increased from 658 to 1,744 between 2000 and 2013 (a growth of 165%) (Dumanovsky et al., 2016). There is however substantial variability in the availability of palliative care throughout the United States. For example, the presence of palliative care team is significantly influenced by geography, hospital size, hospital type (academic medical centers, faith-based institutions), and tax status (for profit versus not for profit) (Dumanovsky et al., 2016). All VA hospitals and over 67% hospitals with more than 50 beds provide palliative care (Spetz et al., 2016).

Hospital-based palliative care consultation is provided by an interprofessional team that can include physicians (including generalists and specialists, as well as psychiatrists), advanced practitioners (nurse practitioners and physician assistants) and nurses, social workers, psychologists, chaplains, pharmacists, and volunteers. A study exploring staffing of palliative care programs registered with the National Palliative Care Registry found only a quarter of the programs had a fully funded team with chaplains and social workers being the most common member who was voluntary or absent. A fully staffed palliative program provides better hospital penetration (percentage of patients who receive a palliative care consultation) and is better able to meet the needs of seriously ill patients with more timely consultations (Spetz et al., 2016). The goals of the palliative care team are to provide expert pain and symptom management, education and communication about achievable goals for care, support for decisions matched to patient and family goals, psychosocial support, and coordination of care. The goal of the consultation service is to support the referring clinician.

While the dominant model for specialty palliative care services is a consultant model, many programs also have a palliative care unit. In the National Palliative Care Registry, 5% of programs had dedicated palliative care units, typically found in larger and more mature programs (Spetz et al., 2016). Palliative care units usually serve patients who have difficult-to-control symptoms; medical needs that cannot be optimally managed in another setting; distressed families in need of a higher level of support; need for transfer out of a critical care setting; patients who are imminently dying. A high-volume palliative care unit may reduce in-hospital care costs by matching treatments provided to patient and family-determined goals for medical care. In one study, a dedicated palliative care unit reduced daily hospital costs by 74% compared with usual care patients (Smith et al., 2003).

Few studies have compared quality of care among different palliative care models. In a phone survey of US Veterans Administration (VA) medical centers that offered both models of inpatient care, family members of patients in a palliative care unit were significantly more likely to report excellent care in the last month of life when compared with families of patients who received a palliative care consultation (Casarett, Johnson, Smith, & Richardson, 2011). The palliative care unit group also scored highest in three of four process measures (do not resuscitate order at the time of death, documented chaplain visit, and bereavement contact after the patient's death).

Bringing palliative care into the emergency department (ED) has also been found to be beneficial. Recently a randomized controlled trial (RCT) of palliative care consultation for patients with advanced cancer showed improved quality of life metrics and median estimated survival (Kavalieratos et al., 2016). Additionally, patients with non-cancer diagnoses such as dementia, congestive heart failure (CHF), and chronic obstructive pulmonary disease (COPD) also benefit from palliative care consultations in the ED with one study showing that these patients had shorter lengths of hospital stay (Wu, Newman, Lasher, & Brody, 2013). Currently, palliative care services in the ED are usually consultations by an inpatient palliative care team. A more comprehensive approach also involves services or training initiated by palliative care champions in the ED and ED partnerships with hospice providers. The nature of the palliative care intervention across randomized trials has been difficult to compare; however nonrandomized trials continue to show benefit from various ambulatory palliative care services (M. Rabow et al., 2013). A recent meta-analysis of 43 RCTs, of which 14 were conducted in the ambulatory setting, examined whether palliative care interventions improve quality of life, symptom burden, healthcare utilization, and patient/caregiver satisfaction. Palliative care was associated consistently with improvements in advance care planning, patient and caregiver satisfaction, and lower healthcare utilization along with statistically significant improvement in quality of life (Kavalieratos et al., 2016).

Ambulatory palliative care programs focus on delivering care aimed at better quality, improved access, and lower costs. Unlike inpatient consultation teams, ambulatory programs tend to have a wide range of structures. They can be consultative clinics in which specialty palliative care teams take referrals from other providers either as stand-alone clinic that is able to take referrals from different specialties or embedded programs within a specialty service. While the benefits of early palliative care consultations in clinics are being increasingly recognized (see below), the growth of outpatient palliative care programs has been less robust. A survey of cancer centers across America found that the ones designated by the National Cancer Institute (NCI) were more likely to have outpatient palliative care services, specifically 59% as compared with 22% in nondesignated centers (Hui et al., 2010).

There is strong evidence supporting outpatient palliative care programs providing early palliative care. Notable studies include outpatient consultations for patients with advanced cancer that showed improvement in fatigue, pain, depression, anxiety, and sleep after at least one initial visit (Yennurajalingam et al., 2012). Also, a widely publicized study from Temel and colleagues showed improved quality of life and depression as well as 2.7 months' increased survival among patients with metastatic non-small cell lung cancer (Temel, Greer, & Muzikansky, 2010). Similar benefits have also been reported in patients with advanced COPD and CHF (M. W. Rabow, Dibble, Pantilat, & McPhee, 2004).

Other models that have been explored for delivering palliative care are in nursing homes and in home-based primary care programs and collaborative care models in the emergency department. In nursing homes, specialty palliative care can be delivered by hospice organizations, external palliative care consultation team, or an internal palliative care team. The consultative team still comprises a physician accompanied by either a nurse or an advance practice provider. Formal palliative care services in the nursing home are rare because regulatory, payment, and staffing barriers prevent implementation (Meier, Lim, & Carlson, 2010). One study showed improved quality of care with palliative care consult, reducing ER visits and depression, and promoted more appropriate care resulting in more favorable clinical outcomes at the end of life (EOL) (Comart et al., 2013). Palliative care teams in the nursing home can provide valuable education to nursing home staff on recognition of adverse prognostic signs among the frail elderly and incorporating palliative care skills into their care.

Home palliative care models are also evolving. Successful home programs such as the Sutter Health Program of Advanced Illness Management in California have shown an increase in hospice referrals up to 60%, 54% reduction in hospital admissions, 80% reduction in ICU days, and 26% reduction in inpatient length of stay (Ciemins, Stuart, Gerber, Newman, & Bauman, 2006). As accountable care organizations (ACO) continue to grow in the United States, there is a high likelihood that more integrated models of palliative care throughout the care continuum will emerge.

Hospice as a System of Provision of Palliative Care at the EOL in the United States

Although the philosophy of palliative care is nearly congruent with that of hospice care, the scope of hospice care is not identical because it differs in terms of both timing and types of patients served. While both improve quality of life, palliative care is available to patients who continue to benefit from life-prolonging treatments. Access to palliative care is not dependent on prognosis, and there are no federal or commercial insurance benefits specific to palliative care with no formal eligibility criteria.

Hospice is both a philosophy of care and a regulated insurance benefit. The Medicare hospice benefit was enacted by the US Congress in 1982 and is the dominant source of payment for hospice care; 84% of patients who receive hospice services in the United States are covered by Medicare. Patients are eligible to receive hospice care reimbursed under the Medicare hospice benefit if they meet the following criteria: (a) the individual has a life expectancy of 6 months or less if the disease follows its expected course, as certified by two physicians, and (b) the individual forgoes Medicare reimbursement for ongoing therapy or curative medical treatment related to the terminal diagnosis. While there are some general guidelines for certifying the presence of a terminal illness that are applicable to all diseases, there are also specific disease-related guidelines. For example, the hospice eligibility criteria for ALS are vital capacity less than 30%, critical nutritional impairment, and life-threatening complications. The presence of any two of these three can qualify a patient for the Medicare hospice benefit for ALS. While these guidelines are helpful, they are based on clinical opinion rather than data (McCluskey & Houseman, 2004).

Since the first program was established in the United States in 1982, it has grown rapidly. Currently there are 6,100 programs in the country, mostly independent agencies. They vary in size; some hospices serve only 50 patients per year to large national corporate chains that care for thousands of patients each day. They also differ in their for-profit status with only about 28% holding not-for-profit tax status. Simultaneously, the number of patients served by hospice has increased from 25,000 in 1984 to almost 1.4 million in 2015 (National Hospice and Palliative Care Organization, n.d.).

Federal regulations require a core of hospice services be provided by all hospice providers. Core services comprise skilled nursing, physician services, volunteer services, counseling services that include bereavement counseling, spiritual care, dietary, and social services. Services that can be outsourced by hospice providers include physical therapy, occupational therapy, speech language pathology, home healthcare, and homemaker services.

Generalist vs. Specialist Palliative Care

With growing recognition of the benefit of palliative care to seriously ill patients, there is an increasing demand for palliative care services to be provided to all patients with life-threatening illnesses. Although this demand has fostered rapid growth of the palliative care specialty, the current model adds another layer of specialized care for seriously ill patients on top of an already complex, expensive health environment. There is tremendous regional variation in the availability of palliative care—ranging from 20 to 100% across the United States.

Some core elements of palliative care, such as outlining treatment with the patient's goals and basic symptom management, should be routine aspects of care delivered by any practitioner. It is important for primary care providers and other existing specialist or generalist clinicians to continue to address basic management of pain and symptoms and basic management of depression and anxiety and have basic discussions about prognosis, goals of treatment, suffering, and code status. Other skills such as communicating with difficult families or more refractory symptom management require specialized training and skills.

Most adult clinicians have to be able to perform core items of palliative care such as breaking bad news, handling pain, managing psychological and cognitive symptoms in seriously ill patients, and talking about advance directives. Sadly, practicing clinicians say they have not received adequate training to accomplish these tasks. To equip providers to provide primary palliative care, they need to be taught the primary palliative care curriculum in their training (Barzansky, Veloski, Miller, & Jonas, 1999). Center to Advance Palliative Care, VitalTalk, and the Harvard Serious Illness Conversation provide training for practicing clinicians. Similar courses are developing around the country, both in person and on the Internet, and focused on diseases such as heart failure, chronic lung disease, Alzheimer's disease, or other conditions. Creating a coordinated palliative care model that allows patients to receive basic palliative care from their primary care physician or treating specialist with a palliative care consultation being initiated for more complex or refractory problems reinforces delivery of primary palliative care by everyone caring for the seriously ill patient while leaving room for specialty palliative care consultation where appropriate (Quill & Abernethy, 2013).

Roles of Palliative Care

Symptom Management

Seriously ill patients often have a significant burden of symptoms. In a review of 400 patients admitted to palliative care in England, the 5 most prevalent symptoms were pain (64%), anorexia (34%), constipation (32%), weakness (32%), and dyspnea (31%). Ninety-five percent of these patients had a cancer diagnosis (Potter, Hami, Bryan, & Quigley, 2003). Similar prevalence of symptoms has been reported in patients with heart disease, COPD, renal disease, or acquired immunodeficiency syndrome. The top three symptoms are pain, breathlessness, and fatigue (Solano, Gomes, & Higginson, 2006). Palliative care strives to address all of these symptoms even as it takes into account some inherent differences between the cancer and non-cancer populations. Non-cancer populations tend to be older and follow different patterns of functional decline and dependency than patients suffering from cancer. A brief explanation of evidence-based management strategies employed by palliative care teams to alleviate symptoms of pain, dyspnea, and anorexia is presented below.

Pain

Pain is common among the patients with advanced cancer. The prevalence of moderate to severe pain in a group of advanced cancer patients referred to palliative care services was 51%, ranging from 43% in stomach cancer to 80% in gynecological cancers (Vainio & Auvinen, 1996). Data suggests that mature palliative care teams decrease severe pain in 66% of patients (Currow et al., 2014). They do this by using a combination of medications including opioids and nonopioid adjuvants, interventional pain techniques, radionuclide therapy, and complementary medicine. Using a multimodal strategy helps to decrease systemic opioid doses and address the different mechanisms by which pain can occur including neuropathic and inflammatory pathways.

Breathlessness

Both patients with COPD and patients with progressive cancer especially lung cancer can experience disabling dyspnea. Among advanced cancer patients, dyspnea can occur between 21 and 78.6% of patients and is reported to be from moderate to severe in 10–63% of the patients (Ripamonti, 1999). About 94% of patients with chronic lung disease experience dyspnea in the last year of life (Edmonds, Karlsen, Khan, & Addington-Hall, 2001). Dyspnea is also common in patients with progressive heart failure. One study of outpatients with heart failure found a rate of dyspnea of 55% (Blinderman, Homel, Billings, Portenoy, & Tennstedt, 2008); in other studies the numbers have been as high as 85–90% (Nordgren & Sorensen, 2003).

Palliative care interventions have been shown to improve dyspnea in a general medicine clinic in patients with chronic lung disease and CHF (Lorenz et al., 2008). Along with oxygen supplementation, opioids are often used to treat dyspnea in both patients with COPD as well as with cancer with studies showing improvement in the levels of dyspnea. Other clinical interventions that can be helpful include acupuncture in COPD (Suzuki et al., 2012) as well as targeted exercise program combined with behavioral therapy done at home (Higginson et al., 2014).

Gastrointestinal Symptoms

Nausea, vomiting, and retching are reported in up to 70% of patients with cancer and also occur frequently in non-cancer diagnoses such as CHF, acquired immunodeficiency virus, and hepatic and renal failure. Causation of these symptoms is frequently multifactorial including metabolic derangements, medications, changes in gastric and bowel motility, central nervous system disorders, and autonomic dysfunction. Part of the palliative care assessment is to obtain a careful history that would help to prescribe medications tailored to the suspected cause. Once probable causes are identified, environmental stimuli can be minimized, and antiemetic therapy that is targeted toward the probable cause of emesis/nausea is initiated (Wood, Shega, Lynch, & Von Roenn, 2007).

Cachexia and anorexia are commonly seen in the palliative care population in the setting of chronic progressive diseases that produce weight loss by a combination of loss of appetite, hypercatabolism and systemic inflammation in cancer, and muscle wasting. The estimated prevalence of cachexia ranges from 5 to 15% in advanced COPD or chronic heart failure to as much as 60–80% in advanced cancer (von Haehling, Morley, & Anker, 2010). Cachexia/anorexia requires multimodal management with priority given to a reversal of symptoms contributing to low dietary intake. Potentially correctable problems, for example, pain, dysphagia, nausea, mouth sores or thrush, and dry mouth, are identified and treated. Important psychological factors such as anxiety, depression, and spiritual distress are also carefully looked for and treated.

Discussing Goals of Care

Another important function of palliative care is to work with patients and families to determine their priorities for care and then to help structure subsequent care to best meet those values. Having such discussions in a timely manner allows patients to receive care that is consistent with their preferences, reduces caregiver distress, and increases the use of hospice while decreasing unwanted interventions like cardiopulmonary resuscitation (Apostol et al., 2015;

Mack et al., 2012; Mack, Weeks, Wright, Block, & Prigerson, 2010). Specialists in palliative care are specifically trained in communication skills and often teach others to have these conversations.

Having such conversations is hard, and many clinicians avoid these conversations because they worry about causing distress and taking away hope. However current evidence does not support the belief that communication about goals of care increases patient anxiety, depression, and/or hopelessness (Bernacki & Block, 2014). Early discussions about goals of care are associated with better quality of life, reduced use of nonbeneficial medical care near death, enhanced goal-consistent care, and positive family post-death outcomes (Bernacki & Block, 2014).

There are growing number of educational interventions to help clinicians develop their palliative care communication skills. Two of the most well known are the Serious Illness Communication Project (Bernacki & Block, 2014) and VitalTalk (n.d.). Common features among them include making sure that the patient understands their medical situation in clear, nonjargon language; attending to patient's emotion and fostering positive coping skills; and eliciting patient values to promote goal-concordant care.

Many of these programs teach mental models for how to give bad news (SPIKES), attend to emotion (NURSE), or talk about goals of care (REMAP). These are summarized in Table 1.

Specialist palliative care–patient interactions lead to improved quality of life, but until recently, how this occurred was unknown. Recent studies suggest that the reason for the positive impact is the effect palliative care specialists have on coping strategies. How one deals with poor prognostic data depends on the patient's coping strategy (Nipp et al., 2016). A secondary analysis of early integration of palliative care among patients with newly diagnosed incurable lung or gastrointestinal cancers found that patients in the palliative care arm used more approach-oriented coping strategies as compared with patients in the usual care group who used more avoidant coping strategies. This was associated with improved quality of life and fewer depressive symptoms (El-Jawahri et al., 2016).

Table 1 Mental models for difficult conversations.

Model	*Components*	*Examples*
SPIKES	Setting	Private setting with seating. All important participants present. Minimize interruptions
	Perception	What have you been told of your medical condition so far?
	Invitation	"Would you like me to talk about the treatment plan?"
	Knowledge	Provide information
	Empathy	Respond empathically (see NURSE)
	Summarize	Summarize patient's concerns and treatment plan
NURSE	Name	"This is hard"
	Understand	"I can't even imagine how difficult this must be for you"
	Respect	"You have done a really good job supporting your loved one"
	Support	"I will be available for you"
	Explore	"Tell me more about……"
REMAP	Reframe	Provide bad news using nonjargon language
	Empathize	Respond to emotion with empathic cues (see NURSE)
	Map	"What is important to you?" "What are your worries about the future?"
	Align	"What I have heard you say is…." "Is it ok if I talk about the plan?"
	Plan	"I would recommend ……"

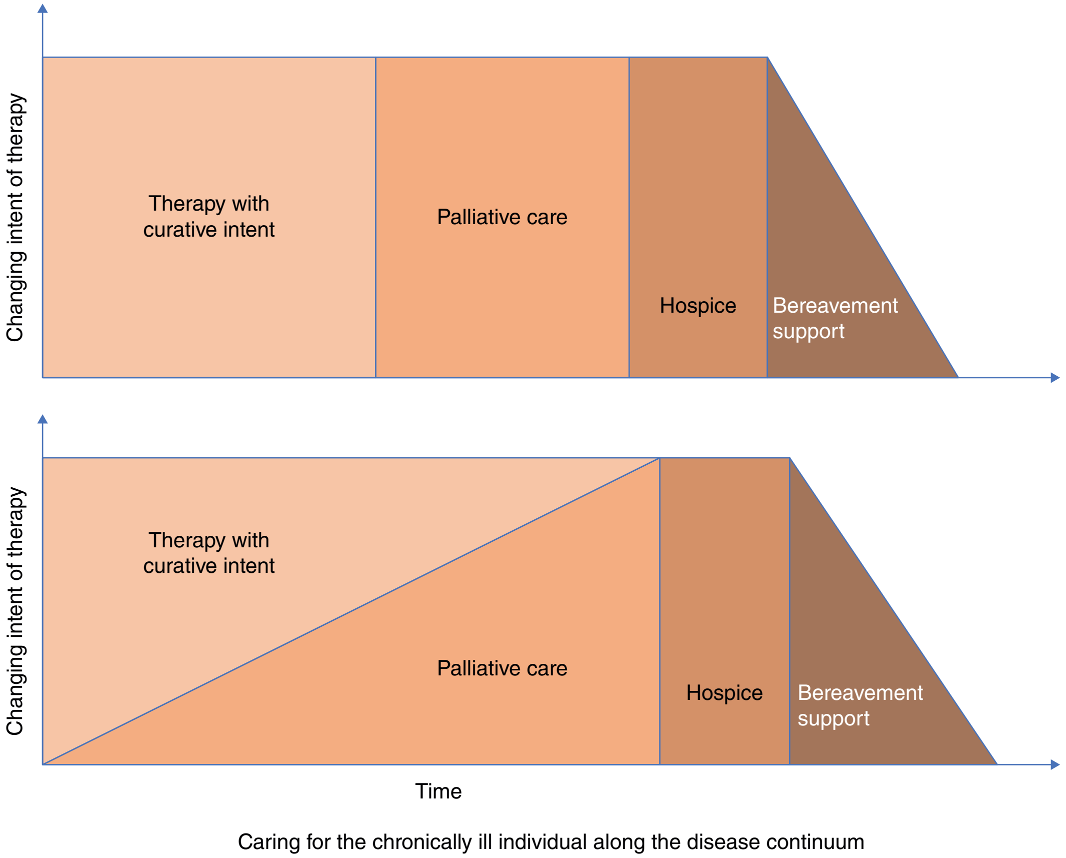

Figure 1 Caring for the chronically ill individual along the disease continuum.

Conclusion

Palliative care is a model of care that focuses on improving quality of life for patients and families by providing relief from symptoms and advocating for care concordant with a patient's wishes while also encouraging positive coping skills in the face of serious illness. Palliative care programs are growing across the country with special focus on ambulatory settings.

Author Biographies

Mamta Bhatnagar, MD, MS, is a clinical assistant professor of medicine in the Division of General Internal Medicine of the Department of Medicine at the University of Pittsburgh. She completed her medical school training in Lady Hardinge Medical College in Delhi, India, and residency at Case Western Reserve University in Ohio. She subsequently completed fellowships in Geriatrics at the Cleveland Clinic and in Palliative Care at Summa Health System in Akron, Ohio. She currently serves as a palliative care physician at UPMC cancer hospital where she also directs the palliative care services. Additionally, she is the medical director of the UPMC Health Plan home palliative care program.

Dr. Bhatnagar's key interests focus on transitions of care and how to enhance communication among providers across the care continuum. Her quality improvement team has published at the ASCO national meeting. Dr. Bhatnagar serves at the Quality Improvement Committee at AAHPM. She codirects Oncotalk, the annual training of all UPMC oncology fellows. In addition she has participated in several communication training courses throughout the UPMC health system teaching clinicians how to efficiently conduct goals of care discussions.

Robert C. Arnold, MD, is a distinguished professor of medicine in the Division of General Internal Medicine of the Department of Medicine at the University of Pittsburgh and in the University of Pittsburgh Center for Bioethics and Health Law. He completed his medical school training at the University of Missouri–Kansas City and residency at Rhode Island Hospital. Subsequently he has been on the faculty at the University of Pittsburgh. In 2000, Dr. Arnold was named the first Leo H. Creip Chair of Patient Care. The chair emphasizes the importance of the doctor–patient relationship, particularly at the end of life. He is the director of the Institute for Doctor–Patient Communication and the medical director of the UPMC Palliative and Supportive Institute. He is clinically active in palliative care. Dr. Arnold has published on end-of-life care, hospice and palliative care, doctor–patient communication, and ethics education. His current research interests are focused on educational interventions to improve communication in life-limiting illnesses and better understanding how ethical precepts are operationalized in clinical practice. He also is working with the UPMC Health System to develop system-wide, integrative palliative services throughout the health system. He is the past president of the American Society for Bioethics and Humanities as well as the American Academy of Hospice and Palliative Medicine.

Patient Navigation/Community Health Workers

Kristen J. Wells and Janna R. Gordon

San Diego State University and SDSU/UC San Diego Joint Doctoral Program in Clinical Psychology, San Diego, CA, USA

Community health worker and patient navigation interventions are designed to assist individuals in obtaining healthcare services and in taking action to increase healthy behaviors and decrease unhealthy behaviors. Community health workers have a long history of assisting with the delivery of healthcare in numerous communities and settings globally. In contrast, patient navigation models were initially developed in the 1990s in the United States and Canada to promote patient-centered care for cancer.

There is evidence that community members have been providing basic health services to other members of the community in which they live for more than 60 years (Lehmann & Sanders, 2007). Internationally, community health workers are known by a wide range of titles, including health promoter, outreach educator, paramedical worker, *promotora*, village health worker, and community health representative (Lehmann & Sanders, 2007). A community health worker has been defined as a "frontline public health worker who is a trusted member of and/or has an unusually close understanding of the community served" (Bovbjerg, Eyster, Ormond, Anderson, & Richardson, 2013). Community health workers are trained to deliver a specific intervention, but have not received formal healthcare training as would be obtained as part of tertiary education. Thus, individuals who have studied psychology are eligible to be community health workers if they are trusted by and have a strong understanding of the community that they are assisting.

Unlike community health worker programs, patient navigation programs are a relatively recent development in healthcare. The first patient navigation program was created in response to findings from hearings in the United States that were described in the American Cancer Society's *Report to the Nation: Cancer in the Poor*. This report indicated that individuals with limited resources face significant obstacles to cancer care, including sociocultural barriers (e.g., limited social support), logistical barriers (e.g., lack of transportation), and financial

barriers (e.g., inability to afford health insurance, Corliss, 1989). In response to this report, Dr. Harold P. Freeman created the first patient navigation program in Harlem, New York, which aimed to improve breast cancer outcomes. The most widely cited definition of patient navigation states that it is a barrier-focused intervention that (a) is provided to individual patients for a defined episode of healthcare, (b) has a definite endpoint when services provided are complete, (c) targets a defined set of health services that are required to complete an episode of healthcare, (d) focuses on the identification of individual patient-level barriers to accessing healthcare, and (e) aims to reduce delays in accessing the continuum of healthcare services (Wells et al., 2008).

There are various conceptualizations regarding the best models of patient navigation interventions (Wells & Nuhaily, 2018), with disagreement on what type of personnel should serve as patient navigators. In one patient navigation model, the most important qualification of a patient navigator is that the patient navigator be a "cultural broker and interpreter" who is from the community served by the patient navigation intervention (Braun et al., 2012). Similar to the definition of a community health worker, this model of patient navigation does not require a "clinical degree" to perform the patient navigation intervention, but emphasizes the patient navigator's ability to work with both the intended audience and healthcare providers, and to serve as an advocate for patients. Thus, individuals with a wide range of educational backgrounds, including psychology, serve as patient navigators. A second model of patient navigation emphasizes the need for professional training of patient navigators, which is usually completed in the fields of nursing or social work. Finally, a model advocated by numerous individuals and agencies indicates that patient navigation should be provided by a multidisciplinary team of both lay and professional navigators (Freeman, 2012; Oncology Nursing Society, the Association of Oncology Social Work, and the National Association of Social Workers, 2010).

There has been substantial research evaluating the effectiveness of various types of community health worker and patient navigation interventions designed to improve health outcomes. Much of this research has been summarized in both narrative and systematic reviews, as described in detail below. This entry will focus on health outcomes for which there has been substantial research on the effectiveness of patient navigation and community health worker interventions.

Communicable Diseases

HIV/AIDS

There has been some research evaluating whether community health workers are effective in improving outcomes among people living with human immunodeficiency virus (HIV). One narrative synthesis examined the characteristics and impact of community health workers who provided services to people living with HIV in sub-Saharan Africa across 21 studies (Mwai et al., 2013). Community health workers delivered several types of services, such as providing education about HIV-related topics, providing counseling to encourage disclosure of HIV status, facilitating adherence to antiretroviral therapy (ART) via telephone reminders or home visits, and facilitating the retention of patients in HIV care. Although none of the studies evaluated the impact of community health worker interventions on HIV-related knowledge, there is some evidence that community health workers had a positive impact on HIV serostatus disclosure and on improved retention of people living with HIV in HIV-related healthcare.

Only one study included in this review examined the impact of community health workers on adherence, finding that patients in South Africa receiving adherence support were more likely to obtain ART medication refills compared with those without this support. Furthermore, two studies found that community health workers were linked with decreased mortality among people living with HIV in Malawi and South Africa.

Peer health navigation has also emerged as a strategy to enhance health outcomes among people living with HIV. A recent systematic review was conducted to evaluate the efficacy of interventions using HIV-positive peer health navigators to increase health services utilization and medication adherence among people living with HIV (Genberg et al., 2016). This review identified nine studies in the United States and sub-Saharan Africa that examined the use of peer navigation on retention in HIV care and adherence to ART used in the management of HIV. They found mixed results for the effect of peer health navigation on ART adherence; out of seven studies, two found increased adherence among those receiving a peer navigation intervention (1,200 pregnant women in South Africa and 20 nonadherent people in Missouri), and one study found a positive effect that was not maintained at follow-up. The other studies found no difference between peer navigation and control conditions immediately following the intervention. In addition, two studies examined the impact of peer navigation on retention in HIV care and found that peer navigation programs had a positive effect on retention among pregnant women in South Africa, as well as adults in Uganda. The authors postulated that peer navigation interventions serving people living with HIV may be most beneficial in resource-constrained settings with a high patient load and limited availability of healthcare professionals.

Tuberculosis

The World Health Organization (WHO) currently recommends the use of community health worker and community health volunteer (unpaid community health workers) interventions as part of a more comprehensive strategy to control tuberculosis, called directly observed treatment (DOT). DOT seeks to enhance medication adherence by providing direct supervision of patients while they take their daily dose of medication. Clinic-based DOT typically requires that individuals travel to a healthcare institution for each dose, where they are supervised by government health workers. In contrast, community-based DOT utilizes community health workers or community health volunteers that have been trained in tuberculosis prevention and care and directly monitor an individual's dose at locations in the community, such as at patients' homes.

Published systematic reviews have evaluated whether community health workers can improve outcomes related to tuberculosis (Karumbi & Garner, 2015; Lewin et al., 2010; Wright, Westerkamp, Korver, & Dobler, 2015). To date, these reviews have been inconclusive in their findings. A systematic review of four studies, which were mostly conducted in low-income communities, found that there was moderate evidence that community health workers improve cure rates among "new" and "retreated" tuberculosis patients (Lewin et al., 2010). Similarly, in a systematic review and meta-analysis, Wright et al. (2015) compared community-based DOT versus clinic-based DOT for tuberculosis treatment outcomes and treatment retention. They identified eight studies conducted in India, the Middle East, and Africa. Two of the eight studies found that treatment was more effective among those receiving community-based DOT compared with clinic DOT. In contrast, five studies found no difference between community-based DOT and clinic DOT. One study found that treatment outcomes did not differ between community-based DOT and clinic DOT for newly diagnosed, treatment-naive patients; however, community-based DOT was more effective for patients already on tuberculosis treatment when compared with clinic-based DOT. When the studies were pooled for meta-analysis, the treatment outcome for community-based DOT was significantly better than for the clinic DOT. Researchers have indicated that community-based DOT may be especially beneficial in contexts in which individuals may have difficulty getting to clinic each day (e.g., long distance to travel, transit is expensive, work responsibilities suffer). However, Wright et al. (2015) found no difference between community-based DOT and clinic DOT with regard to reducing the rate of patients becoming lost to follow-up across seven studies in which this was an outcome.

While Lewin et al. (2010) and Wright et al. (2015) found largely mixed to positive findings regarding the benefit of community health workers in enhancing tuberculosis treatment response, another recent systematic review (Karumbi & Garner, 2015) found limited evidence indicating the effectiveness of this intervention strategy. This study compared the efficacy of various forms of DOT (e.g., family observer, community health worker observer) to self-administered tuberculosis therapy and found no difference between DOT occurring in a healthcare facility and DOT supervised by a community health worker or family member at home (Karumbi & Garner, 2015). Furthermore, they found that DOT did not significantly enhance tuberculosis cure rates or treatment completion rates compared with self-administered tuberculosis therapy, in contrast to the WHO's guidelines for tuberculosis control.

Noncommunicable Diseases

Cancer

Community health worker interventions have been frequently applied to facilitate care related to early detection or prevention for breast, cervical, and colorectal cancer (Kim et al., 2016; Viswanathan et al., 2009; Wells et al., 2011). A 2016 systematic review of randomized controlled trials (Kim et al., 2016) evaluating community health worker interventions designed for vulnerable populations found that the community health worker model was most frequently applied to increase receipt of cervical and breast cancer screening. Several systematic reviews have noted that community health worker interventions are associated with increased rates of uptake of screening mammography (Kim et al., 2016; Viswanathan et al., 2009; Wells et al., 2011). In fact, a 2011 meta-analysis found a small but significant increase in receipt of screening mammography associated with receipt of a community health worker intervention, with a stronger effect noted in randomized trials of these interventions (Wells et al., 2011).

However, fewer high-quality studies have evaluated whether community health worker interventions can improve receipt of cervical cancer screening; thus, there are inconclusive results (Kim et al., 2016; Viswanathan et al., 2009). There have also been few studies included in systematic reviews evaluating whether community health worker interventions improve receipt of colorectal cancer screening. Those studies that have been included in reviews have measured a variety of outcomes (i.e., obtaining an endoscopy appointment, rate of fecal occult blood test) and have yielded mixed findings (Kim et al. 2016; Viswanathan et al., 2009).

Since patient navigation was developed to improve outcomes in cancer and reduce cancer disparities, various patient navigation intervention models have been evaluated to determine their efficacy in improving cancer care. There are multiple published narrative and systematic reviews of patient navigation research in cancer (Baik, Gallo, & Wells, 2016; Freund et al., 2014; Krok-Schoen, Oliveri, & Paskett, 2016; Paskett, Harrop, & Wells, 2011; Robinson-White, Conroy, Slavish, & Rosenzweig, 2010; Wells et al., 2008). Most narrative reviews have found evidence of the efficacy of patient navigation in improving adherence to recommended screening for breast, cervical, colorectal, and prostate cancer (Krok-Schoen et al., 2016; Paskett et al., 2011; Wells et al., 2008). Similarly, most studies indicate that patient navigation increases adherence to recommended diagnostic care and improves timeliness of diagnostic care for patients who have experienced a breast, cervical, colorectal, or prostate cancer abnormality (Krok-Schoen et al., 2016; Wells et al., 2008). A meta-analysis of data collected from 10,521 patients enrolled in the multisite Patient Navigation Research Program indicated that patient navigation did not improve time to diagnostic resolution of a breast, cervical, colorectal, or prostate cancer abnormality between 0 and 90 days, when compared with usual care. However, there were significant differences between patient navigation and control patients 91 and 365 days following identification of a cancer abnormality, suggesting that patient navigation may prevent patients from being lost to follow-up (Freund et al., 2014).

Similar to the findings related to diagnostic resolution of a cancer-related abnormality, differences between patient navigation and comparison groups in initiation of cancer treatment among participants diagnosed with breast, cervical, colorectal, or prostate cancer in the Patient Navigation Research Program were noted between 91 and 365 days following diagnosis of cancer, with participants receiving patient navigation being more likely to initiate cancer treatment (Freund et al., 2014). On the other hand, narrative and systematic reviews of research evaluating patient navigation as an intervention to improve timely receipt of cancer treatment have yielded mixed results regarding its effectiveness (Baik et al., 2016; Paskett et al., 2011).

Cardiometabolic Diseases

Community health worker interventions have been utilized to promote the management and prevention of cardiometabolic diseases, primarily among underserved populations in the United States. Interventions include those designed to improve glycemic control among individuals living with diabetes, as well as those created to decrease cardiovascular disease risk factors or manage cardiovascular disease. A 2016 systematic review of community health worker interventions designed for vulnerable populations found that cardiometabolic disease risk reduction was the second most common application of community health worker interventions for vulnerable populations (Kim et al., 2016). Most (62%) studies targeting cardiometabolic disease risk found that community health worker interventions yielded a significant reduction in risk of these diseases.

Four of eight studies indicated that community health worker interventions were beneficial for blood pressure control compared with control groups, whereas two found no difference between community health worker and control groups, and two studies lacked statistical power. These findings are in contrast to those of a 2007 systematic review (Brownstein et al., 2007), which indicated that 9 of 10 studies found a positive impact of community health worker interventions on blood pressure.

Additionally, six of eight studies included in the 2016 systematic review (Kim et al., 2016) demonstrated that community health worker interventions were associated with improved glycemic control of diabetes, measured by fasting blood glucose or hemoglobin A1c, a measure of blood glucose over the past 6–8 weeks. This finding is consistent with a 2015 systematic review and meta-analysis (Palmas et al., 2015) specifically evaluating the impact of community health worker interventions on A1c levels among medically underserved patients with diabetes. This study found that community health worker interventions, especially those lasting at least one year, were successful in reducing A1c levels when compared with usual care. Furthermore, they noted that improvement in A1c due to community health worker interventions was greatest for those patients with the highest A1c at the outset. This suggests that individuals with the poorest glycemic control may benefit most from such an intervention.

Maternal and Child Health

In addition to focusing on specific health conditions, community health worker interventions have been implemented to improve health and access to healthcare at specific times in the lifespan, with particular emphasis on maternal and child health. There have been numerous systematic reviews that have summarized the research literature in this domain (Gilmore & McAuliffe, 2013; Lewin et al., 2010; Viswanathan et al., 2009). A narrative synthesis of community health worker interventions for maternal and child health in low- and middle-income countries (Gilmore & McAuliffe, 2013) found that these interventions have had a positive impact on malaria prevention practices, food safety practices that resulted in decreased childhood diarrhea, immunization rates, rates of exclusive breastfeeding, skin-to-skin care for prevention of hypothermia, and maternal mental health. Although Lewin et al. (2010) also found preliminary evidence suggesting that community health worker interventions may also reduce infant and childhood mortality, as well as childhood morbidity, they caution that these studies were of low quality. Thus, more research is needed to ascertain the impact of community health worker interventions on infant and childhood morbidity and mortality.

Breastfeeding

Lewin et al. (2010) provided a comprehensive evaluation of the efficacy of community health worker interventions on various outcomes related to breastfeeding, as reported in 18 studies that were primarily conducted in high-income countries. A meta-analysis of 12 studies indicated that community health worker interventions that promoted breastfeeding had a small but significant effect on initiation of breastfeeding and on any breastfeeding at 6 months postpartum. In addition, meta-analysis of ten studies examining engagement in breastfeeding among those receiving community health worker interventions compared with usual care found that community health worker interventions had a significant positive impact on exclusive breastfeeding by mothers up to 6 months postpartum (Lewin et al., 2010).

Pediatric Immunization

Systematic reviews of research evaluating the effectiveness of community health workers in improving pediatric immunization outcomes have determined that the studies are of mixed quality but suggest that community health worker interventions improve rates of being up to date on pediatric immunizations in global settings (Lewin et al., 2010; Viswanathan et al., 2009). In one review that included three studies, a good-quality trial found no difference between the community health worker and control groups, whereas two studies described as "fair" or "poor" indicated that community health workers were associated with increased rates of being up to date on childhood immunizations and fewer children being late on immunizations (Viswanathan et al., 2009). Meta-analysis of the outcomes of four studies evaluating uptake of immunizations among children age 5 years or younger with low socioeconomic status living in high-income communities found that community health worker interventions increased the proportion of children who were up to date on their immunizations compared with usual care (Lewin et al., 2010). Similarly, a narrative synthesis of community health worker interventions for maternal and child health in low- and middle-income countries (Gilmore & McAuliffe, 2013) found that community health worker interventions increase immunization rates.

Summary

While community health worker approaches have been evaluated across global settings, populations, and health concerns, patient navigation research has been more limited to North American countries and conducted to improve outcomes related to cancer and HIV. The evidence for the effectiveness of community health worker and patient navigation interventions is mixed, possibly due to the limited number of studies that have been conducted for certain diseases and health outcomes. There is clear indication that both patient navigation and community health worker interventions improve retention in care for people living with HIV as well as receipt of screening mammograms. Patient navigation also improved adherence to cervical and colorectal cancer screening, although it is not clear whether community health worker interventions are effective in improving adherence to these recommended screening exams. Patient navigation also improves adherence to recommended diagnostic testing for breast, cervical, and colorectal cancer. Community health worker interventions are associated with reductions in cardiometabolic disease risks, including blood glucose and blood pressure, as well as increasing rates of initiation of breastfeeding and pediatric immunizations. However, it is not clear whether community health worker interventions improve tuberculosis health outcomes or whether patient navigation improves cancer treatment outcomes.

There are a number of avenues for future research regarding patient navigation and community health worker interventions. To date, the research examining community health worker and patient navigator interventions has mainly focused on certain diseases, like cancer or HIV, and certain periods of human development, like childhood. Even within the most frequently researched diseases, there are still numerous opportunities to study the effectiveness of these two intervention strategies for other outcomes. For example, most patient navigation studies have been conducted in the context of early detection of cancers for which there is a screening test, including breast, cervical, and colorectal cancer. Thus, there is still an opportunity to examine the effectiveness of these intervention strategies for a wide range of health outcomes, such as treatment initiation or completion among individuals diagnosed with cancer.

In addition, there are numerous opportunities for health psychologists, as well as individuals with general psychology training, to contribute to the development, implementation, and evaluation of community health worker and patient navigation interventions. Health psychologists and clinical health psychologists have an important role in developing community health worker and patient navigation interventions that are based on effective theories of behavior change. Furthermore, with their training in evaluation and psychometrics, psychologists are frequently involved in efforts to evaluate these intervention strategies, both in the context of research and community and healthcare settings. Finally, individuals who have completed undergraduate or graduate training in psychology are well prepared to implement patient navigation and community health worker interventions.

In conclusion, the effectiveness of community health worker and patient navigation interventions has been very well studied for certain health outcomes, but there is very limited research for other health outcomes. Further research is needed to determine the effectiveness of these interventions for other disease outcomes and in other global contexts. Finally, there is a need to regulate, train, support, and credential community health workers and patient navigators who perform this work. There is a significant role for individuals with psychology training in the development, implementation, and evaluation of patient navigation and community health worker interventions.

Author Biographies

Kristen J. Wells, PhD, MPH, is associate professor in the Department of Psychology at San Diego State University and a participating member of the University of California, San Diego Moores Cancer Center, in San Diego, California. Dr. Wells' research emphasizes the use of community-engaged approaches in the development and evaluation of cancer communication and cancer care coordination interventions. She specializes in the development and evaluation of patient navigation programs focused on cancer outcomes.

Janna R. Gordon, MS, is a doctoral student at the San Diego State University/University of California, San Diego Joint Doctoral Program in Clinical Psychology. Ms. Gordon's research has examined cancer across the care continuum, including cancer communication, prevention, detection, and survivorship. She is particularly interested in investigating psychosocial aspects of cancer screening and survivorship among people living with HIV/AIDS (PLWH) and sexual minority individuals.

The Patient Protection and Affordable Care Act and Health Psychology

Ronald H. Rozensky

Department of Clinical and Health Psychology, College of Public Health and Health Professions, University of Florida, Gainesville, FL, USA

"Health care costs affect the economy, the federal budget, and virtually every American family's financial wellbeing. Health insurance enables children to excel at school, adults to work more productively, and Americans of all ages to live longer, healthier lives" (Obama, 2016, p. E2). Ten presidents of the United States, from both political parties—Misters Theodore Roosevelt, Franklin Roosevelt, Harry Truman, Dwight Eisenhower, John Kennedy, Lyndon Johnson, Richard Nixon, Jimmy Carter, Bill Clinton, and Barack Obama—all have advocated for some type of a national healthcare system or changes to the existing system (Jacobs & Skocpol, 2016). There have been various successful modifications to the healthcare system over the years including Medicare, Medicaid, healthcare insurance for children, medication coverage for seniors, and insurance coverage for the uninsured. Each of these changes occurred in the midst of some level of partisan political struggle including philosophical differences about the government's role in the lives of citizens, in human services, and in healthcare specifically. Debates included which citizens should be covered for health and human services, what concrete services should be provided, which healthcare providers should be reimbursed, and what entity (the federal government, state governments, or private insurance companies) should manage payment for and deliver services. For each change in the US healthcare system, whether part of one of the larger national systemic changes or more local modifications of healthcare rules and coverage, health service psychology in general, and the specialty of clinical health psychology in particular, always has been involved in advocating for its patients, for funding of its science, for inclusion of its services in the evolving care system, and for working to make certain its own providers serve as autonomous professionals on the healthcare team.

This chapter will discuss the recent history that has brought about healthcare reform via the passage and implementation of the *Patient Protection and Affordable Care Act* (*ACA*; Public

The Wiley Encyclopedia of Health Psychology: Volume 4: Special Issues in Health Psychology,
First Edition. General Editor: Lee M. Cohen. Volume Editor: Suzy Bird Gulliver.

Law No: 111-148, March 23, 2010). The chapter then will emphasize both the details of the *ACA* and ongoing healthcare reform efforts and how those, and will, impact the education, training, science, and practice of health psychology. It is the aim of the chapter to use that history to help prepare the reader for ongoing, and upcoming, changes to the healthcare system. For a broader view of US healthcare policy, health reform, and the *ACA*, readers are encouraged to consult Jacobs and Skocpol (2016). For a look at the evolution of the *ACA*, Gruber (2011), one of the consultants who helped formulate the *Act*, offers details of the policy and concepts adopted within the law. In an editorial in the *Journal of the American Medical Association*, President Obama (2016), author of the *ACA*, provides the reader a review of the impetus for the law and an assessment of progress since the inception of the *Act*. A series of articles focused on various recognized specialties in health service psychology and areas of psychological practice will be discussed in this chapter along with recommendations for interprofessional education, training, and practice. These can be reviewed in depth as background readings (institutional practice—Rozensky, 2011; academic health centers—Rozensky, 2012b; independent practice—Rozensky, 2013a; education and training in professional psychology—Rozensky, 2012c, 2013b, 2014a; primary care—Rozensky, 2014b; family psychology—Rozensky, Celano, & Kaslow, 2013; pediatric psychology—Rozensky & Janicke, 2012; clinical child and adolescent psychology—Janicke, Fritz, & Rozensky, 2015.)

The Patient Protection and Affordable Care Act

As part of the recent history of healthcare reforms in the United States, Berwick (2009) acknowledged the importance of the use of interprofessional, team-based healthcare. He detailed, for both healthcare providers and the public, that this type of a healthcare system can coordinate primary care providers and healthcare specialists both within episodes of care and for services occurring across episodes of care. Berwick described how this team-based approach was key to the actual quality of ongoing healthcare and is the basis for the redesign of a successful, integrated healthcare system. These comments were built upon Berwick, Nolan, and Whittington's (2008) introduction to what has been called the "triple aim" of healthcare reform; the triple aim is often seen as the impetus for the wave of healthcare reforms that lead to the passage of the *ACA* in 2010. Berwick et al. highlighted the importance of three goals—(a) decreasing the number of uninsured Americans, (b) improving the quality and *efficiency* of healthcare, and (c) reducing the overall costs of healthcare.

The actual implementation of the *ACA* was surrounded by a frenzy of political, legal, and technological issues. Along with ongoing political challenges to the *Act* in the US Congress, the Supreme Court of the United States (SCOTUS) responded to the legal storms by ruling that the *ACA* was constitutional (National Federation of Independent Business v. Sebelius, 2012) clearing the way for its implementation. SCOTUS then ruled that governmental subsidies for insurance also were constitutional (King v. Burwell, 2015). This allowed *ACA*'s ongoing growth. Even in the face of a technically challenged "roll out" (Mortiere, 2013, November 15), components of the *ACA* went into effect (Gruber, 2011; McDonough & Adashi, 2014). Initially more than the predicted seven million initial subscribers signed up by the end of the first enrollment period (April 2014; Goldstein & Eilperin, 2014, April 2). Some 12.7 million citizens were enrolled by February 2016 (https://www.cms.gov/Newsroom/Media Release Database/Fact-sheets/2016-Fact-sheets-items/2016-02-04.html), and the number of uninsured individuals in the United States declined from 49 million in 2010 to 29 million by 2015 (Obama, 2016).

Oberland (2017) described how, during the Spring and Summer of 2017, Republican members of the US Congress, who controlled both the House and Senate, with a Republican president in the White House, mounted a “crusade to dismantle Obamacare [that], at least for now, collapsed” (p. 1). During that brief time period, the House passed the *American Health Care Act* by a margin of four votes in May and followed by the failure of the *Better Care Reconciliation Act* in August. Oberland described how the Congressional Budget Office projected that these two bills would have substantially increased the number of uninsured and would have provide less affordable and less comprehensive care than the *ACA* provisions already in place. “Still, Obamacare’s fortunes remain uncertain. Senate Republicans fell only one vote short of passing legislation, and with pressure on the GOP to fulfill its promise to overturn Obamacare, the party could try to revive repeal” (Oberland, 2017, p. 1).

It is clear that “whatever else might happen politically overtime regarding the *ACA*, changes in healthcare are to be anticipated and must be responded to …” by all healthcare disciplines (Rozensky, 2014b, p. 1) given that the *ACA* is the law, it is operational, and millions have sought and will seek healthcare services through it. The various components of the *ACA* will shape healthcare delivery into the future. This then will have direct implications for the education and training within each healthcare discipline and how members of that discipline will practice, including clinical health psychology.

Components of the ACA and Their Implications for Health Psychology

Rozensky (2012a) presented a series of societal, scientific, and healthcare-related trends that set the stage for the *ACA* or developed in anticipation of, or in response to, healthcare reform. Each of these trends has a direct impact on clinical health psychology.

Health in the APA Bylaws

The trend most germane to this discussion is the ongoing changes in healthcare delivery and the healthcare system. Although many psychologists had been carrying out research and direct clinical services in medical hospitals and clinics for many years, it was not until 2001 that the American Psychological Association (APA) reaffirmed its commitment to psychology as a healthcare profession by adding “health” to its bylaws (Rozensky, Johnson, Goodheart, & Hammond, 2004). This was in direct response to ongoing healthcare reform, reaction to changes in the healthcare landscape, and in anticipation of additional changes to come.

Demographic Shifts

Bodenheimer, Chen, and Bennett (2009) pointed out that 133 million Americans had at least one chronic medical condition and this was expected to increase to 157 million by 2020. Sixty-three million citizens had multiple chronic illnesses, and Bodenheimer et al. (2009) predicted that number would rise to 81 million by 2020. They noted that while aging accounted for some of this increase, behaviorally related risk factors such as obesity and tobacco use were responsible for adding to this increase. Leading to the current epoch of healthcare reform, Bodenheimer et al. raised concerns about increased healthcare costs related to multiple chronic healthcare problems and wondered if “robust public health measures” (p. 66) could flatten the cost curve by preventing many behavioral health risk factors.

The population is aging. The US Census Bureau states that "between 2010 and 2050, the United States is projected to experience rapid growth in its older population" (Vincent & Velkoff, 2010, p. 1) with a doubling of the number of those over the age of 65 from 40.2 million in 2010 to 88.5 million by 2050. Further, "an increase in the proportion of the older population that is Hispanic and an increase in the proportion that is a race other than White" (p. 8) are projected. Consistent with the 2010 census (US Census Bureau, 2011), half of the growth in the US population between 2000 and 2010 was due to an increase in the Hispanic population that grew 43% to 50.5 million in 2010. Thirteen percent of the population was African American, and 5% was Asian, an increase of 43% during that same time period. Ortman and Guarneri (2009) state that the "racial and ethnic diversity of the US population is shown to increase" well into the future with the percentage of White-only population decreasing given overall population growth rate and international migration. Plaut (2010) described this changing picture of the US population on healthcare disparities and access to care.

Recognizing the impact of diversity trends (age, chronicity of illness, ethnic and racial changes), clinical health psychologists, educators, scientists, students, and practitioners are presented with the opportunity to build on psychology's strong commitment to multiculturalism as a core competency (e.g., Rogers, 2009). Assuring this as a focus in the new healthcare system, including the appropriate education and training of our students in preparation for these societal changes, is a key responsibility of all psychologists.

Health Promotion and Disease Prevention

In the section of the *ACA*, Prevention of Chronic Disease and Improving Public Health, the *Act* focuses on issues of public health, health promotion, and disease prevention. Here the law discusses the proposal of evidence-based approaches to health promotion and a national disease prevention model for the public health. Such an emphasis on efficacy, effectiveness, and community-based research and prevention is based on psychology's research and service traditions and reflects what Raczynski and Leviton (2004) noted, "… the behavioral focus of secondary and tertiary prevention often is not significantly influenced by the nature of the risk factor of disease but is rather based on behavioral objective—for example, losing weight, quitting smoking, and so forth" (p. 3). Further, Schneiderman and Speers (2001) describe the role of psychologists and social scientists across health promotion and disease prevention for both individuals and population health.

Given the importance of the behavioral issues in the *ACA*, the next generation of health psychologists must be prepared to engage in population-based approaches to the scientific study and treatment of the human condition. As our healthcare system evolves, use of psychology's data from the bedside and consulting room to the community and population (Rozensky, 2008) will position psychology to use its critical thinking and research skills to bring important changes to the delivery system. Both the *ACA*'s current focus on population health and the US Government's Healthy People 2010 and 2020 (ODPHP, 2020), which has long had a focus on the importance of health behaviors in health promotion, highlight psychology's leading role in understanding health behaviors and will assure clinical health psychology's relevancy on the healthcare team.

Technology

The American Reinvestment and Recovery Act infused over one billion dollars into the US economy to stimulate the "meaningful use" of electronic health records (Shachak & Jadad, 2010, p. 452). This reflects the ongoing growth of the digital age and, as Shachak and Jadad suggest, its impact on cost savings with the adoption of an integrated, electronic healthcare record-keeping system, at the local and national level. They further note that this technology will contribute to health promotion and quality care while enhancing patient-centered care. They warn, however, that "excessive preoccupation with privacy may interfere with quality service" (p. 453) that can be enhanced with efficient electronic information sharing. Sittig and Classen (2010) recommend systematic monitoring to assure that adoption of electronic record systems is done securely. Richards (2009) discusses a balance between professional psychology's focus on its ethical responsibilities for maintaining patient confidentiality, the requirements of the Health Insurance Portability and Accountability Act regarding the sharing of patients' personal health information (HIPAA, 1996), and the potential complications for psychologists working within an integrated, interprofessional healthcare work environment with medically ill patients versus those patients seeking only psychological care.

Health psychologists embarking on the use of electronic record keep and use of enhanced technologies in healthcare should look at Richards' suggestions regarding openly addressing information sharing especially regarding electronic healthcare records, when discussing with patients the limits of confidentiality. As the *ACA* calls for enhanced interprofessional practice, health psychology should provide guidance to itself, per Shackak and Jadad's concerns about not limiting information exchange, so that psychological services can be truly integrated into the expanding interprofessional healthcare milieu.

Federal Responses to the Healthcare System

Wilson, Rozensky, and Weiss (2010) describe the history and development of federal policy recommendations supporting "the integration of interprofessional education (IPE) into health professions education as a means of assuring a more collaborative healthcare workforce" (p. 210) including the role of the Department of Health and Human Services' (DHHS) Advisory Committee on Interdisciplinary Community-Based Linkages (ACICBL). The ACICBL (2011), in preparation for the then upcoming writing of the Affordable Care Act, focused its 2010 annual report to the secretary of DHHS and Congress on the importance of the education and training of the entire interprofessional healthcare workforce to adequately address health behavior change in order to enhance the quality and cost effectiveness of the US healthcare system. This document not only helped reinforce the importance of interprofessional education and team-based practice but also highlighted behavioral health as a key component to integrated healthcare. Clearly assessment and treatment of behavioral health issues is a key competency of clinical health psychologists. This trend toward interprofessional education and care provides a welcomed challenge to health psychology educators and practitioners.

Interprofessional Team-Based Care

Possibly the most far reaching functional trend in healthcare is the *ACA's* focus on interprofessionalism. The *ACA* directly recognizes the importance and impact of interprofessional education, training, and care on quality healthcare and cost effectiveness (cf., Section 3502, *Establishing Community Health Teams to Support the Patient-Centered Medical Home*). The *ACA* makes funding available to establish community-based, interprofessional (primary) healthcare teams that may include behavioral and mental health providers (including psychologists). Also detailed in the Act are interprofessional, integrated disease prevention and health promotion services (including funding for clinical teaching settings such as academic health science centers and community-based teaching health centers) and interprofessional models of healthcare that can include integration of physical and behavioral/mental health services).

The IOM (2013) notes that interprofessional education (IPE) is not "smudging together the professions and saying they are all the same" but is "about learning together to ultimately improve health and the safety of patients" (p. 2–1). Wilson et al. (2010) noted federal support of interprofessional education, while Frenk et al. (2010) opined about this approach to healthcare being "an enlightened new professionalism that can lead to better services and consequent improvements in the health of patients and populations" (p. 1954). Interprofessionality is a developmental step for all healthcare disciplines that moves beyond disjointed practices and is defined as "the development of a cohesive practice *between* professionals from different disciplines" (D'Amout & Oandasan, 2005, p. 9). Scheutz, Mann, and Evertt (2010) described the importance of shared competencies developed during professional education and training that are then utilized in actual practice in integrated, team-based healthcare systems (Interprofessional Education Collaborative [IEC], 2011) whether in a primary or tertiary care setting. The success of this team-based focus is based on competencies shared across disciplines and includes values and ethics, clarification of independent and shared roles and responsibilities for collaborative practice, interprofessional communication skills, and competencies that enhance team work and team-based care.

Belar (2016) detailed interprofessional education in health service psychology and provides brief descriptions of psychology education and training programs with an interprofessional focus. That chapter details the categories of interprofessional behaviors elucidated by the Interprofessional Professionalism Collaborative (2014) and that can be measured to review successful behavior in that practice environment—communications, respect, altruism and caring, ethics, excellence, and accountability. The curriculum for the education and training of health service psychologists should include development of competencies for true interprofessional healthcare (IEC, 2011; Interprofessional Education Collaborative Expert Panel, 2011) for traditional mental or behavioral health services and in providing psychological assessment and treatment of patients with medical diagnoses. Contemporary curricula should include a focus on interprofessional communication skills (including developing skills and comfort with the use of electronic health records) and verbal and electronic sharing of clinical information about patients within teams. The patient-centered healthcare system promulgated by the ACA also includes skills needed to routinely explain to patients the importance of sharing sensitive mental health and psychologically focused information with whole healthcare team to enhance continuity and thus quality care (Shachak & Jadad, 2010).

Competency-Based Education and Quality Care

A general trend in health service psychology has been the competency movement and the expectation that a team of verifiably competent providers enhances quality care. Cubic, Mance, Turgesen, and Lamanna (2012), for example, have opined that "interprofessional educational experiences between psychology and other healthcare providers are vital to insure professionals value one another's disciplines in healthcare reform endeavors, most notably the patient-centered initiatives" (p. 84) including quality improvement efforts. These authors provide descriptions of training opportunities across the graduate and postgraduate education spectrum that includes psychologists and other healthcare professionals learning and working together.

Individual competencies in primary care psychology offered by The Interorganizational Work Group on Competencies for Primary Care Psychology Practice (IWG, 2013) highlight a set of six broad-based competency domains for primary care psychologists: science, systems, professionalism, relationships, application, and education. France et al. (2008) offer a core competency-based model for clinical health psychology that describes both foundational and functional competencies across all venues of care. More recently, the Health Service Psychology Education Collaborative (2013) published *A Blueprint for Health Service Psychology Education and Training* containing several recommendations that include a need for "clearly articulated and understood" (p. 1) competencies for provision of health services, minimal qualifications for those entering doctoral education in health service psychology, and integration of science and practice to successfully implement evidence-based treatment, including the scientific mindedness required to create new knowledge and not simply "consume research findings," and the adoption of "a national standard on accreditation" (p. 1). Each of these sets of competencies responds to trends in healthcare education and practice and provides guidance for curriculum development and goals for each student and practitioner as they learn and work within the changing interprofessional healthcare environment.

Structural Changes in Healthcare

HealthCare Home and Accountable Care Organizations. As the healthcare system changes to meet the challenges of the *ACA*, one trend is the structural reorganization of local healthcare delivery systems and the financial arrangements that support them. The Act is focused on affordable care, but it truly focuses on accountability to assure affordability. It describes the advent of structural changes to the system with accountable care organizations (ACOs) and patient-centered healthcare (medical) homes (PCMH); both built on the foundation of interprofessionalism. Rittenhouse, Shortell, and Fisher (2009) describe ACO aligning financial incentives and accountability across the care continuum, while the PCMH emphasizes strong primary care services as the key to delivery system reforms. For these authors, successful ACOs require a strong primary care base, while the successful PCMH must have a comprehensive delivery system beyond its primary care core. Fisher, Staiger, Bynum, and Gottlieb (2007) recommend that ACOs utilize an extended hospital medical staff model, in concert with hospitals themselves as the hub of the wheel, to assure continuity of care designed to accomplish the mandates of the ACO concept—including performance measures that hold the healthcare professionals (professional staff) and hospitals accountable for quality and cost-effective care. Hospital-based ACOs, most likely, will require enhanced accountability including explicit credentialing of providers. Rozensky (2011, 2012b) noted that credentialing will require graduation from accredited education programs and an increasing expectation of specialty board certification—routine expectations of hospital-based healthcare providers. These system-based expectations should stimulate clinical health psychology to review its national training models and local programs looking at importance of both the general practice and specialized practice. The PCMH is seen as a major improvement to primary care delivery given its focus on access, coordination, and comprehensive/integrated care, and the sustained (long term) personal relationship between patient and provider(s) with patients actively engaged in a healthcare partnership (Nutting et al., 2011). The Carter Center (2011) provided recommendations regarding the education and training of the healthcare workforce to ensure the successful future of primary care. These recommendations include encouraging all health profession education programs to (a) include education about the demographic, socioeconomic, financial, quality, political, and cultural issues affecting healthcare services; (b) educate students about development of high-functioning teams in primary care; and (c) educate providers about the incidence and prevalence of behavioral conditions in primary care settings. The Carter Center also recommends that the healthcare system in general (d) redirects resources to establish appropriate training settings and curricula to prepare the primary care and interprofessional workforce and (e) the development of a research agenda to inform changes to curricula, methods, and processes of healthcare education including measurement of outcomes.

Specialization

Given the enhanced focus on accountability described above, individual health service psychologists have been encouraged that they seek credentialing at the highest level of independent practice in any healthcare system or organization (Rozensky, 2012b; Rozensky & Kaslow, 2012). Clinical health psychology is one of the specialties recognized by the APA (http://www.apa.org/ed/graduate/specialize/recognized.aspx). Individual clinical health psychologists are encouraged to seek board certification (www.abpp.org) in order to have same credential that physician colleagues are expected to obtain to practice in an organization and, as Kaslow, Patterson, and Gottlieb (2011) has noted, consumers expect their healthcare providers to be board certified as a marker of quality care.

Financial Accountability

Clearly a law with affordable care in its title reflects the trend of controlling costs as described by Berwick et al. (2008). When psychological services are studied, healthcare cost savings should be a key research variable in any, and all, applied treatment (efficacy or effectiveness studies) or translational services research (Rozensky, 2011). Translational studies that compare the relative costs for outcomes of various treatment programs can help policymakers determine where to get the "biggest bang for the buck" (e.g., Blount et al., 2007). As such, graduate programs in clinical health psychology, students, and faculty are encouraged to build cost-related variables in their research programs. Curriculum should include both program evaluation competencies as well as measurement of cost offset and cost efficiency skills (Rozensky, 2011). This allows clinical health psychologists to offer a value added skill to the healthcare team based on psychology's robust history as a measurement and research-based discipline.

Clinical Health Psychology, 2020, and Beyond

Each step in the history of clinical health psychology has been motivated by the spirit of that time—spirit based on politics within and external to the profession, scientific developments in psychology and medicine, technological evolution, vicissitudes in contemporary healthcare and healthcare financing, and changes in educational philosophy. The future of clinical health psychology will be based on contemporary *zeitgeist* composed of those same motivating forces and trends today and tomorrow. The successful health psychologist, whether student, early career, or seasoned veteran, can only contribute to the growth of the field by being aware of these changes and plan for them accordingly. Attention, then, should be paid to Berwick (2016) who described three eras in the evolution of healthcare. Era 1, with roots back to Hippocrates, sees healthcare as a noble profession, self-regulating, and beneficent. Scientific data, however, found "enormous variations in practice" (p. E1) that then lead to Era 2 with its ongoing focus on measurement, scrutiny, and accountability leading to incentives and marketing of healthcare. He argues that healthcare providers must move to Era 3 that rejects the protectionism of Era 1 and the reductionism of Era 2. Berwick offers nine changes to the future of healthcare that recast measurement, incentives, and a revenue-based strategy to one of quality that listens to the voice of the people served, builds on "improvement science" (p. E2) and transparency, and rejects greed in a spirit of civility. He urges all individual and professional organizations to take up this challenge.

Contemporary clinical health psychology exists within the broader context of healthcare reform as detailed in the *Patient Protection and Affordable Care Act* and its ongoing implementation and the evolution of health systems as presented by Berwick (2016). The *ACA* recognizes the importance of evidence-based healthcare, quality care including credentialing and specialization, team-based, and interprofessionalism in both education and practice (Rozensky, 2011, 2013a, b). And clearly, education and training in all branches of health service psychology, including clinical health psychology, must address the issues highlighted above both in its curricula, practical training, and evolving scope of practice (Rozensky, 2014a).

Maintaining Autonomy in an Interprofessional World. Rozensky (2004) has argued that lessons from health service psychology's successful history demand that organized psychology maintains its administrative autonomy at the local level so that psychologists always will be in a position to protect their own resources, carry out their own credentialing, and assure noninterference in their academic freedom and scope of practice by another discipline. This is particularly important should such turf battles reignite in times of limited healthcare financing and resources. Such times that might be at hand as the demands of healthcare reform move forward. These lessons of autonomy should be passed down as part of the formal education of the next generation of professional psychologists who will be responsible for psychology's future. Finding the balance of professional autonomy and self-governance within a healthcare milieu demanding increased interprofessional cooperation can be a challenge but necessary for the survival of health psychology as a recognized, independent profession.

The Psychology Workforce

In order to understand where clinical health psychologists will be employed in the future, a clear national, workforce analysis philosophy must be operationalized, and data collected and studied in order to inform educators and practitioners alike as to societal need and employment opportunities (Rozensky, Grus, Belar, Nelson, & Kohut, 2007). Questions like how many psychologists will be needed in primary care, in cardiac care, in cardiac psychology, in psycho-oncology, etc. will help the field have a picture of the future and provide direction to students and early career psychologists planning their education and practice focus. Workforce data will guide faculty in building their curricula and shape advocacy for research funding and educational and training dollars.

Many scholars have described the history and successful evolution of the specialty of clinical health psychology and highlighted the various individuals and organizations that have helped define the education, training, science, and practice of clinical health psychologists (Postupak & Rozensky, 2016). This history reflects a robust science whose application is key to helping those who wish to learn to prevent disease, improve their health, or seek to manage their illness or their reactions to that illness. As Postupak and Rozensky said, clinical health psychologists work to improve the human condition, and each scientist and clinician recognizes, in their day-to-day efforts, what Shakespeare said some 400 years ago, "What wound does not heal but by degree?"

For any health psychologist to succeed in the future, they must be competent in understanding their work in the context of the scientific and political environments that define practice and funding of healthcare. The successful health psychologist must apply that knowledge to education, science, and practice in an ever unfolding interprofessional healthcare context to ensure affordable and quality care and build the best future we can for the profession of psychology.

> Politics is the gizzard of society, full of grit and gravel, and the two political parties are its opposite halves – sometimes split into quarters – which grind on each other. Not only individuals but states have thus a confirmed dyspepsia.
>
> —Henry David Thoreau

Author Biography

Ronald H. Rozensky, PhD, ABPP—Dr. Rozensky is professor emeritus at the University of Florida where he was chair of the Department of Clinical and Health Psychology and associate dean for International Programs. He is founding editor of *The Journal of Clinical Psychology in Medical Settings*, and his area of scholarly work is in healthcare and health policy. He is recipient of both the *APA Heiser Presidential Award for Advocacy* and *Cynthia D. Belar Education Advocacy Distinguished Service Award*. Dr. Rozensky is a cochair of the 2018 APA presidential initiative, Citizen Psychologist, and has participated in six presidential initiatives.

Pediatric Psychology

Christina M. Amaro, Michael C. Roberts,
Andrea M. Garcia, and Jennifer B. Blossom

Clinical Child Psychology Program, University of Kansas, Lawrence, KS, USA

Pediatric psychology refers to the field of psychological research and clinical practice concerned with the complex interaction of physical health and psychological development and health of children and the families. From early in its development, the field has focused on the assessment and treatment of psychological and behavioral conditions related to pediatric medical conditions and behavioral and emotional concomitants of disease, developmental disorders, and injury. Roberts, Aylward, and Wu (2014a) summarized the activities of pediatric psychologists as providing:

> (1) psychosocial services for issues related to pediatric health conditions (e.g., fostering coping and adjustment to the diagnosis of a chronic illness, improving adherence to a medical treatment regimen, pain management, school reintegration); (2) psychological services for mental health problems appearing in medical settings along with a pediatric problem (e.g., behavioral disobedience after hospitalization); (3) assessment and treatment for psychological problems presenting in a medical setting without a concomitant medical condition (e.g., through primary care referrals for attention-deficit/hyperactivity disorder); (4) programs for health promotion, disease and injury prevention, and early intervention; (5) assessment, intervention, and programming to improve functioning for children and adolescents with intellectual and developmental disabilities; and (6) advocacy for public policy supporting children and families and promoting public health advancements. (p. 6)

Pediatric psychologists work in a variety of settings such as inpatient units in children's hospitals, outpatient clinics with pediatricians or family medicine physicians in primary care, interdisciplinary child guidance clinics, specialty clinics and centers for conditions such as developmental disorders or epilepsy, and community agencies and entities to provide services for children outside medical units (e.g., summer camps, after-school programs). Many pediatric psychologists practice in children's hospitals and pediatric clinics to provide psychological services to improve children's functioning with acute and chronic pediatric health conditions. Researchers investigate the relationships of psychological phenomena and health problems,

First Edition. General Editor: Lee M. Cohen. Volume Editor: Suzy Bird Gulliver.

the outcomes of interventions and psychological programs, and the impact of policies and programs for children's healthy development. These roles and functions of pediatric psychologists, the problems, interventions, practice settings, and integrative science are overviewed in this entry. Roberts and Steele (2017) and Roberts, Aylward, and Wu (2014b) present more comprehensive coverage of these issues.

Historical Foundations

A "role model" article in the *American Psychologist* written by Logan Wright in 1967 is often recognized as a founding document for the field, although many commentators had called for collaboration between pediatrics and psychology as far back as the early 1900s. At that time (and to some extent now), pediatricians had little training, insufficient ability, and limited time to respond to the rise of psychosocial issues related to medical, developmental, psychological, behavioral, emotional, and educational problems that were appearing with greater frequency in pediatric practices. Thus, the field arose to deal more effectively with these multiple challenges (Roberts et al., 2014a). Although pediatric psychology concepts and organization predated those of health psychology, the field shares many considerations in common through a child health psychology orientation.

Wright's article in 1967 provides guideposts for evaluating the field today. He articulated that the developing field needed to (a) establish an identity through a formal organization, (b) focus on professional training in the specialty, and (c) construct new knowledge through applied research. The first component was successfully achieved with the founding of the Society of Pediatric Psychology (SPP) in 1968 with 75 full members and 22 affiliate members; it functioned as a special interest group within the Section on Clinical Child Psychology in the Division of Clinical Psychology of the American Psychological Association (APA). The organization provided an organizational home and information exchange for psychologists scattered across the country. By 1972, SPP had expanded to 650 members and later became a Section in the Division; in 2000 SPP became Division 54 of the APA. In 2016, there were 2,038 members (including 660 students and several international members).

As the organizational home for the field, SPP has provided formal definitions revealing the evolution of concepts. In 1976, the masthead of the *Journal of Pediatric Psychology* indicated: "The field and the contents of this Journal are defined by the interests and concerns of psychologists who work in interdisciplinary settings such as children's hospitals, developmental clinics, and pediatric or medical group practices." In 1988, in recognition that the field had expanded its coverage, pediatric psychology was defined for the journal as an "interdisciplinary field addressing the full range of physical and mental development, health, and illness issues affecting children, adolescents, and families…[such as] the relationship between psychological and physical well-being of children and adolescents including: understanding assessment, and intervention with developmental disorders; evaluation and treatment of behavioral and emotional problems and concomitants of disease and illness; the role of psychology in pediatric medicine; the promotion of health and development; and the prevention of illness and injury among children and youth" (Roberts, La Greca, & Harper, 1988, p. 2). According to the SPP website, an updated "Mission Statement" of the organization presents that "SPP aims to promote the health and psychological well being of children, youth and their families through science and an evidence-based approach to practice, education, training, advocacy, and consultation." An even more concise organizational "Vision Statement" states "Healthier children, youth, and families."

In terms of the professional training needs outlined by Wright (1967), the field started giving specific attention to training issues in the 1980s. Later, an SPP task force focused on the knowledge, attitudes, and skills of a competent pediatric psychologist in terms of general training domains expanded to cover the effects of pediatric medical treatments, children's development and disease processes, and child health psychology (Spirito et al., 2003). More recently, another SPP task force formulated an elaborated set of training sequences for the field even more distinctive from other areas of psychological application (Palermo et al., 2014). Thus, professional training sequences are increasingly formalized through doctoral, internship, and postdoctoral experiences, fulfilling Wright's articulated needs for the field.

In the third component outlined by Wright for building the field, developing a knowledge base, pediatric psychologists have dramatically expanded the scientific basis for understanding children's development, the relationship of psychological constructs and approaches with pediatric conditions, and evidence-based assessment and intervention to improve functioning. Pediatric psychology research is published in many different journals. SPP sponsors two professional journals for reports of research and clinical applications (*Journal of Pediatric Psychology*, *Clinical Practice in Pediatric Psychology*) and the publication of the *Handbook of Pediatric Psychology* (now in its fifth edition; Roberts & Steele, 2017). SPP holds an annual conference with over 600 attendees for interactions and education on the multitude of research and clinical activities of pediatric psychologists. Additionally, pediatric psychology researchers and practitioners participated in interdisciplinary conferences in pain, obesity, diabetes, sleep, and other child health-oriented areas. All of the components that Wright outlined have been successfully achieved. Thanks to contributions of multiple leaders and the ongoing work of pediatric psychologists in multiple locations, the field is thriving with professional opportunities to improve children's mental and physical health.

Perspectives and Systems

Pediatric psychologists take a developmental perspective that recognizes the progression of change over time in childhood. This perspective orients the professional to expect change to occur and be alert to development gone awry, when intervention and prevention services should be provided, and how to provide psychological services that return the child to appropriate developmental functioning. Pediatric psychologists also ascribe to an expanded biopsychosocial model that identifies multiple systems including families, schools, peers, and healthcare, which affect children and their functioning, particularly as these systems might interact over changes in the child and family due to psychological and physical health conditions (Steele & Aylward, 2009; Wu, Aylward, & Roberts, 2014).

Ethical Issues

Psychological practice and research invoke ethical and legal issues such as informed consent and assent, privacy, confidentiality, and record keeping. Pediatric psychologists also frequently deal with ethical issues particular to interprofessional relationships in medical settings and treatment challenges associated with improving psychological functioning of children with medical conditions and their families. These involve decision making and substituted judgment about withholding or changing medical and health treatments, self-responsibility for care, and disability access to care, among others. Pediatric psychologists work within numerous legal and ethical guidances including federal and state regulations (e.g., educational and healthcare laws, discrimination laws and rulings, professional licensing requirements), institutional policies and practices (e.g., electronic health records), and the Ethical Principles of Psychologists and Code of Conduct (APA, 2010).

Major and Crosscutting Issues

There are several major and crosscutting issues that occur across a range of areas. Outlined below are some exemplars within the field of pediatric psychology: adjustment to chronic illness, consultation–liaison (CL) services, primary care, adherence, sleep, pain, and health promotion and prevention.

Adjustment to Chronic Illness

A large component of pediatric psychology research and clinical practice relates to youth and family's adjustment to and coping with medical conditions and treatments. There are many aspects of treatment of chronic illnesses that can have an impact on children and adolescents, including brief procedures (e.g., injections), invasive methods (e.g., bone marrow aspiration), and adverse side effects (e.g., nausea, sleepiness). Some youth may experience relatively short periods of adjustment (e.g., experiencing brief infection), whereas other illnesses are lifelong and require ongoing adjustment (e.g., diabetes; Kazak, Sood, & Roberts, 2016). Many youth and their families demonstrate good coping mechanisms and adjustment, whereas others may need additional support, and pediatric psychologists work with them to determine appropriate approaches given their specific concerns and needs (Kazak et al., 2016).

Consultation–Liaison Services

As noted earlier, pediatric psychologists work in a variety of settings, such as hospitals and medical academic centers, and perform numerous roles in these environments. One important activity is CL services in the hospital (Kazak et al., 2016). When providing inpatient consultation, a pediatric psychologist may receive a referral from a physician or a specific service to conduct an assessment of a patient and provide recommendations for treatment. Pediatric psychologists typically respond to a referral within 24 hr and communicate impressions and recommendations back to the physician and/or team members in a timely matter. However, they may also be involved in the longer-term implementation of treatment recommendations (Kazak et al., 2016). In a liaison position, a pediatric psychologist may be a team member of subspecialty service (e.g., gastroenterology) and has a portion of time dedicated to providing mental health services. Overall, CL includes a range of assessment (e.g., screening, evaluation of psychological functioning) and indirect or direct treatment (e.g., teaching coping skills, assisting with adjustment to medical condition, enhancing adherence) services to promote the psychosocial well-being of youth with chronic illnesses and their families.

Primary Care

Pediatric psychologists may also work in primary care settings, such as pediatric and family medicine clinics. Within primary care settings, pediatric psychologists provide mental and behavioral health services (e.g., assessment, treatment, consultation) that span a range of concerns (e.g., prevention, health promotion, psychosocial functioning), and they work alongside other medical providers, such as pediatricians, nurse practitioners, and family medicine physicians to enhance children's mental and physical health (Stancin, Sturm, Tynan, & Ramirez, 2017). The number of psychologists working in this type of setting as well as research in this area is limited compared with tertiary care or hospital practice. However, effective models for pediatric psychology activities in primary care have been developed. For example, Schroeder established a model in the 1970s in which psychologists provided behavioral services to patients and families seen in a pediatric clinic. Psychologists and their trainees served in multiple roles, including therapist, case manager, educator, consultant, and researcher with the pediatricians and their staff (Stancin et al., 2017). Due to recent changes in the United States' healthcare system, greater psychology involvement in primary care appears warranted. Pediatric psychologists, in particular, are prepared to provide services in numerous areas including prevention, screening and early intervention, psychoeducation to parents, brief individual psychotherapy for youth, and care coordination (Stancin et al., 2017). Further, many interventions for youth with chronic illnesses and their families (e.g., self-management training, relaxation skills) are also provided by pediatric psychologists in primary care settings.

Adherence

Adherence to medical regimens is important in the maintenance of health for youth with chronic illnesses, yet nonadherence continues to be a significant behavioral health concern, with a majority of individuals failing to follow treatment recommendations from healthcare providers (Hommel, Ramsey, Loiselle, & Ryan, 2017). Nonadherence has been associated with numerous negative consequences including diminished health-related quality of life, drug resistance, increased use of healthcare, and poorer treatment outcomes (Hommel et al., 2017). Further, research suggests that there are several modifiable and non-modifiable individual factors that influence pediatric adherence including cognitive functioning, illness knowledge, health beliefs, psychological or behavioral problems, and treatment awareness. Family (e.g., parental involvement in self-management, family functioning, parental psychopathology) and peer (e.g., social support, social stigma) factors may also influence youth treatment adherence (Hommel et al., 2017).

Although there are several types of interventions for pediatric nonadherence, recent meta-analyses and systematic reviews suggest that behavioral interventions (e.g., problem solving, rewards, monitoring and goal setting) may be effective in improving adherence to treatment (Hommel et al., 2017; Kazak et al., 2016). Additionally, interventions targeting family concerns (e.g., communication about illness-related responsibilities, parental involvement in disease management) may also be helpful in pediatric adherence (Hommel et al., 2017; Kazak et al., 2016).

Sleep

Sleep is important to children and adolescents' development, and youth may experience a range of pediatric sleep disorders including insomnia (e.g., problems falling and staying asleep) and parasomnias (e.g., events that disrupt sleep, such as sleepwalking). Sleep problems are associated with a range of negative outcomes including worse emotion regulation, increased externalizing symptoms, and diminished cognitive functioning (Honaker, Meltzer, & Mindell, 2017). Youth with chronic illnesses are likely to have comorbid sleep issues, and sleep problems may exacerbate medical symptoms (e.g., a bidirectional relationship between sleep and pain). Further, research has suggested that sleep problems are particularly pronounced in youth with a range of medical conditions, such as asthma, traumatic brain injury, oncology, epilepsy, and cystic fibrosis (CF) (Honaker et al., 2017). Given that sleep is often an issue for youth, pediatric psychologists require training and a knowledge base in sleep in both typically developing youth and youth with chronic illnesses. Within clinical settings, an important role for pediatric psychologists is to assess pediatric sleep and provide treatment as necessary. There are multiple domains of sleep that a pediatric psychologist should assess for including bedtime routine (e.g., behaviors at bedtime, time it takes to fall asleep), sleep environment (e.g., location, room condition), sleep throughout the night (e.g., number of nighttime wakings, nocturnal enuresis), and how the child feels during the day (e.g., difficulties waking up and staying awake; Honaker et al., 2017). A range of effective behavioral strategies address pediatric sleep problems. For example, pediatric psychologists may help families to establish a regular bedtime routine to decrease bedtime resistance and night wakings (Honaker et al., 2017).

Pain

Similar to sleep, pain often occurs among typically developing children and adolescents as well as youth with chronic illnesses. There are various types of pain, such as procedural pain and recurrent or chronic pain. Children routinely undergo medical procedures (e.g., immunizations, stitches) that may result in pain. There are several strategies that can be implemented before, during, and after the procedure to assist youth with procedural pain and distress (Cohen et al., 2017). Using a developmentally appropriate approach, pediatric psychologists can assist parents with preparing their children for a more invasive medical procedure (e.g., bone marrow aspiration, burn dressing changes). Psychologists may discuss what information to provide to children ahead of time and what language to use. During a procedure, youth may benefit from a range of strategies, such as the use of distraction (e.g., bubbles, pop-up books) and relaxation techniques (e.g., deep breathing; Cohen et al., 2017). After a procedure, use of coping skills can be reinforced, and parents can reward children for good behavior during the procedure.

Chronic or recurrent pain refers to pain that occurs regularly (e.g., for 3 months or more). Recurrent pain may occur as the result of a severe injury or chronic illness (e.g., arthritis, sickle cell disease); however, sometimes an underlying cause is not identified, and this is known as idiopathic chronic pain (Law, Noel, Nagel, & Dahlquist, 2017). Youth with chronic pain often experience significant interferences in their daily lives, such as problems with sleep, school absences, and impaired social and physical functioning. Pediatric psychologists help to promote techniques for self-management, which include identifying specific environmental or psychosocial triggers. Cognitive and/or behavioral interventions are available for chronic pain and may consist of challenging and changing maladaptive thoughts around pain, relaxation strategies, and promotion of physical activity and well-being (e.g., sleep hygiene). Growing evidence exists for the use of acceptance and commitment therapy in the treatment of pediatric chronic pain (Law et al., 2017).

Health Promotion and Prevention

Prevention refers to engaging in behaviors to avoid the development of problems, whereas health promotion refers to the adoption of health behaviors to promote a healthy lifestyle. Further, behaviors developed in childhood may impact youth's quality of life, and those behaviors also have the potential to persist throughout adulthood. Therefore, it is important for pediatric psychologists to conduct research and administer interventions related to health promotion and prevention in youth. Historically, health promotion and prevention have been topics of interest within pediatric psychology; however, these areas appear to have received less attention in comparison to issues related to pediatric chronic illnesses. Given recent changes in healthcare reform, more opportunities may be available to help support health promotion and prevention activities (Kazak et al., 2016).

There are several examples of prevention applications in pediatric psychology including seat belt safety and the use of immunizations to prevent diseases. Further, pediatric psychologists have conducted research and developed interventions to prevent and control childhood injuries. Health promotion efforts have examined increasing pediatric health behaviors such as physical activity, sleep, and diet to promote healthy lifestyles and decrease the risk of disease (e.g., obesity, type 2 diabetes).

Specific Examples Within Pediatric Psychology

Pediatric psychologists encompass many roles, including consultant, researcher, and an evidence-based practice provider. As clinicians, many pediatric psychologists work with and may conduct interventions for a wide variety of pediatric conditions. However, the approach to any intervention involves conceptualization of the presenting problems and understanding that the child functions within a system. Approaches for case conceptualization often use the biopsychosocial model noted earlier, which examines the extent to which biological, psychological, and social factors as well as their interactions influence health and illness. Understanding such reciprocal multidimensionality of pediatric conditions, pediatric psychologists often work as part of an interdisciplinary or interprofessional team to help manage and intervene with the health issues related to pediatric conditions.

Pediatric psychologists implement various psychosocial treatments focused on individual treatment as well as provide support to the child's family. Moreover, considerations for appropriate interventions include the child's developmental level as well as a biopsychosocial approach. Pediatric psychologists have successfully employed effective treatments with frequently used individual approaches including behavioral techniques, cognitive techniques, cognitive behavioral therapy (CBT), or a multicomponent approach in which multiple strategies are integrated to address the presenting problems. For example, psychological interventions promoting adherence to the medical regimen by children with chronic illness frequently employ the use of multiple components. Behavioral procedures involve contingency management approaches to help improve self-control (e.g., behavioral disobedience after hospitalization), pain management, and self-management in order to increase medical treatment adherence. CBT involves identifying unhelpful thoughts related to either disease or treatment and challenging obstructive thoughts through cognitive restructuring and developing adaptive behaviors (e.g., problem solving and functional coping). Lastly, cognitive techniques involve self-management such as cognitive coping skills to reduce anxiety, impulse control, and depression. Pediatric psychologists also work with families of children with pediatric conditions, providing psychosocial interventions focused extensively on addressing barriers, psychosocial targets, family functioning, and intensive crisis intervention. The following sections discuss examples of how pediatric psychologists apply evidence-based practice in pediatric health conditions: asthma, oncology, CF, and type 1 diabetes (T1D).

Asthma

Asthma is a chronic inflammatory disorder of the airways that causes the airways to swell and narrow leading to shortness of breath, chest tightness, and coughing. Challenges faced by children with asthma and their families include frequent missed school days and hospital visits. Typical treatments for managing symptoms include self-management, control of environmental triggers (e.g., allergens, stress), and prescribed pharmacological treatments. Pediatric psychologists help self-management and adherence to prescribed treatments by providing behavioral educational and technology-based interventions. For example, web-based delivery of intervention content focuses on self-management and symptom management. Similarly, pediatric psychologists also provide the family with educational information on how to manage their child's asthma, as well as behavioral and educational interventions to promote self-management for children with asthma.

Oncology

Advances in modern medicine have significantly increased the survival rate of children with cancer; however, diagnosis, treatment, and surviving cancer are compounded with psychological, social, and biological challenges. Specific challenges include neurological challenges (e.g., problems with executive functioning, processing speed, attention, working memory), health challenges (e.g., endocrine problems, cardiopulmonary), and psychosocial challenges (e.g., isolation, depression, pediatric medical traumatic stress). Interventions for children with cancer focus on social skills (e.g., forming new friendships), psychological well-being (e.g., benefit finding, self-efficacy managing internalizing behaviors), and transitional skills to independent functioning (e.g., independent living, medication adherence). Moreover, interventions help children and adolescents manage the negative side effects of chemotherapy through the use of cognitive coping strategies.

Cystic Fibrosis

CF is a progressive genetic, life-limiting illness, which primarily affects the functioning of the lungs and pancreas through abnormal mucus secretions. Given the progressive and disabling prognosis, CF is associated with many challenges including psychological adjustment, diminished quality of life, and adherence concerns. Treatment is often complex and can be intrusive, involving numerous medications, dietary changes, and exercise; prognosis is largely dependent upon these behavioral changes. However, children frequently do not adhere to their medical regimens. Reasons for this noncompliance include the aversive nature of the treatments, length of the regimen, and the child's developmental level. Interventions to increase the adherence of medical regimens for children with CF often include parental strategies and frequently involve multicomponent incorporating psychoeducational, parent training, exercise, and nutritional management. Further, these interventions encompass cognitive and behavioral strategies for child and parents. For instance, behavioral management interventions seek to decrease negative parent–child interactions around treatment adherence, exercise programs, and nutritional intake.

Diabetes

T1D is an endocrine disorder in pediatric populations, caused by an autoimmune process that destroys insulin-producing cells that regulate glucose, fat, and protein metabolism. Treatment of T1D encompasses a complex regimen, which includes dietary management, blood glucose checks, frequent daily insulin injections or an insulin pump, and regular exercise. Challenges for children with T1D include frequent hospitalizations due to limited adherence to regimen and poor stress management. Similar to other pediatric conditions, nonadherence with the diabetes treatment program significantly influences prognosis and likelihood of medical complications including hospitalizations. Behavioral interventions and psychosocial interventions may focus on enhancing adherence to treatment regimens, improving family functioning, and reducing psychosocial stress.

Overall, pediatric psychologists provide effective and evidence-based treatments for various pediatric conditions in hospitals and other diverse interdisciplinary settings. Pediatric psychologists receive training that allows them to translate research into practice, conceptualize presenting concerns through a biopsychosocial perspective, and provide individual patient and family support and treatment. Understanding that children and adolescents do not exist in a microcosm, pediatric psychologists work to provide psychological support for children and adolescents in order to help them be successful at home, school, and with peers.

Future Directions in Clinical Practice and Research

eHealth

One future direction in pediatric psychology is the use of digital technologies to improve youth and family health, which is also known as eHealth. Electronic devices can be used to assist with a range of functions within pediatric psychology, including measuring health behaviors (e.g., wearable device that tracks physical activity and sleep) or adherence (e.g., electronic sensors that track the number of times a prescription bottle is opened). Additionally, eHealth interventions (e.g., web based, text messages) have been implemented to manage conditions as well as promote health behaviors (Kazak et al., 2016). However, there are some unique challenges in the use of eHealth interventions, including issues with keeping up with the most current technologies. Additionally, eHealth interventions may be costly and require a significant amount of time to develop initially. However, eHealth interventions may help to increase access to pediatric psychology interventions (Kazak et al., 2016).

Mentorship

From its roots, pediatric psychology has placed substantial emphasis on the role of mentorship within the field, covering all areas of practice from research (both project conceptualization and through the peer-review process) to clinical practice. Recent and developing initiatives continue to shape and contribute to the mentorship process. For example, SPP coordinates a mentorship program between students and career psychologists. Important future directions for such programs might include mentorship of undergraduate students. Further, this process would provide an opportunity for graduate students to develop mentoring experience that they might carry over into their professional careers.

Bridging the Gap and Crosscutting Issues

Fundamental to the field of pediatric psychology is the focus on integration of research and practice. Thus, the future direction of the field of pediatric psychology as a whole assumes these are two interrelated processes, rather than distinct and wholly separate phenomena. In line with broader healthcare practice, pediatric psychologists often provide clinical services within the context of interdisciplinary, or interprofessional teams, a more common practice than the traditional one-on-one model. However, an ongoing limitation in this area is the lack of strong, clearly defined evidence-based practice protocols across all health conditions (similar to adult health psychology). The integrative research–practice model will likely improve this situation as the field develops.

Another potential method of bridging the potential gap between the research–practice arenas is through quality improvement activities. Within interprofessional programs, quality improvement studies gather information about ongoing practice to make developmental changes and assess for effects within incremental changes made as indicated. For example, quality improvement research may target adherence or examine immunization procedures. Randomized control trials, or large-scale research projects within existing clinics, although important for some areas, face numerous functional limitations. The need for information about process and outcomes can be addressed through quality improvement. Quality improvement projects represent an important focus for future directions in pediatric psychology, providing multiple benefits over traditional research studies, including immediate application within functioning clinics and provision of cost–benefit information.

Although the future of pediatric psychology will likely continue to focus on the psychosocial needs of children with chronic disease, the field will also grow through research and applications in preventive integrated primary care programs. While prevention and primary care efforts have historical roots within pediatric psychology, these also represent essential areas for future research and practice. Continued research and program development are needed to identify effective models of preventive interventions and psychosocially based care within primary care settings. Another important future direction in the field of pediatric psychology will be to understand collaboration processes and to develop interprofessional research and services teams. Many of the challenges facing children and adolescents in physical and mental health require solutions integrated from different disciplines and viewpoints in recognition of the biopsychosocial model including collaboration and coordination, such as examining and facilitating the input and contributions of multiple professionals.

Author Biographies

Christina M. Amaro, MA, is a doctoral candidate in the Clinical Child Psychology Program at the University of Kansas. Her research interests include pediatric health promotion, child and family adjustment to chronic illness, program evaluation, and professional psychology issues, such as mentoring and training.

Michael C. Roberts, PhD, ABPP, is the dean of Graduate Studies and professor in the Clinical Child Psychology Program at the University of Kansas. His research and professional interests revolve around the application of psychology to improving physical and mental health, particularly for children and adolescents, and in professional issues of health service psychology.

Andrea M. Garcia, MEd, received her MA from the Clinical Child Psychology Program at the University of Kansas. She has interests in autism spectrum disorders and developmental outcomes, neonatal intensive care unit, resilience in children and families with chronic illness, and health promotion.

Jennifer B. Blossom, MS, is a doctoral candidate in the Clinical Child Psychology Program at the University of Kansas and psychology resident at the University of Washington School of Medicine—Child Track. Her research interests include the development, dissemination, and implementation of evidence-based assessment and intervention for youth internalizing problems in community settings, with an emphasis on integrated care settings (e.g., primary care), as a method to reduce mental health disparities and increase service use, access, and efficiency.

Placebo Effect

Diletta Barbiani[1] and Fabrizio Benedetti[2]

[1]*Department of Neuroscience, University of Turin Medical School, Turin, Italy*
[2]*Hypoxia Medicine, Plateau Rosà, Switzerland*

Definition

Placebos are often defined as inert substances, devoid of any therapeutic property for the condition being treated. However, this definition is not completely correct, because placebos are made of many things, such as words and rituals, symbols, and meanings, and all these elements are active in shaping the patient's brain. Thus, a better definition of placebo should embrace both the inert substance and the psychosocial context around the patient and the therapy. Although inert substances are of great validity in the clinical trial setting, the clinical trialist has always drawn attention to the inertness of the substance itself, thus diverting it from the real meaning of placebo. If drawing attention to the inert substance is correct in pragmatic clinical trials, whereby the only purpose is to see whether drugs are better than placebos, this surely does not help understand what a placebo is (Benedetti, 2014).

A real placebo effect is a psychobiological phenomenon occurring in the patient's brain following the administration of an inert substance or of a sham physical treatment such as sham surgery, along with verbal suggestions (or any other cue) of clinical benefit (Price, Finniss, and Benedetti, 2008). Saline solutions or sugar pills do not have intrinsic therapeutic properties. Instead, the effect is due to the psychosocial context that surrounds the inert substance and the patient. In this sense, to the clinical trialist and to the neuroscientist, the term "placebo effect" has different meanings. Whereas the former is interested in any improvement that may occur in the group of patients who take the inert substance, regardless of its origin, the latter is only interested in the improvement that derives from active processes occurring in the patient's brain. In fact, the improvement in patients who are given a placebo can be ascribed to a vast array of factors, such as spontaneous remission of the disease (the so-called natural history), regression to the mean (a statistical phenomenon due to selection biases), patient's and doctor' biases, and unidentified effects of co-interventions. In pragmatic clinical trials, the trialist is interested in the improvement irrespective of its cause, because

The Wiley Encyclopedia of Health Psychology: Volume 4: Special Issues in Health Psychology,
First Edition. General Editor: Lee M. Cohen. Volume Editor: Suzy Bird Gulliver.

he/she only needs to establish whether the patients who take the true treatment, be it pharmacological or not, are better off than those who take the placebo. Instead, if the interest is focused on the understanding of what a real placebo effect is and how it works, it becomes necessary to separate it from spontaneous remissions, regression to the mean, and biases (Benedetti, 2014).

Therefore, the true placebo effect is only the psychobiological phenomenon, and all the other phenomena can be ruled out by using the appropriate methodological approach. For example, in order to rule out spontaneous remission, the placebo group must be compared with a no-treatment group that serves as a measure of the natural history of the disease. Similarly, in order to rule out biases, such as those which may occur in subjective symptoms, objective outcome measures must be assessed.

The real placebo response, that is, the real psychobiological phenomenon, is not irrelevant, and its contribution to the clinical improvement is substantial. For example, in antidepressant clinical trials, it has been shown that the natural history of the disease (i.e., spontaneous remission) accounts for 23.87% of the overall effect, the real placebo effect (i.e., expectations of benefit) for 50.97%, and the drug effect for 25.16% only. Thus, placebo responses in depression are usually large, and they have been found to increase over time, with stronger placebo responses in more recent studies. A similar increase over time has been found in pain.

Today we know that there is not a single placebo effect, but many, with different mechanisms at play across different diseases, systems, and therapeutic interventions (Benedetti, 2013, 2014; Finniss, Kaptchuk, Miller, & Benedetti, 2010).

Psychobiological Mechanisms

Two main mechanisms have been the focus of attention: expectation and learning. Expectation is a conscious event whereby the subject expects a therapeutic benefit. The link between expectation and the clinical improvement is twofold. First, positive expectations may reduce anxiety, and anxiety is known to affect different symptoms, such as pain, in opposite directions, that is, either decrease or increase, depending on the circumstances. Second, expectation of a positive event, that is, the therapeutic benefit, may activate reward mechanisms. Learning mechanisms, ranging from behavioral conditioning to social learning, are crucial, because the previous experience of effective treatments leads to powerful placebo responses. Expectation and learning are not necessarily mutually exclusive, since learning can lead to the reinforcement of expectations or can even create de novo expectations. The following overview is aimed at briefly describing the main psychological mechanisms that have been identified in the past few years (see Benedetti, 2014, for a detailed review).

The opioid system activated by placebos is the most studied and understood (Figure 1a). The opioid antagonist, naloxone, prevents some types of placebo analgesia, thus indicating that the opioid system plays an important role. The cholecystokinin (CCK) antagonist, proglumide, enhances placebo analgesia on the basis of the anti-opioid action of CCK, whereas the activation of the CCK type 2 receptors with the agonist pentagastrin disrupts placebo analgesia. Therefore, the activation of the CCK type 2 receptors has the same effect as the μ-opioid receptor blockade, indicating that the balance between CCK and opioids is crucial in placebo responsiveness in pain (Figure 1a). Some brain regions in the cerebral cortex and the brainstem are affected by both a placebo and the opioid agonist remifentanil, which suggests a related mechanism in placebo-induced and opioid-induced analgesia. In vivo receptor-binding techniques show that placebos activate μ-opioid neurotransmission in the dorsolateral prefrontal cortex, the anterior cingulate cortex, the insula, and the nucleus accumbens. Recent studies in rodents confirm these pharmacological findings in humans.

The CCK pro-nociceptive system has also been found to mediate nocebo hyperalgesia (Figure 1b). The nocebo response is a phenomenon that is opposite to the placebo response, whereby negative expectations may lead to clinical worsening. For example, expectations of pain increase lead to nocebo hyperalgesia, and this increase can be blocked by the CCK antagonist proglumide. Anticipatory anxiety plays a key role here, for nocebos are anxiogenic and induce negative expectations. Again, a social defeat model of anxiety in rats supports this view.

When nonopioid drugs, like ketorolac, are administered for 2 days in a row and then replaced with a placebo on the third day, the placebo analgesic response is not reversed by naloxone, whereas the CB1 cannabinoid receptor antagonist, rimonabant, blocks this placebo analgesia completely. Therefore, in some circumstances, for example, following previous exposure to nonopioid drugs, placebo analgesia is mediated by the CB1 cannabinoid receptors. Interestingly, there is compelling experimental evidence that the whole lipidic pathway, involving arachidonic acid, endogenous cannabinoid ligands (e.g., anandamide), and the synthesis of prostaglandins (PG) and thromboxane (TX), is important in the modulation of the placebo response in pain (Figure 1c). For example, the functional missense variant Pro129Thr of the gene coding fatty acid amide hydrolase (FAAH), the major degrading enzyme of endocannabinoids, affects the analgesic responses to placebo as well as placebo-induced μ-opioid neurotransmission. Moreover, cyclooxygenase (COX), which is involved in PG and TX synthesis (Figure 1c), has been found to be modulated by both placebo and nocebo in hypobaric hypoxia, or high altitude, headache with a mechanism similar to that of aspirin.

Hypoxia headache has been found to represent an excellent model to investigate these mechanisms. In fact, there are at least two pathways responsible for triggering this type of headache. The first is represented by the acute effects of hypoxia on PG synthesis through the COX enzyme, with the formation of PGD2, PGF2, PGE2, PGI2 (prostacyclin), and TX A2. One of the most important effects of PGs, particularly of PGE2, is represented by vasodilation, which is thought to be the principal factor inducing acute hypoxia headache. The second pathway is represented by hypoxia-related hyperventilation that, in turn, induces the excessive elimination of carbon dioxide (CO_2), with a subsequent increase in blood pH (alkalosis). In a recent study, Benedetti and Dogue (2015) used placebo oxygen inhalation and placebo aspirin administration, both proven to be effective treatments for high altitude headache, to induce placebo responses after repeated associations between headache reduction and either the oxygen mask ritual or the aspirin pill ritual. In other words, both placebos were given after a conditioning procedure, whereby either real oxygen or real aspirin was administered for three consecutive sessions to reduce headache pain. Interestingly, after oxygen conditioning, placebo oxygen induced pain relief along with a reduction in ventilation, blood alkalosis, and salivary PGE2, though without any increase in blood oxygen saturation (SO_2). Instead, after aspirin conditioning, placebo aspirin induced pain relief through the inhibition of all the products of COX, namely, PGD2, PGE2, PGF2, PGI2, and TXA2, yet without affecting ventilation and blood alkalosis. Therefore, two distinct therapeutic rituals used two different and independent pathways to reduce headache pain. Since a decrease in PGE2 was observed in both situations, PGE2 reduction might be the final common pathway of the analgesic effect of both the mask and the pill ritual.

Dopamine is involved in placebo responsiveness in at least two conditions: pain and Parkinson's disease. In placebo analgesia, an increase in dopamine binding to D2/D3 receptors and in opioid binding to μ-receptors occurs in the nucleus accumbens, whereas a decreased binding to the same receptors is present in nocebo hyperalgesia (Figure 1d). Likewise,

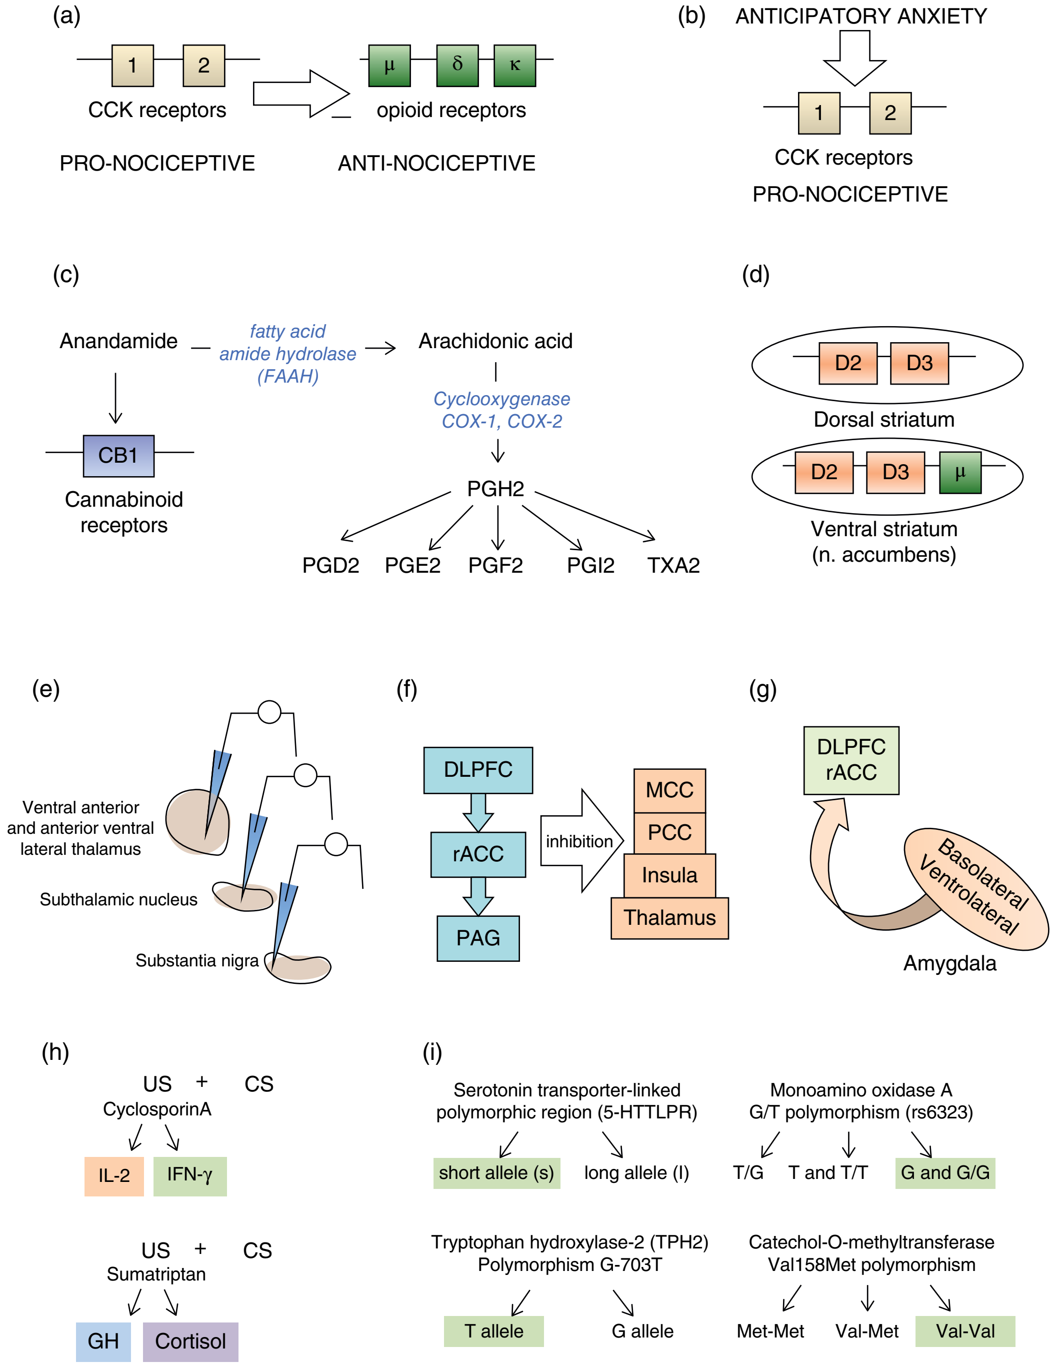

Figure 1 Principal neurobiological mechanisms of the placebo response that have been identified across a variety of conditions. (a) The antinociceptive opioid system is activated in placebo analgesia in some circumstances, and the μ-opioid receptors play a crucial role. The pro-nociceptive cholecystokinin (CCK) system antagonizes the opioid system, thus blocking placebo analgesia. (b) The pro-nociceptive CCK system is activated by anticipatory anxiety in nocebo hyperalgesia, with some evidence that the CCK-2 receptors are more important. (c) Different lipidic mediators have been identified in placebo analgesia and nocebo hyperalgesia. Whereas placebos activate the CB1 cannabinoid receptors and inhibit prostaglandin (PG) synthesis in some circumstances, nocebos increase PG synthesis. In addition, different genetic variants of FAAH affect the magnitude of placebo analgesia. (d) The activation of D2/D3 dopamine receptors in the striatum is related to the placebo response in Parkinson's disease.

dopamine receptors are activated in both ventral (nucleus accumbens) and dorsal striatum when a placebo is administered to patients with Parkinson's disease (De la Fuente-Fernández et al., 2001) (Figure 1d). The release of dopamine corresponds to a change of 200% or more in extracellular dopamine concentration and is comparable with the response to amphetamine in subjects with an intact dopamine system. Dopaminergic activation in the nucleus accumbens in both pain and Parkinson's disease suggests that reward mechanisms could play an important role in many conditions.

Intraoperative single-neuron recording in placebo-treated Parkinsonian patients during the implantation of electrodes for deep brain stimulation (Figure 1e) shows that when placebo is administered, the firing rate of the neurons in the subthalamic nucleus and substantia nigra pars reticulata decreases, whereas the firing rate of thalamic neurons in the ventral anterior and anterior ventral lateral thalamus increases, along with the disappearance of bursting activity in the subthalamic nucleus (Benedetti, 2013, 2014). Although the dopamine findings and the electrophysiological data were obtained in different studies, the changes in firing pattern of the subthalamic and thalamic neurons are likely to be triggered by dopamine release.

Modern brain imaging techniques have been fundamental in the understanding of the placebo response, particularly placebo analgesia, and many brain imaging studies have been carried out to describe the functional neuroanatomy of the placebo analgesic effect (Tracey, 2010; Wager & Atlas, 2015). A meta-analysis of brain imaging data using the activation likelihood estimation method identified two phases: the expectation phase of analgesia and the pain inhibition phase (Amanzio, Benedetti, Porro, Palermo, & Cauda, 2013). During expectation, areas of activation are found in the anterior cingulate, in the precentral and lateral prefrontal cortex, and in the periaqueductal gray. During pain inhibition, deactivations are found in the mid- and posterior cingulate cortex, in the superior temporal and precentral gyri, in the anterior and posterior insula, in the claustrum and putamen, and in the thalamus and caudate body. Overall, many of the regions that are activated during expectation are likely to belong to a descending pain inhibitory system that inhibits different areas involved in pain processing (Figure 1f).

In social anxiety disorder, positron emission tomography has been used to assess regional cerebral blood flow during an anxiogenic public speaking task, before and after 6–8 weeks of treatment with selective serotonin reuptake inhibitors (SSRI) under double-blind conditions. Conjunction analysis reveals a common attenuation of regional cerebral blood flow from

---

Likewise, in placebo analgesia, there is an activation of D2/D3 receptors and μ-opioid receptors in the nucleus accumbens, whereas in nocebo hyperalgesia there is a deactivation of D2/D3 and μ receptors. (e) Placebo administration in Parkinson patients produces a decrease of firing rate and bursting activity of the subthalamic nucleus neurons. It also produces a decrease of firing rate in the substantia nigra pars reticulata and an increase in the ventral anterior and anterior ventral lateral thalamus. (f) The neuroanatomy of placebo analgesia has been described through brain imaging. Different regions are modulated by both placebos and nocebos, but the most studied and understood regions are the dorsolateral prefrontal cortex (DLPFC), the rostral anterior cingulate cortex (rACC), and the periaqueductal gray (PAG), which represent a descending pain-modulating network. This, in turn, inhibits those regions that are involved in pain processing, such as the mid and posterior cingulate cortex (MCC, PCC), insula, and thalamus. (g) In social anxiety disorder, placebos affect the basolateral and ventrolateral amygdala as well as its projections to DLPFC and rACC. (h) In the immune and endocrine system, the mechanism of the placebo response is classical conditioning, whereby an unconditioned stimulus (US) is paired with a conditioned stimulus (CS). For example, after pairing a CS with either cyclosporine A or sumatriptan, the CS alone can mimic the responses to cyclosporine and sumatriptan. (i) Different polymorphisms have been found to be associated to low (colored squares) or high placebo responsiveness. Source: From Benedetti (2014), Cell Press.

pre- to posttreatment in responders to SSRI and placebo in the left basomedial/basolateral and right ventrolateral amygdala, including amygdala-frontal projections to dorsolateral prefrontal cortex and rostral anterior cingulate cortices (Figure 1g). This pattern correlates with behavioral measures of reduced anxiety and differentiates responders from nonresponders, with no differences between SSRI responders and placebo responders. Therefore, this pattern is capable of differentiating responders from nonresponders to both SSRI and placebos, suggesting that drugs and placebos act on common amygdala targets and amygdala-frontal connections.

High temporal resolution techniques, such as electroencephalography (EEG), have also been used to better understand the effects of expectation and learning. In different studies on laser-evoked potentials (LEPs), placebos have been reported to affect both pain perception and the N2–P2 complex, which represents the largest LEP response with peaks at approximately 200–350 ms after painful stimulation. These data show that placebo effects can be investigated at the electrophysiological level, thus providing in the future an interesting approach to a more detailed temporal analysis.

Immune and endocrine responses can be behaviorally conditioned. When an unconditioned stimulus (US), for example, the effect of a drug, is paired with a conditioned stimulus (CS), for example, a gustatory stimulus, after repeated pairings, the CS alone can mimic the effect of the drug (conditioned response [CR]). Since the CS is a neutral stimulus, it can be conceptualized as a placebo in all respects. Indeed, both immune mediators, like interleukin-2 (IL-2) and interferon-γ (IFN-γ), and hormones, like growth hormone (GH) and cortisol, can be conditioned in humans (Figure 1h). After repeated associations of a CS with cyclosporine A or sumatriptan, which produce IL-2/IFN-γ decrease and GH increase/cortisol decrease, respectively, the CS alone can induce the same immune and hormonal responses.

An association of placebo responsiveness with some genetic variants has been described in some conditions (Figure 1i). Patients with social anxiety disorder have been genotyped with respect to the serotonin transporter-linked polymorphic region (5-HTTLPR) and the G-703T polymorphism in the tryptophan hydroxylase-2 (TPH2) gene promoter. Only patients homozygous for the long allele of the 5-HTTLPR or the G variant of the TPH2 G-703T polymorphism show robust placebo responses and reduced activity in the amygdala, whereas carriers of short or T alleles do not show these effects. In addition, in patients with major depressive disorder, polymorphisms in genes encoding the catabolic enzyme monoamine oxidase A are associated to the magnitude of the placebo response. Patients with monoamine oxidase A G/T polymorphisms (rs6323) coding for the highest activity form of the enzyme (G or G/G) show small placebo responses. Functional Val158Met polymorphism of the catabolic enzyme catechol-*O*-methyltransferase (COMT) has been found to be associated with the placebo response in irritable bowel syndrome. The lowest placebo responses occur in Val/Val homozygotes. As already described above, also the functional missense variant Pro129Thr of the gene coding FAAH has been found to affect the analgesic responses to placebo.

Treatments Without Expectations

Hidden administration of therapies has provided compelling evidence that expectation is a key element in therapeutic outcome (Benedetti, Carlino, & Pollo, 2011; Colloca, Lopiano, Lanotte, & Benedetti, 2004). If the patient is unaware that a treatment is being performed and has no expectations about any clinical improvement, the therapy is less effective or not effective at all. For example, the effectiveness of the benzodiazepine diazepam is reduced or completely abolished when it is administered unbeknownst to the patient.

This holds true for other conditions as well, such as pain and Parkinson's disease. In post-operative pain following the extraction of the third molar, a hidden intravenous injection of 6–8 mg morphine corresponds to an open intravenous injection of saline solution in full view of the patient (placebo). In other words, telling the patient that a painkiller is being injected (with what is actually a saline solution) is as potent as 6–8 mg of morphine. This holds true for a variety of painkillers, such as morphine, buprenorphine, tramadol, ketorolac, metamizole, and remifentanil.

Bingel et al. (2011) investigated how divergent expectancies altered the analgesic efficacy of the μ-opioid receptor agonist remifentanil in healthy volunteers under three experimental conditions: with no expectations of analgesia (told saline, gets remifentanil), with expectation of a positive analgesic effect (told remifentanil, gets remifentanil), and with negative expectation of analgesia (told interruption, gets remifentanil). Interestingly, expectation of remifentanil (told remifentanil, gets remifentanil), namely, positive treatment expectancies, substantially enhanced, in fact doubled, the analgesic effect of the drug compared with no expectation (told saline, gets remifentanil). Conversely, expectation of interruption (told interruption, gets remifentanil) overcame the analgesic potential of remifentanil to the extent that the effects of drug were completely abolished. The subjective effects were substantiated by fMRI data showing that the enhancement of analgesia in the positive expectation condition was associated with activity in the dorsolateral prefrontal cortex and pregenual anterior cingulate cortex, whereas negative expectation of interruption was matched with activity in the hippocampus. The activity in the hippocampus is thought to stem from an increase in pain perception via anxiety mechanisms. As already pointed out, anxiety represents a powerful modulator in nocebo hyperalgesia, most likely via the activation of the endogenous CCK system.

The understanding of whether the effects of expectation and drugs combine in an additive or synergistically interactive manner is of crucial importance. Atlas et al. (2012) used a balanced placebo design to directly investigate the relationship between opioid analgesia and placebo analgesia by manipulating expectations and remifentanil concentration. The potential interactions between expectation about treatment (placebo) and remifentanil were first assessed on pain reports (behavioral experiment). In a separate experiment (fMRI experiment), participants were given intravenous remifentanil during fMRI scanning in an open–hidden design to test whether the physiological effects of remifentanil would differ as a function of treatment context (open vs. hidden administration). The results clearly challenge the notion that expectancy effects interact synergistically with opioidergic drugs. Indeed, remifentanil and expectancy both reduced pain, but drug effects on pain reports and fMRI activity did not interact with expectancy. Regions associated with pain processing showed drug-induced modulation during both open and hidden conditions, with no difference between drug effects as a function of expectation. Instead, expectancy modulated activity in the frontal cortex, with a separable time course from drug effects. Therefore, expectancy seemed to operate alongside, but independent of remifentanil, without mutual interference.

A natural situation in which hidden therapies are delivered is represented by impaired cognition. Cognitively impaired patients do not have expectations about therapeutic benefits, so the psychological (placebo) component of a treatment is absent. The placebo response of an analgesic therapy has been found to be correlated with both cognitive status and functional connectivity among different brain regions; according to the rule "the more impaired the prefrontal connectivity, the smaller the placebo response." A number of studies support this view (Benedetti, 2013). First, the individual placebo analgesic effect is correlated with white matter integrity indexed by fractional anisotropy, as assessed through diffusion tensor magnetic resonance imaging; stronger placebo analgesic responses are associated with increased mean fractional anisotropy values within white matter tracts connecting the periaqueductal gray with the rostral anterior cingulate cortex and the dorsolateral prefrontal cortex. Second, inactivation of the frontal cortex with repetitive transcranial magnetic stimulation completely blocks the analgesic placebo response. Third, the opioid antagonist naloxone blocks placebo analgesia, along with a reduction in the activation of the dorsolateral prefrontal cortex, suggesting that a prefrontal opioidergic mechanism is crucial in the placebo analgesic response. Therefore, both magnetic and pharmacological inactivation of the prefrontal lobes have the same effects as those observed in prefrontal degeneration in Alzheimer's disease and reduced integrity of prefrontal white matter.

The Placebo Effect and the Doctor–Patient Relationship

Doctors, nurses, caregivers, and therapists are essential elements of the whole atmosphere around the therapy, and the doctor–patient relationship may include many placebo and placebo-related effects. Indeed, any element of the psychosocial context is embedded in the doctor–patient interaction and seems to rely on the presence of the doctor, who uses communication, words, and medical instructions, as well as administration of pills, injections, and medications. Words and actions of healing elicit patients' trust, hope, and expectations, and these may, in turn, produce changes in the perception of symptoms or in the progress of illness (Benedetti, 2013). It is therefore not surprising that, if a treatment is surreptitiously administered without a nurse or doctor in the room, it is less effective than when it is given overtly according to routine medical practice (Benedetti et al., 2011; Colloca et al., 2004). Indeed, the decreased effectiveness of hidden therapies indicates that awareness about a treatment affects the therapeutic outcome (see previous section).

Physicians have long known the effects of the relationship with their patients and, accordingly, have used appropriate words and attitudes with them. For example, blood pressure, blood sugar, functional status, and overall health status are consistently related to specific aspects of the physician–patient communication. Moreover, a significant reduction in postoperative pain as well as a lower requirement for narcotics is present in patients who had been informed about the course of their pain and encouraged to overcome it compared with patients who did not achieve any informational or emotional support.

Placebo effects can be experimentally separated through a graded dose escalation of component parts according to the following schema: (a) assignment to a group with only evaluation and observation (waiting list), (b) group with therapeutic ritual alone (placebo acupuncture), and (c) group with therapeutic ritual with an augmented doctor–patient relationship (placebo acupuncture with a patient–practitioner relationship augmented by warmth, attention, and confidence). At 3 weeks, the proportion of the patients reporting adequate relief was 28, 44, and 62%, respectively, indicating that the doctor–patient relationship was a crucial element in the therapeutic outcome.

Positive and negative consultations in medical practice have a great impact on patients who suffer from minor illnesses. Doctors who adopt an empathic behavior are more successful than those who opt for a more formal and detached style of communication. There is also evidence that only a warm and empathic communication combined with positive expectations lead to a relevant decrease in anxiety state, thus suggesting the importance of communication style.

The positive effect of a good relationship is of particular relevance in psychotherapy. Indeed, several authors claim that psychotherapy works only through a benign human relationship. For example, it has been found that students with different psychological problems who were encouraged to interact with practiced psychotherapists with more than 20 years of experience in one case and with teachers of English, mathematics, and philosophy with renowned reputation for warmth and trustworthiness (though without previous experience as therapists) in the other, recovered in both occasions, regardless of the amount of training the real psychotherapists had achieved. It was therefore concluded that the relief that students had experienced could simply have been due to the healing effect of a positive human contact.

Overall, there are a number of studies that have shown that the doctor–patient relationship plays an important role in the outcome of illness and even diagnostics tests, which have nothing or very little to do with therapy, may induce clinical improvement. Besides expectations of improvement, other factors may be at play. For example, it is possible that a better interaction between the doctor and the patient might lead to a better compliance with drug regimens. In this regard, it is worth mentioning the Coronary Drug Project, a randomized double-controlled trial evaluating the efficacy of lipid lowering drug in the long-term treatment of coronary heart disease. The 5-year in 1,103 men treated with clofibrate was 20%. Those patients who were found to take at least 80% of their prescribed medication (good adherers) had significantly lower mortality (15%) than poor adherers (24.6%). Virtually identical findings occurred in those assigned to the placebo group, in which good adherers had 15.1% mortality and poor adherers had 28.3% mortality. This suggests that placebo may be quite powerful, and its effects may be intertwined with other phenomena, such as compliance and adherence.

The recent advances of neuroscience paved the way for an integration of the doctor–patient relationship within a neurobiological domain, as this unique social interaction involves many physiological processes in the patient's brain, from the very beginning of the illness to the therapeutic act. From a behavioral and biological viewpoint, to become and to be a patient involves at least four different steps, each of which is amenable to a true neuroscientific investigation (Benedetti, 2013) (Figure 2).

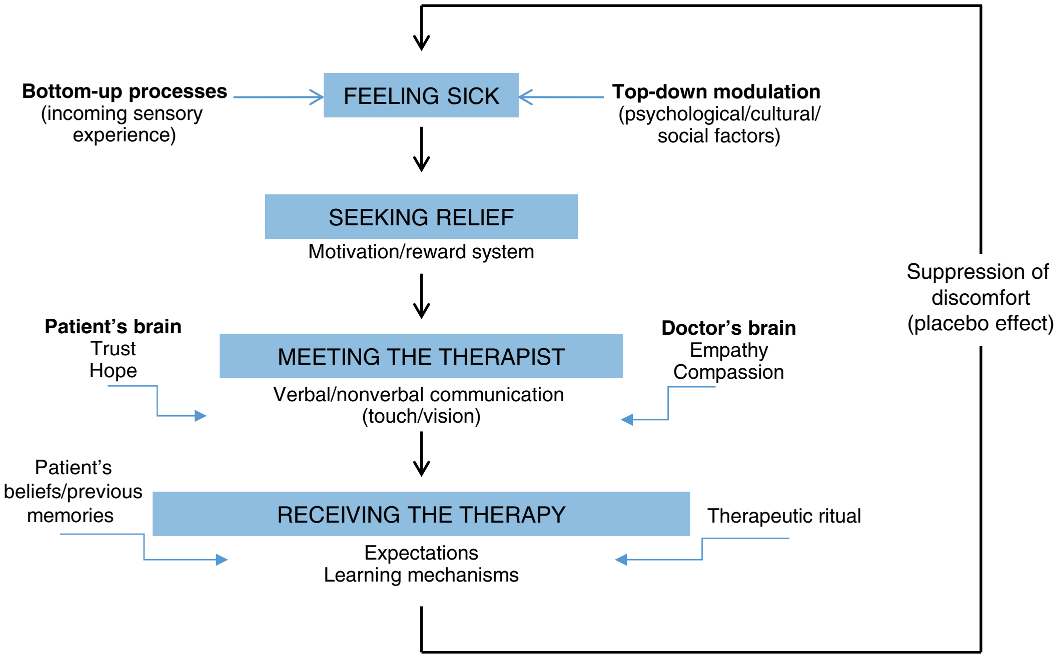

Figure 2 The four different steps of the doctor–patient relationship. The interaction between the healer/therapist and his patient can be considered as a homeostatic system in which the variable to be controlled is represented by the feeling of sickness. The mere ritual of the therapeutic act may generate therapeutic responses through the patient's expectations and beliefs (placebo responses), which sometimes may be as powerful as those generated by real medical treatments.

The first is the step of “feeling sick,” a crucial starting point that triggers the subsequent behavior. The feeling of sickness is a complex combination of events that may arise from damaged peripheral tissues as well as from their modulation by psychosocial factors. For example, the perception of a symptom such as pain is the product of bottom-up processes taking place in the peripheral and central nervous system and of top-down modulation from cognitive/evaluative and emotional/motivational brain regions (Benedetti, 2013). The physical and psychological unease experienced by the individual triggers motivational and reward mechanisms that are aimed at overcoming discomfort and seeking pleasure. “Seeking relief” is the second step of the doctor–patient relationship and represents a kind of motivated behavior that drives the patient to look for a healer/doctor who himself represents a powerful and active therapeutic agent. Indeed, the whole patient’s reward circuitry is active while he seeks relief.

The third step is when the patient “meets the therapist,” a special and unique social interaction in which the doctor represents the means to suppress discomfort. Here, many intricate mechanisms are at play, such as trust and hope in the patient’s brain and empathy and compassion in the doctor’s brain.

Trust behavior has been found to undergo hormonal modulation by oxytocin. An increase in plasma oxytocin was found in subjects who participated in a trust game whereby cooperative behavior can benefit both parties. The neural circuitry of trustworthy behavior was studied by combining the intranasal administration of oxytocin with functional magnetic resonance imaging, and it was found that oxytocin induced no change in trusting behavior after the subjects learned that their trust had been breached several times, while the control subjects who had not received oxytocin decreased their trust.

Oxytocin has been found to enhance the placebo analgesic response. Male participants were randomly assigned to a double-blind intranasal administration of oxytocin or saline and were then exposed to a set of painful stimuli administered on two different sites of each participant’s forearm. Despite identical thermal stimulation on both sites, pain ratings for the placebo site were significantly lower compared with the control site across both treatment groups, and the placebo analgesic response was significantly higher in the oxytocin group compared with the saline group. The pharmacological enhancement of the placebo analgesic response via intranasal oxytocin administration could be justified by an increased believability of the instructions provided by the experimenter. Indeed, the trust-inducing properties of oxytocin could have more favorably inclined participants to embrace the experimenter’s verbal suggestions, thus reinforcing their belief toward the “healing” properties of the “anesthetic”—actually placebo cream. Moreover, the potential of oxytocin to reduce stress and anxiety might have increased responsiveness to placebo manipulation. Since the brain distribution of oxytocin receptors overlaps with those of arginine vasopressin and the two peptide hormones are both critically involved in regulating social behavior, nonselective vasopressin agonists for both Avp1a and Avp1b receptors have been found to enhance placebo effects.

The final step of the doctor–patient relationship is when the patient “receives the therapy.” The mere ritual of the therapeutic act may generate therapeutic responses through the patient’s expectations and beliefs (placebo responses), which sometimes may be as powerful as those generated by real medical treatments. As we have seen throughout this review, these placebo responses may be approached from a biological perspective, whereby the biochemical, anatomical, and physiological link between expectation and therapeutic effect has been partially unraveled.

It is worthy to point out that these four steps can be conceived as a homeostatic system that is always at work, regardless of whether the healer administers effective or ineffective therapies. Even if the therapy is totally ineffective, the patient’s expectation of benefit (the placebo response) and the trust toward health professionals may be sufficient to inhibit discomfort. By contrast, distrust toward health professionals and therapies may elicit unwanted effects as a result of negative expectations, and these may reduce, or even conceal, the efficacy of some treatments (Benedetti, 2013). All this evidence indicates that the therapeutic encounter per se has a profound impact on the patient's brain, so it may be important for doctors, nurses, psychologists, and all other medical and paramedical personnel to enhance their interaction with patients.

Beyond the Healing Context: Physical and Cognitive Performance

All available data indicate athletes' expectations as important elements of physical performance, in spite of the fact that very different experimental conditions have been investigated. These range from short anaerobic sprints to long aerobic endurance cycling, and many different outcome measures have been used, such as time, speed, and weightlifted. These placebo responses acquire a very important meaning if central mechanisms of muscle performance and fatigue are considered, as postulated early in the 1910s through the concept of central command. The notion of central command, or central governor, implies that several physiological parameters like heart rate, arterial blood pressure, pulmonary ventilation, and muscle performance could be altered by manipulating the subject's perception of exercise. Muscle fatigue has also been found to be affected by a central governor. In many studies, athletes are usually asked to perform at their limit, and placebos apparently act by pushing this limit forward. It is interesting to note that the concept of a central governor has been applied to health as well, thus extending from fatigue and physical performance to the healing environment. Physical performance has also been found to be worsened by nocebos.

A number of studies suggest that placebos and expectations can also enhance cognitive performance and other cognition-related tasks, such as reaction times. Unfortunately, nothing is known about the underlying mechanisms, but it is interesting to note that a placebo, which subjects believed to be a memory-boosting drug, has been found to increase short-term memory through the activation of the endogenous opioid systems.

Prescriptive Authority for Psychologists

Wendy P. Linda and Robert E. McGrath

School of Psychology, Fairleigh Dickinson University, Teaneck, NJ, USA

Since its inception three decades ago, the movement to obtain prescriptive authority for psychologists, often abbreviated as RxP, has been perhaps the most controversial issue in professional psychology (McGrath, 2010). This has resulted in several preliminary evaluations of prescribing psychologists, particularly in the military, and survey research evaluating support for RxP among psychologists and medical professionals. This description of the RxP movement begins with a history of the movement, followed by a discussion of the controversy surrounding it.

A History of the Prescriptive Authority Movement

Though two task forces of the American Psychological Association (APA) in 1981 and 1985 suggested expanding the scope of practice of healthcare psychology to include biological interventions, the birth of the RxP movement is typically attributed to a speech made in 1984 by Senator Daniel Inouye of Hawaii to the Hawaiian Psychological Association, publicly recommending that psychologists pursue prescriptive authority to increase the availability of quality prescribing providers to serve a much broader patient base (Fox, 2003). As a result of Senator Inouye's interest in RxP, the Department of Defense (DoD) established the Psychopharmacology Demonstration Project (Newman, Phelps, Sammons, Dunivin, & Cullen, 2000). This program trained 10 Army, Navy, and Air Force psychologists to prescribe between the years 1991 and 1997. The evolution of the curriculum of this program is charted by Sammons and Brown (1997). Four governmental and nongovernmental evaluations of this project were conducted with generally positive findings regarding the quality of care provided. In particular, the evaluators failed to identify any adverse patient outcomes for those seeking treatment with a prescribing psychologist (McGrath, 2010).

First Edition. General Editor: Lee M. Cohen. Volume Editor: Suzy Bird Gulliver.

Though this program was terminated, the three branches of the military with healthcare services all currently have guidelines in place for privileging psychologists to prescribe. The Public Health Service and Indian Health Service have also allowed psychologists to prescribe, though those agencies have so far limited the privilege to psychologists who have obtained a license to prescribe in a state that has approved RxP.

APA has actively supported the effort to extend RxP to the states. In 1990, APA convened a task force on psychopharmacology, and RxP was adopted as official association policy in 1995 (Fox, 2003; Smyer et al., 1993). The task force recommended three levels of preparation in pharmacotherapy for psychologists. Level 1 was appropriate for all healthcare psychologists, Level 2 for those interested in collaborating with medical providers in medication decision making, and Level 3 for those who wanted to pursue independent prescriptive authority. Though training curricula were ultimately developed for all three levels, only the Level 3 curriculum has been considered important enough to merit updating (APA, 2009). In 1997, the APA Practice Organization also began the development of a competency examination called the Psychopharmacology Examination for Psychologists (PEP) that could be used as a separate licensing examination should states authorize psychologists to prescribe. Efforts to achieve this authorization soon followed.

In 1993 the licensing law for psychologists in Indiana was revised to allow prescriptive authority for psychologists participating in federally sponsored training or treatment programs, a bill that would have allowed graduates of the Psychopharmacology Demonstration Project to prescribe in Indiana. Though this was the first instance where a state approved psychologists to prescribe, to date not a single psychologist has used approval by the military to prescribe as a basis for prescribing in Indiana.

In 1999 the territory of Guam passed legislation allowing psychologists to become prescribers as long as they had a collaborative agreement with a physician in the same specialty area. However, because of issues associated with implementation of regulations, it seems that no psychologist in Guam has yet obtained prescriptive authority.

Four states have now approved prescriptive authority for psychologists using the curriculum defined by APA as the basis for their law. All require passing the PEP, licensure as a psychologist, and additional training in psychopharmacology. However, the laws differ in a number of key respects.

New Mexico and Louisiana passed legislation authorizing psychologists to prescribe in 2002 and 2004, respectively. In Louisiana, the legal title for a psychologist prescriber is *medical psychologist*. The Louisiana law requires completion of a master's degree in psychopharmacology and passage of the PEP. The medical psychologist must obtain concurrence from the patient's physician on all prescriptive decisions and is unable to prescribe to patients without a primary care physician. However, the Louisiana legislature subsequently amended this requirement. Now after 3 years of practice without any complaints, a medical psychologist can apply for a certificate of advanced practice that will allow prescribing without physician concurrence.

In the state of New Mexico, after completing coursework and passing the PEP, a psychologist must first complete an additional 480 hr of practicum experience, including 80 hr of physical examination training, and then work as a conditional prescriber under the supervision of a physician for 2 years. Only after this supervisory period may the psychologist in New Mexico prescribe independently, and continued collaboration (not necessarily concurrence) with a primary care physician is required.

In 2014, Illinois approved prescriptive authority for psychologists. This is a particularly restrictive bill, requiring the following in addition to the completion of coursework and the PEP: undergraduate biomedical courses in medical terminology, chemistry or biochemistry, human physiology, human anatomy, anatomy and physiology, microbiology, and general or cell and molecular biology; a full-time practicum of 14 months comprising at least 36 credit hours, with specific rotations enumerated; and maintenance of a written collaborative agreement with a physician. Also, psychologists are not allowed to prescribe to patients younger than 17 or older than 65, pregnant women, or patients with serious medical conditions. However, the Illinois bill is the only one that allows psychologists to receive psychopharmacology training as part of their doctoral program rather than after licensure.

In 2016, Iowa approved prescriptive authority. In addition to the standard training, the psychologist must complete a supervised practicum. The psychologist then prescribes under a conditional prescription certificate, which requires the supervision of a licensed physician. After 2 years, the psychologist may apply for a prescription certificate, which requires only a collaborative practice agreement with a physician.

In most years, RxP bills are put before the legislature in 5–7 states, with the large majority defeated each year. It is unclear at this point whether recent victories in Illinois and Iowa will represent anomalies as was true for Louisiana and New Mexico or represent a turning point in efforts to achieve prescriptive authority.

The Controversy

Whether the idea becomes more acceptable to legislators, it is an idea that has not been acceptable to medical organizations or to many psychologists. This section will outline the arguments that have been raised for and against RxP.

Training

The depth and quality of training for prescribing psychologists is a central point of contention between opponents and supporters. One issue is whether the training is sufficient to allow for safe practice. In particular, few psychologists complete the undergraduate-level foundational science coursework required of nurse practitioners and physician assistants (Ball, Kratochwill, Johnston, & Fruehling, 2009). Robiner, Tumlin, and Tompkins (2013) argued that such foundational science knowledge is critical to understanding how the body responds to medication, comprehension of the complex interaction of bodily systems, and the impact and interaction of various medications. also argued that a single administration of the PEP is inferior to the United States Medical Licensing Examination, a stepped procedure that evaluates competency at various points in the training sequence.

In response to criticisms focusing on differences between RxP training and training for physicians, it should be noted that basic science coursework is mandated as part of the APA curriculum for prescriptive authority and that the scope of practice being pursued is much more limited than is true for the medical providers referenced by. Proponents of the RxP movement have also pointed to the success of nonphysician prescribers (nurse practitioners, optometrists, dentists), who consistently receive less rigorous training than physicians (Bell, Digman, & McKenna, 1995). When compared with physicians, nurse practitioners who prescribe have demonstrated comparable outcomes and receive higher ratings for satisfaction, signaling that a medical school education is not necessarily a prerequisite for safe and effective prescribing (Lenz, Mundinger, Kane, Hopkins, & Lin, 2004).

Muse and McGrath (2010) sought to compare training programs for prescribing psychologists with training relevant to prescribing psychotropic medications for physicians and nurse practitioners up to the point at which they were legally authorized to prescribe such medications. They included topic areas they considered relevant to optimal practice that are not emphasized in traditional medical education, such as research training. While they found physicians received greater instruction in biochemistry and neuroscience, the psychologists' curriculum incorporated much more information specifically about psychopharmacology. For example, psychologists trained to prescribe were found to have received over four times as much coursework in pharmacology as physicians and six times as much as psychiatric nurse practitioners. Additionally, psychologists received much more training in the diagnosis of mental health disorders and in alternative treatments to medication than either physicians or psychiatric nurse practitioners. However, Heiby (2010) noted some flaws in the Muse and McGrath (2010) study. Specifically, though they are not required before a physician can prescribe, the study failed to consider undergraduate prerequisites, apprenticeships, and post-degree training such as residencies that almost all physicians complete before they do prescribe.

Supporters of RxP have criticized the training model from a very different perspective, arguing that the training should be incorporated into the doctoral program. Resnick, Ax, Fagan, and Nussbaum (2012), for example, proposed that a doctoral-level training model might prove to be economically advantageous for psychologists and would encourage the selection of students with a much stronger undergraduate background in natural sciences.

Safety

Concerns relate to a prescribing psychologist's ability to account for drug–drug interactions, or the impact on comorbid health problems when making prescribing decisions (Bell et al., 1995). In response, Fox et al. (2009) reported that over 70 psychologists certified to prescribe in New Mexico and Louisiana had collectively written over 250,000 prescriptions "without incident" (p. 264).

As noted previously, evaluations of the DoD Psychopharmacology Demonstration Project were favorable in terms of patient outcomes. In fact, graduates of the program served in the military as prescribers for a number of years with no untoward outcomes. Though the evaluations of the DoD program provide the most extensive evaluation to date of prescribing psychologists, it has been suggested they have limited generalizability to psychologists in the private sector (Robiner et al., 2002), because the training model was more extensive than that recommended by APA (APA, 2002 [see McGrath, 2010, for a comparison]).

Only two studies have addressed the safety and effectiveness of RxP outside the context of the demonstration project. Shearer, Harmon, Seavey, and Tiu (2012) conducted a survey of 65 medical staff, most of whom were physicians or residents, working with a prescribing psychologist in a primary care clinic. The authors found that medical staff found the presence of the prescribing psychologist helpful, safe, convenient, and overall resulting in better patient care outcomes. Over 90% of the sample reported that they had confidence in the safety of referring their patients to a prescribing psychologist for psychotropic medication management, that the prescribing psychologist would prescribe appropriate medications and dosages, and that the prescribing psychologist could determine when patients needed to be referred for additional medical evaluation.

Unfortunately, the study was flawed in that all ratings were of a single prescriber who was working as part of a team in a primary care clinic in a major US Army medical facility. The study has recently been replicated using a larger sample of both medical providers and prescribing psychologists across New Mexico and Louisiana (Linda & McGrath, 2016).

The researchers found that 30 psychologists and 24 medical colleagues overwhelmingly considered prescribing psychologists competent in the realms of safety, knowledge, and training. The most common benefit reported by medical colleagues of working with prescribing psychologists involved sharing expertise. However, more research is needed before the hypothesis of adequate safety can be considered to have been corroborated.

Another key point made by proponents of the RxP movement, arguing for the safety of the prescribing psychologist, is that a psychologist's strong foundational training in psychosocial intervention may lead prescribing psychologists to prescribe less frequently and may move more patients safely off medication, compared with other prescribers lacking such training (McGrath, 2010). However, Linda and McGrath (2016) did not find evidence supporting this hypothesis.

Access to Care

A key argument for proponents of the RxP movement is that it could increase the number of mental health professionals available to treat underserved populations (Gutierrez & Silk, 1998). At present, a general medical practice is the most frequent treatment setting for individuals with psychological disorders, and in the majority of doctor visits where psychotropic medication is prescribed, the prescriber is a nonpsychiatric prescriber (Mark, Levit, & Buck, 2009). Despite a growing need, the overall number of psychiatrists has actually fallen in recent history (Rao, 2003), especially in remote areas, and Thomas, Ellis, Konrad, Holzer, and Morrissey (2009) conservatively estimated that 96% of US counties do not have enough prescribers with specialty training in mental disorders to meet the need. As a result, psychiatric visits are decreasing in duration, and such visits often last less than 10 min (Olfson, Marcus, & Pincus, 1999). Psychiatry also has the lowest rate of participation in insurance of all medical specialties (Bishop, Press, Keyhani, & Pincus, 2013). Kaplin and Dacunto (2014) made the point that if psychologists continue to see patients weekly, the amount of time they spend with patients would be substantially greater than other prescribers who typically meet with patients monthly or less. Further, prescribing psychology may represent a more efficient model of treatment as patients can receive all of their mental healthcare from one provider.

Moore and McGrath (2007) also argued that, particularly for the military, an increase in prescribing psychologists could reduce the demand placed on nonpsychiatric physicians, freeing medical staff to allocate attention to other urgent medical needs. In a similar vein, Ax, Fagan, and Resnick (2009) proposed that the RxP model could prove beneficial to the incarcerated population. These authors reported that mental health services in correctional settings are already provided by a range of professions, including correctional counselors with minimal and often informal training in mental health issues. Fagan et al. (2004) made the case for the need for psychologist prescribers in Department of Veterans Affairs hospitals, as the number of veteran patients has increased in recent years. In those facilities, prescribing psychologists might improve access to healthcare in a setting where they could easily team with a primary care physician.

In response to concerns that prescribing psychologists are likely to be concentrated in the same metropolitan areas as other prescribers, Vento (2014) found that over 90% of prescribing psychologists surveyed in New Mexico accepted Medicaid payments and 62.6% of patients served were reported by the prescribers to be living in rural areas. However, it is unclear whether the New Mexico experience would generalize to other states. did not see the decrease in the number of psychiatrists as an argument for psychologist prescribers, but rather as a call for enhanced training for primary care physicians, nurse practitioners, and physicians' assistants, which could possibly create a far larger pool of competent prescribers than would result from allowing psychologists to prescribe. The authors also recommended further training for psychologists to work collaboratively alongside physicians. The authors did not address the issue of how many medical providers could or would pursue additional training without any financial return.

Building on Current Practices

Proponents of the RxP movement are often quick to point out that many treating psychologists are already well aware of their patients' medical regimens, and the psychologist is often included as part of a team making medical decisions or is kept apprised of medication changes or medical issues (Bell et al., 1995). VandenBos and Williams (2000) conducted a survey assessing the professional activities of 596 practicing psychologists. The majority indicated that they were involved with a patient's medication regimen in a variety of ways. It is notable that 99% of the respondents reported that they have at some time collaborated with a physician who prescribed psychotropic and other types of medication. Over 90% indicated that they had made recommendations for medication and that they had consulted with a physician about the need to alter a patient's medication. Finally, 87% of these practitioners reported having been directly involved in the decision-making process about whether to prescribe medication to a patient. Based on these findings, prescriptive authority can be conceptualized as a sequential step in a psychologist's care of a patient, rather than a break with current practice as opponents of RxP have suggested (e.g., Robiner et al., 2002).

Financial and Professional Incentives

McGrath (2010) proposed that prescriptive authority could increase financial and professional opportunities in the field of psychology, similar to the experience of nurses after obtaining prescriptive authority. Linda and McGrath (2016) found that one of the most common changes reported by psychologists since prescribing was increased salary. One unexpected outcome has been the inclusion of psychologists among the authors of some major texts in the field of psychopharmacology (Julien, Advokat, & Comaty, 2011; Stahl & Moore, 2013).

Loss of Identity

Internal concerns among psychologists focus on how the RxP movement might irrevocably change or negatively impact the identity of the profession of psychology as a whole (DeNelsky, 1996; Hayes & Heiby, 1996). Given economic forces to minimize contact with more expensive providers and pressure from insurers for a rapid cure, psychologists worry that their profession could lose the historic focus on psychosocial intervention, and as Shearer et al. (2012) noted, psychologists could become "junior psychiatrists." There is also concern that psychologists might surrender psychosocial intervention to master's level providers such as social workers or other counselors (McGrath, 2010). Further, DeNelsky (1996) predicted that because there is a greater risk of legal action for medication-related decisions than for psychological interventions, more time may need to be devoted to learning about medication in the continuing education of prescribing psychologists at the expense of psychosocial intervention strategies.

DeNelsky (1996) also argued that medications cannot be conceptualized as simply another "tool" in the psychologist's toolbox. The concern is that, as occurred with psychiatrists, this one tool would come to dominate practice, in part because of aggressive marketing by the pharmaceutical industry but also because of increased demands on the psychologist's time. LeVine, Wiggins, and Masse (2011) found that 13 of 17 prescribing psychologists working in private practice in the states of New Mexico and Louisiana reported that sales representatives from pharmaceutical companies had not particularly targeted them, but a few did receive drug samples and small gifts such as pens. It is reasonable to hypothesize, however, that if the RxP movement expands, psychologists will experience greater pressure from the pharmaceutical industry. This also does not address the influence of more subtle marketing such as manipulation of publications.

In line with this concern, McGrath (2004) argued that it would be naive to believe that prescribing psychologists will not experience similar pressure to emphasize medication over other interventions, particularly from insurers, and in anticipation of such pressure, psychologists will need to develop strategies for resistance. He suggested one possible response to those external forces would be for psychology to develop an ethical guideline forbidding psychologists from prescribing to individuals for whom they are not also providing psychosocial interventions. However, this may stand in the way of the RxP's goal of overall increasing access to psychopharmacological care.

Ethical Implications

Buelow and Chafetz (1996) argued that the RxP movement comes with a range of ethical considerations for a "subfield" that touches on territory not previously considered or entered into by psychologists. The authors proposed some ethical standards appropriate to the situation, including the importance of clear therapeutic contracts, transparent and delineated treatment objectives, and agreement by the patient about which modalities of treatment will be used. Psychologists will need to be open about the risks and the benefits of different forms of treatment. Parameters of informed consent will need to be reconsidered as well, and professional relationships will need to readjust along with the shifting role of the psychologist within the healthcare system. Mantell, Ortiz, and Planthara (2004) raised the lack of empirically based research approaches for the appropriate combination of medical and psychological interventions as an ethical issue. However, an increase in the number of psychologist prescribers may foster the development and validation of such treatment protocols.

Though ethical standards specific to prescribing have not yet emerged in psychology, APA (2011) has adopted practice guidelines relevant to psychologists' involvement in pharmacotherapy. Unlike ethical standards, which for psychologists are mandatory and enforceable, practice guidelines are intended to represent optimal practice related to a domain of practice, are aspirational in nature, and represent optimal practice recommendations.

Conclusions

Opinion related to psychologists prescribing is also still evolving. Research demonstrates that the majority of psychologists favor prescriptive authority for psychologists (RxP; Fagan et al., 2004; Rae, Jensen-Doss, Bowden, Mendoza, & Banda, 2008; Walters 2001), though there is still opposition within the field (Robiner et al., 2013). This opposition has often centered on how prescriptive authority will impact the practice of psychology, leading to questions regarding the abandonment of psychosocial intervention (DeNelsky, 1996; Hayes & Heiby, 1996). However, with additional legislation for RxP, more research on the practices of prescribing psychologists, and new guidelines for their practice, opinions may shift. Organized psychiatry continues to oppose RxP, and both the American Psychiatric Association and the American Medical Association have lobbied against legislation (Robiner et al., 2013). Again, these views of RxP may evolve over time with more prescribing psychologists working in integrated healthcare settings and more research related to patient outcomes.

In one important way, the debate about whether psychologists should prescribe is irrelevant, in that psychologists have been prescribing for over 20 years, with no evidence of incompetence, and therefore unlikely to evaporate. Whether it will reshape the nature of the profession and whether tensions will emerge over time between prescribing and non-prescribing psychologists are questions to be followed closely.

Author Biographies

Wendy P. Linda, PhD, received her doctorate in clinical psychology from Fairleigh Dickinson University, Teaneck, NJ. Currently, she is finishing a postdoctoral fellowship focused on inpatient psychology at Long Island Jewish Medical Center–Zucker Hillside Hospital of Northwell Health, Glen Oaks, New York. Her clinical and research interests include the treatment of chronic and severe mental illness, trauma and substance use, and professional issues in healthcare psychology.

Robert E. McGrath, PhD, received his doctorate in clinical psychology from Auburn University, Auburn, AL. He is a professor of psychology at Fairleigh Dickinson University in Teaneck, NJ. He is also a senior scientist for the VIA Institute on Character in Cincinnati, OH. He maintains an active research program in professional issues in health service psychology, character, and program evaluation.

Overview

Quality of life (QoL) is a broad construct that encompasses multiple dimensions of a person's current status. The construct has been defined in numerous ways. Most definitions of QoL focus on people's perceptions of physical, psychological, and social well-being. However, definitions of QoL are wide ranging. Some definitions additionally include an individual's perceptions of all aspects of life including occupation, housing, neighborhood, culture, values, and spirituality. Other definitions assert that QoL is composed of both objective and subjective components; that is, in addition to self-perceptions of one's current status, QoL also includes objective components that can be measured using biological, social, or behavioral indicators of one's status.

While several definitions of QoL exist, a widely accepted definition of QoL has been delineated by the World Health Organization (WHO). The WHO defines QoL as "an individual's perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards and concerns" (WHOQOL Group, 1997, p. 1). The WHO's definition of QoL encompasses people's "physical health, psychological state, personal beliefs, social relationships, and their relationship to salient features of their environment" (WHOQOL Group, 1997, p. 1), as well as spirituality and religion.

Health-related quality of life (HRQoL) is a sub-construct of QoL. Like QoL, HRQoL is a multidimensional construct that has been defined in several ways. HRQoL has been generally conceptualized as the domains of QoL specifically related to health; that is, it includes the impact of health, disease, and treatment on QoL. Similar to QoL, the construct of HRQoL is also composed of both subjective and objective components. HRQoL includes individuals' perceptions with regard to physical, psychological, social, and other domains of health, as well

First Edition. General Editor: Lee M. Cohen. Volume Editor: Suzy Bird Gulliver.

as individuals' actual functioning and objective ratings in the context of these domains. HRQoL has also been defined with regard to values assigned to particular health states, for example, as "the value assigned to duration of life as modified by the impairments, functional states, perceptions, and social opportunities that are influenced by disease, injury, [and] treatment" (Patrick & Erickson, 1993, p. 22).

The construct of HRQoL arose in order to complement traditional indices of health used in the medical field, namely, mortality and morbidity. While research on QoL began in the 1950s, interest in HRQoL increased in the 1970s. With greater prevalence of chronic versus acute disease and reductions in disease-related mortality due to advancements in medical technologies, an increasing number of individuals began living with chronic disease for extended periods of time. HRQoL arose as an important indicator of health in these contexts, in which outcomes such as mortality fail to capture the health status of an individual coping with a long-term chronic disease and its treatment.

Measurement

HRQoL has typically been assessed through self-report measures because of the need to capture people's perceptions of their health-related status. Many instruments are completed in paper-and-pencil or computer-administered versions; measures can also be administered via in-person interview or telephone or even by proxy (e.g., caregiver) if the individual is unable to complete the measure. HRQoL measures can be generic and/or specific. Generic measures can be used with any adult population, regardless of diagnosed disease, treatment received, or demographic background. In contrast, specific measures are tailored to a particular disease, condition, treatment setting, symptom, or population.

Generic Self-Report Measures of HRQoL

Generic HRQoL measures allow for assessment across groups with varying disease types, disease severity, and demographic characteristics. Generic measures are broad in nature and assess attributes of QoL that are applicable to diverse groups and diseases. Generic measures are commonly used in cost-effectiveness studies comparing outcomes across various groups or interventions. While such measures allow for cross-group comparison, these instruments may not capture important aspects of HRQoL specific to a particular disease or group.

Examples of commonly used generic measures of HRQoL include the Medical Outcomes Study 36-Item Short-Form Health Survey (SF-36) and shortened versions of the instrument (RAND Corporation, 2017; Ware & Sherbourne, 1992), the World Health Organization Quality of Life (WHOQOL) assessments (WHOQOL-100 and WHOQOL-BREF) (WHOQOL Group, 1997, 1998), Health and Activity Limitation Index (HALex) (Erickson, 1998), EuroQol-5 Dimension (EQ-5D) (Brooks, Rabin, & de Charro, 2003), Health Utilities Index Mark 2 (HUI2) and Health Utilities Index Mark 3 (HUI3) (Horsman, Furlong, Feeny, & Torrance, 2003), Quality of Well-Being Scale Self-Administered (QWB-SA) (Seiber, Groessl, David, Ganiats, & Kaplan, 2008), and Patient-Reported Outcomes Measurement Information System Global Health Scale (PROMIS Global Health) (Hays, Bjorner, Revicki, Spritzer, & Cella, 2009). Additionally, quality-adjusted life years (QALYs) can be calculated from several generic measures to allow for broad comparisons across studies (Kaplan & Frosch, 2005).

The SF-36 is a 36-item measure of health status that is one of the most widely used generic measures of HRQoL worldwide (Ware & Sherbourne, 1992). The instrument assesses eight domains for which scores are calculated, namely, "(a) limitations in physical activities because of health problems; (b) limitations in social activities because of physical or emotional problems; (c) limitations in usual role activities because of physical health problems; (d) bodily pain; (e) general mental health (psychological distress and well-being); (f) limitations in usual role activities because of emotional problems; (g) vitality (energy and fatigue); and (h) general health perceptions," and additionally contains a single item measuring perceived change in health (Ware & Sherbourne, 1992, p. 473). Shortened versions of the SF-36 include Short Form-6 Dimension (SF-6D), 12-Item Short Form Survey (SF-12), and 20-Item Short Form Survey (SF-20) (RAND Corporation, 2017).

The WHOQOL-100 and the WHOQOL-BREF are two widely used measures of QoL developed by the WHOQOL Group (WHOQOL Group, 1997, 1998). The WHOQOL-100 and WHOQOL-BREF are included in this section on HRQoL assessment tools because the instruments were designed for use and are commonly used in health contexts (WHOQOL Group, 1997). Notably, because most assessment instruments have been developed for use in one specific cultural setting, the WHOQOL Group designed the WHOQOL-100 and the WHOQOL-BREF as assessment tools that could be used internationally in health contexts both within and across various cultures. The WHOQOL-100, a 100-item measure, was developed in fifteen centers simultaneously around the world (WHOQOL Group, 1997, 1998). The WHOQOL-100 contains items that assess overall QoL and health as well as 24 facets of QoL, which can be grouped into 4 domains: physical, psychological, social relationships, and environment (WHOQOL Group, 1998). The instrument generates scores for overall QoL and health, facets of QoL, as well as for each of the four domains (WHOQOL Group, 1997). The WHOQOL-BREF, a 26-item short form of the WHOQOL-100, was developed thereafter and contains items measuring both overall QoL and the same facets of QoL assessed by the WHOQOL-100 (WHOQOL Group, 1997). The WHOQOL-100 and WHOQOL-BREF are available in more than 20 different languages and are used to capture health both within and across cultures (WHOQOL Group, 1997).

The HALex is a measure of health that takes into account two components: (a) perceived health and (b) perceived activity limitation, that is, an individual's perception of their ability to perform age-relevant social roles (Erickson, 1998). The HALex yields a total score representing HRQoL that is a composite of the aforementioned components (Erickson, 1998).

The EQ-5D is a measure of perceived health status that is used with individuals with a variety of health conditions (Brooks et al., 2003). The EQ-5D is composed of five domains: mobility, self-care, usual activities, pain/discomfort, and anxiety/depression. The instrument yields five one-digit numbers expressing how problematic each domain is for the respondent. The five one-digit numbers are combined into a single five-digit number representing a single summary index of health. Additionally, the measure has a visual analog scale, which provides a measure of perceived general health status (Brooks et al., 2003).

The HUI2 and HUI3 are multidimensional measures of perceived health status (Horsman et al., 2003). Both instruments yield information about overall health as well as functioning pertaining to specific health-state attributes. HUI2 provides information about seven health-state attributes (sensation, mobility, emotion, cognition, self-care, pain, and fertility), whereas the HUI3 provides information about eight health-state attributes (vision, hearing, speech, ambulation, dexterity, emotion, cognition, and pain). Both the HUI2 and HUI3 are composed of two systems. One system, the "generic comprehensive health status classification system," provides written descriptive ratings of a person's ability or disability with regards to each health-state attribute (Horsman et al., 2003, p. 2). The other system, the "generic HRQoL utility scoring system," yields scores representing level of morbidity for each health-state attribute as well as a score representing overall health (Horsman et al., 2003, p. 2). HUI2 and HUI3 differ with regard to the health-state attributes each include as well as the fact that HUI3 descriptive ratings are more detailed than those of HUI2 (Horsman et al., 2003).

The QWB-SA is a measure of perceived health status commonly used in cost-effectiveness research (Seiber et al., 2008). The instrument is composed of five parts that assess (a) chronic symptoms, (b) acute physical symptoms and mental health symptoms, (c) mobility, (d) physical activity, and (e) social activity. The QWB-SA yields a single index measuring wellness.

PROMIS Global Health is a measure of perceived overall health (Hays et al., 2009). The measure was created through the National Institutes of Health (NIH) Patient-Reported Outcomes Measurement Information System (PROMIS) Roadmap initiative, which focuses on the development of a computerized system measuring patient-reported outcomes. PROMIS Global Health contains ten items and yields summary scores for physical health and mental health. Items from PROMIS Global Health can also be examined separately to assess perceptions of general health, social roles, physical function, pain, fatigue, and emotional problems (Hays et al., 2009).

QALYs are an additional index that can be used to summarize health outcomes (Kaplan & Frosch, 2005). QALYs summarize health status by taking both morbidity and mortality into account. QALYs describe "well years of life," that is, they describe years of life with adjustments for HRQoL (Kaplan & Frosch, 2005). QALYs apply weights to years of life lived to describe the value of HRQoL each year. QALYs range from 0.0 to 1.0, representing death and optimal health, respectively. QALYs are advantageous as they can be computed from several commonly used measures of HRQoL including the SF-6D, HALex, EQ-5D, HUI2, HUI3, and QWB-SA and then used to make broad comparisons across various studies or interventions.

Specific Self-Report Measures of HRQoL

Specific HRQoL measures provide in-depth assessment of attributes relevant to groups of individuals with specific health conditions or challenges. These measures allow for detailed assessment of HRQoL in the context of a particular disease, condition, treatment, symptom, or population. Disease-specific measures often exhibit greater sensitivity to change than generic measures and are commonly used in studies assessing clinically significant changes in HRQoL within a given population or group. Specific measures, however, do not allow for comparisons across different groups or diseases and have limitations when used with individuals with multiple medical comorbidities.

An example of a disease-specific measure is the European Organisation for Research and Treatment of Cancer (EORTC) Core Quality of Life Questionnaire (QLQ-C30) (van Andel et al., 2008). The EORTC QLQ-C30 is a measure of HRQoL developed specifically for use in the context of cancer. Add-on modules to disease-specific measures are also available. For instance, the EORTC Quality of Life Questionnaire module for prostate cancer (QLQ-PR25) is an example of an add-on module to the EORTC QLQ-C30 that specifically evaluates HRQoL in the context of prostate cancer (van Andel et al., 2008). Specific measures of HRQoL also exist as stand-alone instruments. An example of a specific stand-alone instrument is the Expanded Prostate Cancer Index Composite for Clinical Practice (EPIC-CP) (Chang et al., 2011). This instrument assesses attributes of HRQoL specifically integral to prostate cancer including urinary incontinence and irritation and bowel, sexual, and vitality/hormonal health that would likely not be captured using generic measures.

Interventions

Interventions exist to improve HRQoL. Patient self-management is the main intervention used in this regard. Patient self-management is a multicomponent psychoeducational intervention designed to facilitate a patient's daily management of all aspects of a chronic illness including its symptoms, treatment, and physical and psychological sequelae (Jonkman, Schuurmans, Groenwold, Hoes, & Trappenburg, 2016), with the ultimate goal of improving or maintaining HRQoL. Self-management interventions emphasize the role of the patient in conjunction with a healthcare team in managing a chronic illness. Patient self-management can be implemented in both group and individual formats and often focuses on patient education as well as the acquisition of skills such as effective problem-solving and decision making, resource utilization, and action taking. Self-management interventions designed to improve HRQoL exist for a variety of chronic illnesses including arthritis, diabetes, asthma, hypertension, and chronic obstructive pulmonary disease.

In addition to self-management, several additional evidence-based interventions exist to improve or maintain the various domains of HRQoL. For instance, there are evidence-based pharmacological (e.g., pain medications) and behavioral (e.g., sleep hygiene) interventions available to address physical components of HRQoL. There are also evidence-based interventions available to address components of the psychological domain of HRQoL, such as cognitive behavioral therapy for anxiety and depression. Further, effective interventions exist to improve the social domain of HRQoL, including interventions to enhance and/or utilize social support and interventions involving or focused on caregivers. The multitude of evidence-based interventions that exist to improve patient physical, psychological, social, and other aspects of well-being can be used to promote HRQoL among individuals facing various health issues.

The Roles of Health Psychologists in Surgery

Lauren Decaporale-Ryan[1] and John D. Robinson[2]

[1]Departments of Psychiatry, Medicine, & Surgery, University of Rochester Medical Center, Rochester, NY, USA
[2]Department of Surgery and Department of Psychiatry and Behavioral Sciences, Howard University College of Medicine/Hospital, Washington, DC, USA

Clinical health psychologists today are uniquely prepared to impact healthcare systems with expertise and knowledge in the biopsychosocial framework, impacts of medical illness on psychological well-being, communication, and systems thinking. With such skill sets, psychologists have increasing opportunity to care for patients in medically integrated settings and to serve as educators to interprofessional learners. Though interprofessional roles have mainly evolved in primary care settings, they are vital in all medical specialties, as today's healthcare systems must pay increased attention to patient satisfaction and incorporation of patients' psychosocial needs. While surgical departments have long appreciated the importance of consultation for preoperative evaluations, there is increasing awareness among surgeons of the value of psychological consultation and intervention in other areas as well.

Surgeons receive a great deal of technical training but can significantly benefit from psychologists' knowledge and analytical approach to problem solving. Specifically, psychologists are well versed in subjects pertinent to surgical practice, including ethics, professionalism, and burnout. This chapter provides recommendations on how to orient oneself to surgical culture and explores the possible roles psychologists may find themselves in, or wish to create, in surgery departments. Special considerations are offered that will influence psychologists' work in surgical environments.

The Wiley Encyclopedia of Health Psychology: Volume 4: Special Issues in Health Psychology,
First Edition. General Editor: Lee M. Cohen. Volume Editor: Suzy Bird Gulliver.

Surgical Culture: The Importance of Observation

Psychologists are trained in the art of behavioral observation with the awareness that observation allows understanding. It is imperative when entering any setting outside our normal purview that we apply these skills to best understand the culture. Knowledge of cross/multicultural issues enables clinical health psychologists to interact effectively in various environments and with different professional groups. When entering a world that is unknown and for which we are not trained, we must take time to become better informed about the environment and its people before offering recommendations. Though surgical settings are influenced by individual system factors, there are certain commonalities across surgery departments. These features deeply influence the collaborative work that occurs between psychologists and surgeons. For example, surgery departments do not function solely from nine to five. To effectively save lives, surgeons are on call 24/7 and operate at all hours of the day and sometimes through the night; this is a drastic difference in culture for a psychologist.

Action Oriented

The mindset of a surgeon must also be understood, as it is generally different even from other physicians (Katz, 1990; Page, 2011) and especially from that of a psychologist. While psychology emphasizes supporting others to identify a problem and develop a solution, surgeons traditionally are action oriented (Page, 2011), tending to see a problem and quickly fix it. Speed and decisiveness are critical skills in the operating room (OR); surgeons frequently face life-or-death situations, which require immediate action and could have drastic consequences if delayed. They are trained to be both confident and decisive (Katz, 1990). This approach is of course what is medically necessary but can be deleterious when managing things other than direct patient care. Surgeons, like all other physicians, should be encouraged to take time for reflection. Such introspection can reduce risk of surgeon burnout and improve the patient and team experience (Page, 2011).

In this context, psychologists have much to offer to surgical culture. Psychologists can encourage surgeons to methodically evaluate non-urgent situations so that they can more wholly define the problem, give more thorough explanations, and provide a more comprehensive plan of intervention. Application of their critical thinking skills and analytical approach can then result in more meaningful and long-lasting solutions for nonsurgical team members and surgical systems. Facilitation of such reflection and analysis also supports development of a healthy team environment that allows for information exchange and sharing of ideas outside of the OR.

Surgical Hierarchy

The surgeon is a part of a much larger team, which often reflects a defined and established hierarchy. Though other settings may have deemphasized hierarchy, it remains a part of surgical culture. Surgeons' leadership styles differ from other medical disciplines in authority and responsibility, which are necessary due to the action-oriented structure of surgery and the need to intervene quickly. It is important to understand that there is a reason this particular hierarchy exists and observe how and why it works and can be more efficient. One may also observe that this system is personality driven and suits the general personality of surgeons, which may be markedly different than internist, psychiatrists, and other physicians. The psychologist's knowledge of personality styles is invaluable. An understanding of the system will also allow the clinical health psychologist to apply his or her knowledge in a very effective manner. It is important to be a member of the team with skills that become valued by its constituents. Being part of a team and recognized as a specialist with unique skills is important just as the various surgical specialists (plastic, ENT, CT, etc.) are each valued members of the surgical team with different skills to offer.

Creating an environment where such hierarchy is respected but also allows for shared communication can be challenging. One must respect others but challenge inappropriate behaviors, lack of professionalism, and poor communication when necessary. When hierarchy is appropriately managed, it promotes patient safety and supports education. Prentice (2007) has noted that hierarchy allows surgical faculty to evaluate both the technical and social readiness of learners in the OR and their preparedness to take on more tasks. Psychologists can help promote and teach about healthy hierarchical boundaries, ensuring that hierarchy does not endorse microaggressions (or outward aggressions) and instead values the importance of collegiality and collaboration.

Different Divisions, Different Needs

It is important for a psychologist working in a surgical environment to remember that their job is not to make the surgeon a psychiatrist, but to make them a better, more effective surgeon. As psychologists become acquainted with the surgery environment, they will also find that different surgical specialties have unique attributes and needs. The demands on a trauma surgeon are unlike those placed on a cardiothoracic surgeon. The skills (technically, cognitively, interpersonally) required of each setting are intricate and determined by the clinical operations, the teams, and the larger medical setting in which a surgery service is embedded. Often times, these details may result in apparent changes in individual and team behavior and communication.

Moreover, these distinctions influence the learning environment and how trainees engage with faculty surgeons. For example, surgical residents in training may find that they have greater autonomy and ability to run a team when the stress level is deemed more manageable; conversely, they may have to rely more heavily on faculty guidance or work more closely with mid-level providers if the residents' knowledge base and technical skill are not adequate enough for safe patient care. Recognizing these differences in settings allows psychologists to adapt and appropriately assess, consider, and respond to the needs of surgeons in these cultures effectively. How a psychologist might become integrated, give feedback, or teach in one surgical setting may not apply in the very next corridor. Psychologists should use their observational and assessment skills to determine the needs in that particular setting based on their assigned duties.

Surgeons Are Stressed, and So Are the Patients

Surgery goes beyond the scalpel and sutures and leaves scars, both seen and unseen (Balch, Shanafelt, Sloan, Satele, & Freischlag, 2011). Anton, Montero, Howley, Brown, and Stefanidis (2015) note that 40% of surgeons reported witnessing an intraoperative complication that was directly related to the surgeon's stress. Stress in the OR is just one forum that challenges the psychological well-being of surgeons; this clinician population must also deliver bad news and communicate about death and other forms of loss to patients and families.

Moreover, surgery to a patient is much more than a procedure. Surgery has significant implications for patients and their loved ones, as it creates personal, professional, and financial disruptions that are often unexpected (Petry, 2000). In this context, patients' anxiety can be heightened, changing how they interface with the medical team. Psychologists are well prepared to recognize the signs and symptoms of anxiety (or other psychological distress) and can help surgeons' identify and respond to such affect so that patients are heard and understood. Meeting the needs of patients while also responding to the administrative and revenue obligations required by the hospital system is taxing. Psychology has the opportunity to offer consultation regarding coping strategies to enhance surgeons' effectiveness and support their emotional well-being as well.

Observations Made, Now What?

The psychologist must not only observe surgical culture but also become a part of the milieu. This is no easy task. It requires a clear role, tough skin, and a surgical champion who supports the psychologist's work. Surgery departments may not know the exact ways in which psychology can contribute. However, when surgeons identify and acknowledge a need for support of any kind, there are many opportunities for psychology to critically influence the environment. To do so most effectively, psychologists should strongly advocate to be directly embedded in the department. There are some relatively easy ways to initiate this type of working relationship, such as having an office on a surgical floor: be centrally located to the rest of the department so that faculty, staff, and learners have access to share information, exchange ideas, and ask questions. Additionally, based on the defined role and responsibilities, psychologists should find ways to become integrated into meetings, training curriculums, and team rounds. Such efforts will also help identify additional roles that psychologists might be interested in and well trained to support.

In order to have maximum effectiveness, it is valuable for the psychologist to be seen as a part of the surgical faculty, not as a visitor from another department with no ties to surgery. Therefore, a dual/joint faculty appointment with surgery is ideal. Once in the department, the psychologist should make attempts to not only understand the difference in culture but to also be seen as part of it; as a dedicated member of the team, the psychologist can make significant contributions.

The Potential Roles of Psychology in Surgery

Exploration of the culture and observations may reveal multiple possible roles for the psychologist who wishes to support surgical departments. Clinical health psychologists are well prepared to take on any number of tasks from preoperative patient evaluations to assessment and consultation regarding team effectiveness and individual clinician well-being to administrative and teaching roles. Robinson and Baker (2006) have discussed some of these roles and duties in a general medical/academic health center. Surgical faculty, staff, and learners will value psychologists' ability to listen and help them deal with concerns that impact the efficiency of the department.

Psychologists as Educators

Psychologists are uniquely positioned as experts in communication to support a breadth of training experiences in surgical education and for medical teams. While physicians have some exposure to communication techniques that support enhanced patient care and clinician efficiency, such methods are rarely reiterated throughout surgical residency. Psychologists can provide consultation regarding best practices at the bedside and also offer more knowledge of how to implement techniques like teach-back and balancing open and close-ended questions. There is clear evidence that communication has direct impact on patient care experiences, influencing postoperative outcomes, malpractice lawsuits, and general patient satisfaction (Greenberg et al., 2007). In this context, psychologists are appropriately suited to provide education to surgical residents, faculty, and staff about how to best approach patient and family dialogue, thus enhancing the physician–patient relationship. Models of this vary from one institution to the next but can include didactic training, simulation exercises, or even one-to-one coaching.

Such training initiatives can also reveal the other learning needs of clinicians in surgery. For example, surgeons are expected to run teams but may have minimal training (aside from lived experience) about team culture, managing different personality styles, and pertaining to leadership. Additionally, each surgeon (like all of us) comes with their own strengths and shortcomings as a leader: some have an innate ability to take a systems' perspective, while others struggle to build a trusting relationship with even one team member. Psychologists, especially those with specialized training in medical integration and systems thinking, can offer important perspective that supports development of surgeons as professionals in nonoperative roles and as leaders of the medical field.

Presently, the Accreditation Council for Graduate Medical Education (ACGME) requires assessment of a range of competencies. These competencies not only reflect knowledge about patient and team communication but also reflect the need to train clinicians who carry themselves professionally and who can navigate complex medical ethics and understand the biopsychosocial needs of patients. Psychologists offer unique perspective on these subjects and have opportunity to create psychosocial curriculum including content in ethics and professionalism. Such training can be built into surgical education over the course of a resident's education.

Notably though, the psychologist who serves in this educational capacity must articulate and maintain clear boundaries. Specifically, the psychologist who serves as an educator (and therefore evaluator of knowledge and behavior) should not also serve as a clinician to residents or faculty members. In such instances, it is important to remind others of the role as an educator and support referral to an outside clinician (ideally someone who is familiar with the demands of medical settings).

Psychologists as Clinicians

Of course, psychologists often serve as direct clinical care providers. Psychologists are increasingly embedded in surgical departments or sought as consultants for preoperative assessments. In this context, psychologists can conduct psychosocial evaluations that help to identify risk factors that may influence surgical outcomes. Bariatric and transplant surgeries have both demonstrated the importance of psychological evaluation. Preoperative psychological evaluations are now required for metabolic and bariatric surgery centers to be accredited by the American College of Surgeons and the American Society for Metabolic and Bariatric Surgery (American College of Surgeons, American Society for Metabolic and Bariatric Surgery, 2014; Mechanick et al., 2013). Similarly, preoperative psychosocial evaluations for transplant surgery have been shown to positively contribute to the ultimate success of surgery and overall care (Dobbels, Verleden, Dupont, Vanhaecke, & De Geest, 2006).

Evaluations identify patients' available social supports, level of cognitive functioning, and capacity to implement and sustain behavioral change after surgery. As such, psychologists can speak to individuals' strengths and vulnerabilities and offer recommendations to enhance the success of surgical intervention and mitigate possible risk (Dobbels et al., 2006). Recommendations may include additional psychoeducation to support patients' full understanding of the surgery or necessary behavior change afterward, pharmacological management of mood, and psychotherapy pre- and/or post-surgery to support adjustment to physiological changes. The psychoeducational group approach has been used by organ transplant programs for some time (Stewart, Kelly, Robinson, & Callender, 1995).

Psychologists can also provide clinical care in response to conditions such as needle phobias, distress in preparation of surgery, trauma related to past healthcare experiences, and so on. Such interventions are brief in nature and focused on improving patients' coping strategies, problem-solving abilities, and general management of anxiety in healthcare settings (Petry, 2000). When able, psychologists should offer these services in the healthcare setting, allowing for ease of access to care, collaboration with patients' treatment team, and an opportunity to observe patients' needs in this environment. It is important to remember that when patients are facing surgery, this can be one of the most stressful periods of time in their lives (Petry, 2000). Psychologists can support patients through this period and can also help surgeons better recognize and respond to patient affect.

When surgeons struggle with this work or do not have adequate time to explore the psychosocial needs of patients, clinical health psychologists may find that this results in increased referrals for therapeutic intervention. In these cases, the psychologist should definitely be aware of shared information with the clinical team and make these limits on boundaries of confidentiality clear to the patient. This work may frequently focus on providing psychoeducation on the mind–body relationship and the influence of stress on physiological health and about the manifestation of somatic symptoms. With a collaborative approach, patients' biopsychosocial needs are more readily identified, and psychologists can work with patients to reduce distress and physiological symptoms, including pain (Turk & Gatchel, 2013) and GI distress (Palsson & Whitehead, 2013).

Psychologists as Consultants

Psychologists can provide a range of additional consultation that reflects the unique range of skills of the discipline. Similar to what is outlined above, clinical health psychologists embedded in healthcare settings, including surgical departments, can provide consultation regarding patients. Such consultation might be pertaining to acute management of anxiety, in support of facilitating effective family meetings, or if there is awareness that psychiatric symptoms are hindering establishment of safe discharge planning. Such roles are more frequently and formally met by psychiatric services. The surgical clinical health psychologist may be asked to provide formal consultations or more informal "curbside" consultation.

Additional roles of consultation that directly support surgical colleagues are easily identifiable. Surgeons face many professional stressors, including tragic and unanticipated losses (Shanafelt et al., 2009). Though surgeons have the opportunity to learn from such events through morbidity and mortality conferences, this venue focuses on clinical skill and how management of patient care could have been navigated differently. Others have advocated that surgeons should also have the opportunity to explore their emotional reactions following adverse events to support their learning, growth, and healing (Plews-Ogan et al., 2016). Psychologists can offer space to process the emotional aspects of patient death and more broadly as it relates to the demands of the job. Such consultation can occur on a one-to-one basis or in group venues that allow for exploration of affect, normalizing grief, and establishment of coping strategies to minimize distress.

It is not uncommon that the professional stress that surgeons face creates interpersonal struggles outside of work and psychological impairment. Surgeons, like physicians across many other disciplines, face high rates of burnout, depression, and increased substance abuse (Oreskovich et al., 2014; Spickard, Gabbe, & Christensen, 2002). Moreover, they may struggle to share their experiences with family and friends who cannot fully appreciate the nature of their work with significant impact on their family system. Home life experiences and conflict between work and home balance influence rates of burnout among surgeons (Dyrbye, Shanafelt, Blach, Satele, & Fresichlag, 2011). Psychologists can promote a culture that supports individual wellness and/or may provide direct care to surgeons. It is important to note that psychologists who serve as educators and administrators should not provide this direct clinical care to individuals but can support establishment of referrals to others who have sophisticated knowledge of medical culture. However, those embedded in surgery departments can help establish a curriculum that promotes wellness, training surgeons about techniques that support mindfulness and reduced distress.

Special Considerations

The OR and Other Elements of the Clinical Environment

Physicians' exposure to the OR occurs early in their medical school training and continues for surgeons through residency and often fellowship training. Surgeons are required to participate in a defined number of major operative cases with a designated role during the course of their residency training as defined by ACGME. This means they are well equipped to navigate cutting, suturing, knotting, and the like. The capacity to engage in this work requires extraordinary technical skill, a balance between detachment and appropriate intimacy with patients (Katz, 1990), and critical thinking and confidence to respond to changes in medical status quickly and through crisis. To be most effective at this work, surgeons also must know their team members well and have an ability to communicate instructions, needs, and plans. Not everyone can do this work: it requires a sharp mind, a high tolerance to work under pressure, and the capacity to separate from the person behind the surgical drapes.

Psychologists may find themselves in this setting, observing the team and providing direct consultation about the surgeon's engagement with others. It is strongly recommended that the clinical health psychologist in a department of surgery observe at least one major surgical procedure in order to get a different understanding of the surgeon's world and the stressors involved. This also assists the psychologist in being seen as a member of the team who also has an understanding of the demands of the service and the skills needed by the team.

Psychologists doing this work should take time to understand the OR: know the setting, the expectations for team participation (including one's self), and the expected course of the procedure. Knowing how to remain out of the way to maintain a sterile environment is crucial, and yet, determining how to be able to see all aspects of the room is important if you are to observe or provide feedback regarding the team's dynamic. Knowing one's own limits is also critical to the process: the OR is not for everyone, and you may encounter things you are not accustomed to seeing.

Time

Surgery happens at all hours of the day. Though psychologists frequently provide emergency consultation and are accessible much of the time, the demands placed on a surgeon are quite different. Specifically, when considering that most surgeons have already begun operating before 8 am, this means that education efforts, clinical collaboration, and so on must occur before that time. For psychologists, this means moving away from the expectations of a "typical" 9 am to 5 pm day. Surgeons will make themselves available on nights, weekends, holidays, and, of course, in the very early morning. To be effective, psychologists must be willing to be flexible with their time.

And Remember, You Are Not a Surgeon

It goes without saying that psychologists receive very different training than surgeons. To actively work in a surgical environment requires that psychologists not only modify their schedule but take time to best understand the experience and culture of surgery departments and the subsequent lifestyle of surgeons. This requires, in many ways, becoming a part of the surgical world. Despite this, maintaining identity as a psychologist is crucial. The job is not to be a surgeon, to act like a surgeon, or even to think like a surgeon. Psychologist's role can be to understand how surgeons think and support them to improve efficiency, to develop a broader perspective about patient care, and, in some instances, to help them slow down.

Psychologists must be confident in their role identity and competence. As a nonsurgical clinician, psychologists may have to prove their knowledge, skill, and value. Worth will be demonstrated in the ability to positively influence patient and team interactions, to foster clinician efficiency, and to improve culture. Enter with awareness that often there will be opinions about social sciences (e.g., "this stuff is fluff, it can't possibly matter") and remember that this judgment is not personal (though it may feel that way). Assertive communication skills, ability to set appropriate boundaries, and grit will all support the psychologist to feel comfortable and confident in the surgical setting.

In addition to the above, clinical health psychologists in medical settings should consider seeking board certification, which is a standard medical practice. Nearly all surgeons, and most physicians, in academic health centers and large nonacademic hospitals are board certified by an organization such as the American Board of Surgery (ABS), the American Board of Psychiatry and Neurology (ABPN), etc. If psychologists seek to be seen as peers in this environment, it is important that they have a recognized credential equivalent to medical board certification. The American Board of Professional Psychology (ABPP) offers this examination based and nationally recognized board certification. Specialty certification is available in areas such as clinical psychology, clinical health psychology, clinical child and adolescent psychology, geropsychology, clinical neuropsychology, and others.

Conclusions

In sum, opportunities abound for psychologists interested in working in a surgical environment. Such work comes in many rewarding forms, allowing psychologists to express creativity, generate innovative ideas, and engage in a challenging and ever-changing landscape. Surgical environments may have a clearly defined need and identified role for psychologists entering the setting. Despite this, surgeons will look to psychologists to be the expert of their own trade to help guide program implementation and sustainability whether for education or clinical care. Clinical health psychologists must take the time necessary to build relationships with surgical colleagues and become part of the milieu to create effective change that supports patients, families, staff, trainees, and surgeons alike.

Author Biographies

Lauren DeCaporale-Ryan, PhD, is an assistant professor in psychiatry, medicine, and surgery at the University of Rochester Medical Center. She is the assistant program director of General Surgery in Wellness, the associate program director of the Primary Care Family Psychology Fellowship, and the director of the Adult Psychology Internship. She completed her doctorate in clinical psychology at the University of Missouri–St. Louis in 2011 and went on to a fellowship in Primary Care Family Psychology with specialty focus in geriatrics and internal medicine at URMC. She provides communication coaching to residents, faculty, and staff clinicians, aiming to improve both bedside manner and team operations. She is the current recipient of the George W. Merck Dean's Teaching Fellowship and is subsequently implementing and evaluating a curriculum for surgical residents to develop leadership skills.

A graduate of the University of Texas at Austin, the University of Massachusetts at Amherst, and Harvard University, John D. Robinson, EdD, MPH, ABPP, is currently professor emeritus in both the Department of Surgery and the Department of Psychiatry and Behavioral Sciences at Howard University College of Medicine. He served as chief of behavioral medicine for both the organ transplant program and the bariatric program at Howard with a clinical appointment as professor of psychiatry at Georgetown University School of Medicine. Dr. Robinson is a former Navy psychologist and former president of both the American Board of Clinical Psychology and American Board of Clinical Health Psychology (ABPP). His specialty focus is working with patients who require surgical intervention, graduate medical education, and cultural competence training. He has over 40 years of experience as a mentor to medical students, medical/surgical residents, and psychology graduate students and interns.

Introduction to Sleep

Sleep is “a reversible behavioural state of perceptual disengagement from and unresponsiveness to the environment” (Carskadon & Dement, 2011). Sleep is composed of two distinct states: non-rapid eye movement (NREM) and rapid eye movement (REM) sleep. NREM sleep is further composed of three stages: N1, N2, and N3. Each successive stage represents a deeper stage of sleep. Sleep oscillates among the stages, with NREM stages followed by REM stages. This oscillation takes about 80–100 min and is repeated 3–4 times each night. The exact timing and composition of sleep episodes are complex and affected by a number of factors. A full explanation is beyond the scope of this chapter, and the interested reader is referred to several excellent sources for more information (Borbély, 1982; Carskadon & Dement, 2011; McCarley, 2007; Ohayon, Carskadon, Guilleminault, & Vitiello, 2004).

Sleep is essential for health and well-being. A recent expert consensus conference convened by the American Academy of Sleep Medicine and Sleep Research Society determined, based on an extensive literature review, that adults should regularly obtain at least 7 hr of sleep per night to promote optimal health in a variety of key areas. Less than 7 hr of sleep per night increases likelihood of obesity, diabetes, cardiovascular disease, depression, and mortality, among other negative consequences (Watson et al., 2015).

Inadequate nightly sleep has major consequences for daytime functioning, resulting in reduced alertness, poor attention and concentration, daytime sleepiness, and increased risk of

accidents, as well as compromising immune, cardiovascular, and metabolic systems (Besedovsky, Lange, & Born, 2012; Ferrie et al., 2007; Knutson, Spiegel, Penev, & Van Cauter, 2007). Cognitive performance is impaired in domains including executive function, processing speed, working memory, visual learning, memory, decision making, and judgment (Czisch et al., 2012; Diekelmann & Born, 2010; Drummond, Anderson, Straus, Vogel, & Perez, 2012; Fischer, Diekelmann, & Born, 2011; Killgore, Balkin, & Wesensten, 2006; Lim & Dinges, 2008; Wolfson & Carskadon, 1998). These deficits cannot always be compensated for by use of stimulants (Killgore, Grugle, & Balkin, 2012).

Assessing Sleep

Sleep can be assessed in a variety of ways, including objectively and subjectively, retrospectively and prospectively. Naturally, some methods are more labor intensive than others. A brief overview of the major assessment tools is presented here, from most to least labor intensive and costly.

Polysomnography (PSG)

Polysomnography (PSG) is the gold standard of objective sleep measurement. It uses electroencephalography (EEG) electrodes attached to the scalp to measure electrical brain activity, from which sleep and wake states can be distinguished. Other information about the body is measured concurrently: eye and leg movements, muscle tone, heart rate, oxygen levels in the blood, and breathing patterns (Berry et al., 2012). This provides highly accurate and clinically relevant information for diagnosis of many sleep disorders, and can be conducted either in lab or at home, using fewer numbers of electrodes. For further information, refer to reviews by Geyer, Talathi, and Carney (2009) and Vaughn and Giallanza (2008).

Multiple Sleep Latency Test (MSLT)

The Multiple Sleep Latency Test (MSLT) is an objective measure of daytime sleepiness. Standard MSLT protocols exist and are widely used in both clinical and research settings (Arand et al., 2005). Individuals have four to five designated sleep opportunities throughout the day after a typical night's sleep while connected to PSG. Each nap opportunity lasts 20 min and occurs every 2 hr. Level of sleepiness due to sleep deprivation can be assessed, as well as some sleep disorders (Carskadon & Dement, 1982). For further information, refer to Carskadon et al. (1987) and Littner et al. (2005).

Actigraphy

Sleep can be profiled objectively without PSG. Actigraphy uses a wristwatch-like device that includes an accelerometer, and often a light sensor, to measure movement as a proxy for sleep (Sadeh, 2011). This is less invasive and has greater ecological validity than an in laboratory PSG as the device can be worn at home, for many nights in a row. Practice guidelines suggest it be used in combination with a sleep diary (Kawada, 2013; Sadeh, 2011). Information collected between actigraphy and PSG is different. No brain activity or sleep architecture is recorded with actigraphy. Instead, movement allows the determination of sleep and wake. For further information, refer to Sadeh and Acebo (2002) and Ancoli-Israel et al. (2015).

Sleep Diary

The most detailed way to assess subjective sleep is with a daily sleep diary. While many investigators and clinicians use a diary of their own design, there is a consensus diary recommending the minimum information one should obtain (Carney et al., 2012). Typical measures collected with a sleep diary include bedtime and wake time, length of time to fall asleep, number and length of nocturnal awakenings, and time out of bed. Naps, caffeine and alcohol intake, and a variety of other variables are also commonly obtained. When compared with PSG, healthy individuals tend to overestimate their sleep, while people with insomnia underestimate their sleep (Bixler, Kales, Leo, & Slye, 1973). Nonetheless, it is highly useful, particularly in diagnosis and treatment of sleep disorders such as insomnia (Morin & Espie, 2003). Indeed, sleep diaries form one of the key underpinnings of cognitive behavioral therapy for insomnia (CBTI), discussed later in this chapter. For more information about use of sleep diaries, refer to Carney et al. (2012).

Self-Report Questionnaires

Validated questionnaires are widely utilized in both healthy populations and those with sleep, psychiatric, and medical disorders. Some of the most common include the Pittsburgh Sleep Quality Index (global sleep quality) (Buysse, Reynolds, Monk, Berman, & Kupfer, 1989), the Epworth Sleepiness Scale (trait sleepiness) (Johns, 1991), Karolinska Sleepiness Scale (state sleepiness) (Åkerstedt & Gillberg, 1990), the Insomnia Severity Index (insomnia symptoms) (Morin, Belleville, Belanger, & Ivers, 2011), the STOP-BANG (sleep apnea risk) (Chung et al., 2008), and the Horne–Ostberg Morningness-Eveningness Questionnaire (chronotype) (Horne & Ostberg, 1976).

The Bidirectional Relationship Between Sleep and Health

There is a bidirectional relationship between sleep and health. Sleep problems increase the risk of developing various physical and mental health conditions, and in turn, many disorders have characteristic sleep sequelae.

Poor sleep comes in many forms. Within this chapter, three major categories of poor sleep will be discussed: (a) inappropriate sleep quantity, (b) insomnia, and (c) sleep-disordered breathing (SDB), in particular obstructive sleep apnea (OSA). All three of these categories have direct links with physical and mental health and carry huge economic burdens (Deloitte Access Economics, 2011; National Institutes of Health, 2005). Targeting sleep as a health behavior has downstream effects for other health domains. By treating the sleep problems, many comorbid health problems improve too. The following sections provide an overview of the relationship between sleep and health in each of these three areas, greater detail on one specific aspect of health within each, and an overview of how treating sleep can improve health.

Inappropriate Sleep Quantity

Like many things in health, sleep works on the principle of optimization, as opposed to the principle that more is better. Epidemiological studies show there is an inverted U-shaped curve describing the relationship between sleep and health (Kojima et al., 2000; Kripke, Garfinkel, Wingard, Klauber, & Marler, 2002; Kripke, Simons, Garfinkel, & Hammond, 1979; Patel et al., 2004). This relationship was first observed by Hammond (1964), where the lowest risk of mortality was observed in individuals sleeping 7 hr per night. This has been consistently replicated in the literature since, with most studies showing 7–7.5 hr being optimal for health outcomes (Cai et al., 2015; Ferrie et al., 2007; Hublin, Partinen, Koskenvuo, & Kaprio, 2007; Kripke et al., 2002; Patel et al., 2004). As sleep duration becomes progressively further away from this in either direction, risk of poor health outcomes, including mortality, increases. Interestingly, though, the specific negative health outcomes of short versus long sleep duration often differ.

Sleep Duration and Health

The most obvious consequence of short sleep duration is daytime sleepiness. However, short sleep also has more dangerous health effects. Sleep loss causes characteristic neurological (EEG) changes, alterations in autonomic functions including cardiovascular function, respiration rates, biochemical and metabolic changes, and altered gene expression, due to stress placed on the body by prolonged wakefulness with insufficient recovery sleep between wake periods (Aho et al., 2013; Banks & Dinges, 2007; Buxton et al., 2012). These underlying physiological processes then lead to poor health outcomes. Bidirectional relationships exist between short sleep (<6 hr) and weight gain/obesity, impaired glucose tolerance, type 2 diabetes mellitus (T2DM), hypertension, cardiovascular disease, stroke, anxiety symptoms, depression, impaired immunity, increased pain, and increased risk of accidents and mortality (Dew et al., 2003; Ferrie et al., 2007; Karimi, Hedner, Häbel, Nerman, & Grote, 2015; Prather, Janicki-Deverts, Hall, & Cohen, 2015; Sivertsen et al., 2015; Watson et al., 2015; Zhang & Chan, 2014). Additionally, animal studies have shown that complete sleep loss kills animals in approximately the same amount of time as total food deprivation (Rechtschaffen & Bergmann, 1995).

Long sleep is also associated with increased mortality, perhaps to an even greater extent than short sleep. In an epidemiological study by Patel, Malhotra, Gottlieb, White, and Hu (2006), long sleepers had increased likelihood of depression, lack of physical exercise, and lower socioeconomic status, all of which are independently associated with poor health. Long sleepers were also more likely to have a diagnosis of medical and psychiatric disorders including diabetes, obesity, hypothyroidism, seizures, multiple sclerosis, stroke, cardiovascular disease, hypertension, rheumatoid arthritis, osteoarthritis, herniated disc, asthma, chronic obstructive pulmonary disease, cancer, inflammatory bowel disease, anxiety disorders, depression, restless legs syndrome, and snoring (Ohayon, 2004; Patel et al., 2006).

The reasons long sleep is associated with increased mortality are less clear than the well-established links between short sleep/sleep deprivation and health. Grandner and Drummond (2007) identified six main contributors to the link between long sleep and poor health: sleep fragmentation, fatigue, altered immune function, circadian abnormalities, lack of physiological challenge, depression, or underlying disease processes (e.g., OSA, heart disease, or failing health). In addition, reports of sleep duration may actually represent total time in bed, rather than truly time asleep (Ferrie et al., 2007). Long time in bed often reflects increased sleep fragmentation, which in its own right has significant associations with poor health (Bennett, Barbour, Langford, Stradling, & Davies, 1999; Dew et al., 2003). In essence, long sleep may be problematic because it is a proxy for general poor or declining health, rather than mechanistically responsible for poor health outcomes.

Based on the large sleep and health literature, sleeping 7–7.5 hr per night is thought to be optimal for health, and as cited above, the current recommendation is that adults sleep a minimum 7 hr per night. Worryingly, fewer hours of sleep and greater levels of sleep disturbance have become widespread in industrialized societies, largely due to trading off sleep to fit in more work and leisure activities (Bartlett, Marshall, Williams, & Grunstein, 2008; Ferrie et al., 2007). Such voluntary restricted sleep duration is a common occurrence in modern society. In Australia, a 2010 community study found 18.4% of adults slept less than 6.5 hr per night and 11.7% reported chronic sleepiness (Bartlett et al., 2008). This prevalence is even higher in the United States: 30% of all workers and 44% of night shift workers reported sleeping less than 6 hr per night (Luckhaupt, 2012). Some populations are more prone to obtaining insufficient sleep and/or experiencing sleep disruption than others, including shift workers, physicians, truck drivers, parents, and teenagers. This increases risk of many health problems and also directly impacts daytime functioning the day after a night of short sleep.

Impaired Glucose Tolerance

One important example of a negative health consequence of inappropriate sleep duration is impaired glucose tolerance. The importance of sleep to glucose metabolism, and the influence of sleep on development of T2DM, is well documented. Epidemiology studies indicate both short and long sleepers are at significantly increased risk of developing T2DM (Cespedes et al., 2016). A meta-analysis by Shan et al. (2015) showed the risk of T2DM with suboptimal sleep length, finding in 482,502 participants with follow-up between 2.5 and 16 years that the lowest risk of T2DM was seen in those sleeping 7–8 hr per night. For each hour regularly slept below this, T2DM risk significantly increased by 9%, and for each hour above 8 hr, risk increased by 14%.

The process by which short sleep[1] leads to glucose abnormalities is well documented. Short sleep leads to decreased glucose tolerance and insulin sensitivity and reduced glucose disposal throughout the body (Buxton et al., 2010; Donga et al., 2010; Schmid et al., 2011; Spiegel, Leproult, & Van Cauter, 1999). In a seminal study, glucose tolerance was 40% lower after only four nights of short sleep, relative to long sleep, leading to a 30–40% decrease in glucose effectiveness in the body (Spiegel et al., 1999). During short sleep, sympathetic nerve activity increases, resulting in reduced β-cell responsiveness and reduced pancreatic insulin secretion (Buxton et al., 2012). At the same time, the sleep-deprived brain increases its glucose uptake, increasing circulating glucose levels (Herzog et al., 2013). Short sleep duration also leads to food cravings and increased calorie intake: sleep-restricted individuals increase their daily energy intake by up to 20% (Nedeltcheva et al., 2009; St-Onge et al., 2011). Therefore, short sleep duration contributes to insulin resistance and T2DM mechanistically through both reduced insulin production and increased glucose levels. Recent prospective research indicates some of these negative effects on metabolism and glucose tolerance may be due to inappropriate timing of food consumption throughout the day, rather than due to short sleep per se (Briançon-Marjollet et al., 2015; Gale et al., 2011; Sherman et al., 2012). Nonetheless, inappropriate timing of eating in these cases is still driven by the short sleep opportunity.

In addition to increasing risk of T2DM directly through changes in insulin and glucose, short sleep duration increases T2DM risk through multiple indirect pathways. For example, epidemiological and experimental studies show an association between short-duration sleep, high ghrelin, low leptin, and increased obesity risk, which is itself a risk factor for T2DM (Schmid, Hallschmid, Jauch-Chara, Born, & Schultes, 2008; Spiegel et al., 2004; Taheri, Lin, Austin, Young, & Mignot, 2004). Therefore, a combination of several endocrine abnormalities leads to the development of T2DM and obesity in short sleepers.

The reciprocal relationship between T2DM and sleep also exists. Individuals with T2DM are at increased risk of restless legs syndrome and OSA, which have debilitating effects on sleep and health (Lopes et al., 2005; Resnick et al., 2003; Sanders & Givelber, 2003). The association with OSA is thought to be due to metabolic abnormalities and not due to other common risk factors such as weight (Peppard & Young, 2004; Schmid, Hallschmid, & Schultes, 2015). Additionally, T2DM can result in peripheral neuropathy. This damage to nerves in the feet and legs is another cause of sleep disruption, due to the numbness, tingling, or burning pain (McDermott, Toelle, Rowbotham, Schaefer, & Dukes, 2006; Rosenstock, Tuchman, Lamoreaux, & Sharma, 2004; Vinik, Emir, Cheung, & Whalen, 2013). Thus T2DM can also contribute to sleep disturbances, which may, in turn, worsen the T2DM via the mechanisms described above.

Treatment Effects on Health

Despite the major health consequences of sleep loss and overly long sleep, treatment and management of inappropriate sleep duration in "an otherwise healthy" individual is rarely addressed by clinicians. There are no formal treatment guidelines for managing sleep loss. The most popular professional advice is to take a short nap (Veasey, Rosen, Barzansky, Rosen, & Owens, 2002) and to sleep longer on a regular basis. The former is not particularly efficacious for health, and the latter may be perceived as impractical advice. Furthermore, catching up on sleep during the weekends is not sufficient to return functioning to baseline levels (Klerman & Dijk, 2005; Szymczak, Jasinska, Pawlak, & Zwierzykowska, 1993).

While there are no evidence-based guidelines for managing sleep duration in healthy populations, health improvements seen with improved sleep duration have been investigated in two ways: longitudinal epidemiological studies and experimental studies that systematically restrict the sleep of individuals in a laboratory setting and then observe over a period of recovery. A recent longitudinal epidemiological study investigated how increasing sleep duration to the healthy range improved mortality risk (Ferrie et al., 2007). When regular sleep length increased from 5–6 to 7–8 hr over the 3-year follow-up period, there were decreases in risk of both cardiovascular and non-cardiovascular disease-related mortality. This has not been consistently replicated in other epidemiological studies though (Dew et al., 2003; Hublin et al., 2007), suggesting the relationships observed by between sleep duration and mortality may be mediated by other specific health improvements, which were not explicitly reported.

Impaired Glucose Tolerance

In the experimental literature cited above, studies indicate a return to sufficient sleep duration after short sleep improves glucose regulation. This has direct clinical implications for preventing T2DM. Clinically, T2DM has stages of progression. Impaired glucose regulation is an intermediate stage between normal glucose tolerance and T2DM. This altered metabolic state may be a stage where appropriate sleep duration can improve regulation and protect against T2DM development (Ip & Mokhlesi, 2007).

The protective mechanism of adequate sleep has been consistently demonstrated. Experimental periods of partial or total sleep deprivation in healthy human and animal models have shown consistent decreases in glucose metabolism and insulin response that reverse after recovery sleep. Sleep restricted to 4 hr per night for between four and seven nights resulted in a 16–29% reduction in insulin sensitivity, without a similar magnitude of insulin release to compensate. After five to seven nights of recovery sleep, levels of plasma glucose and insulin responses returned to baseline levels (Barf, Meerlo, & Scheurink, 2010; Broussard, Ehrmann, Van Cauter, Tasali, & Brady, 2012; Buxton et al., 2010; Spiegel et al., 1999). However, the extent of sleep required to reverse metabolic effects of chronic short sleep, and whether it is possible to reduce these to baseline levels, is still under investigation.

Of course, while these short-term experimental studies are promising, it may also be the case that T2DM risk can reach a threshold where adequate sleep no longer helps protect against development. One epidemiological study found that once T2DM risk developed, fixing sleep was not adequate to completely reverse risk. In a longitudinal study of 59,031 women, those who slept <6 hr per night in 1986 were found to be at higher risk of developing T2DM than those who sleep 7–8 hr per night, as assessed by validated diabetes symptom questionnaires. When assessed again in 2000, those who had increased their sleep habits to 7–8 hr per night were still at the same elevated risk of developing T2DM as those who were still restricting their sleep to <6 hr (Cespedes et al., 2016). In this case, the women may have passed the threshold of sleep's usefulness as a protective factor. However, the improvements seen in short-term studies indicate sleeping appropriate duration may lower risk for T2DM before its full development.

Insomnia

The current Diagnostic and Statistical Manual (DSM-5) defines insomnia disorder as a combination of dissatisfaction with sleep quality or quantity, characterized by (a) difficulty initiating sleep, maintaining sleep, or early-morning awakening with inability to return back to sleep and (b) a negative impairment in some aspect of daytime functioning, which the individual relates back to poor sleep (i.e., they believe the poor sleep causes or exacerbates the daytime impairment). The insomnia occurs on at least three nights per week for a minimum of 3 months, occurs despite adequate opportunity for sleep, and is not fully explained by another sleep–wake disorder or other mental or medical disorder, nor is it attributable to physiological effects of a substance (American Psychiatric Association [APA], 2013). It is important to note the concept of "secondary insomnia" is no longer considered valid. A diagnosis of insomnia disorder can occur in the context of any other physical or mental health condition and is considered a comorbid diagnosis, not a secondary diagnosis. This is because once insomnia becomes chronic (i.e., ≥3 months in duration), it typically needs specific and independent treatment and does not respond adequately to treating the "other" diagnosis.

Insomnia is one of the most common sleep disorders and is among the most prevalent of all mental health disorders, affecting 10–15% of adults worldwide (Bartlett et al., 2008; Ford & Kamerow, 1989; Morin, LeBlanc, et al., 2011; National Institutes of Health, 2005; Ohayon & Bader, 2010). Insomnia commonly presents with a range of psychiatric and medical comorbidities. As such, insomnia represents a huge health burden. In an epidemiological study of almost 15,000 individuals aged 15–100 years in the United Kingdom, Germany, Italy, and Portugal, only 2% of individuals meeting criteria for insomnia disorders had "pure" insomnia, without any current or past psychiatric history (Ohayon & Roth, 2003). In the literature, comorbid insomnia accounts for up to 90% of insomnia, leading to increased healthcare burden (Ford & Kamerow, 1989; Klink, Quan, Kaltenborn, & Lebowitz, 1992). A 2010 report estimated that in Australia, insomnia and attributable conditions cost the economy A$10.9 billion (Deloitte Access Economics, 2011). This is minor in comparison with other places around the world. In the province of Québec alone, the total annual cost of insomnia and associated health concerns was estimated at C$6.6 billion (Daley, Morin, LeBlanc, Gregoire, & Savard, 2009).

Insomnia is characterized by chronicity. Approximately 80% of individuals with insomnia experience it for at least 1 year, and 40% for 5 years (Bixler, Kales, Soldatos, Kales, & Healey, 1979; Hohagen et al., 1993; Morin, LeBlanc, Daley, Gregoire, & Merette, 2006). Despite this, it is vastly undertreated. One estimate suggests only 13% of individuals who complain of insomnia symptoms seek professional help (Morin et al., 2006).

Insomnia and Health

Given the high rates of comorbidity and the chronic nature of the disorder, chronic insomnia is linked with substantial decreases in quality of life, including by measures of absenteeism, accidents, and decreased vitality and social functioning. Insomnia plays key roles in the course of many psychological problems, contributing to their development or relapse, and exacerbating symptoms. These disorders include anxiety, depression, bipolar disorder, posttraumatic stress disorder (PTSD), adjustment disorder, panic disorder, somatoform disorder, schizophrenia, neurocognitive disorders, eating disorders, and substance use disorders, and physical health problems including arthritis, cancer, hypertension, chronic pain, cardiovascular disease, and T2DM (APA, 2013; Buysse et al., 1994; Foley et al., 1995; Ohayon, Caulet, & Lemoine, 1998). In particular, depression is highly comorbid with insomnia. Depression itself carries a large economic burden, estimated to cost the Australian economy A$12.6 billion per year and the US economy $210.5 billion per year (Greenberg, Fournier, Sisitsky, Pike, & Kessler, 2015; LaMontagne, Sanderson, & Cocker, 2010). The two disorders have a bidirectional and complex relationship.

Depression

About three-quarters of all depressed patients complain of insomnia symptoms, and 41% report sufficient symptoms to warrant an insomnia diagnosis (Staner, 2010; Stewart et al., 2006). Until recently, when the two disorders were comorbid, insomnia was viewed as a symptom of depression and so was not considered a focus of treatment. More recent research indicates a more complex bidirectional, relationship. While insomnia typically has its origins before depression develops, high levels of depressive symptoms are classified as a premorbid psychological vulnerability to insomnia (Ford & Kamerow, 1989; LeBlanc et al., 2009).

The Nord-Trøndelag Health Study (HUNT) is a large Norwegian population-based prospective study investigating this bidirectional relationship. A sample of 24,715 individuals completed questionnaires assessing whether they had depression and insomnia on 2 occasions, approximately 10 years apart. Participants with insomnia when first assessed were 6.2 times as likely to develop depression by follow-up assessment as those without insomnia. Equally, those with depression at first were 6.7 times more likely to develop insomnia by their follow-up assessment than those without depression (Sivertsen et al., 2012).

Insomnia impacts not only the development but also the course of depression once developed. It can perpetuate depression, exacerbate depression, and increase risk of its recurrence. In a multisite randomized control trial (RCT) of elderly depressed patients, participants were randomized to receive either specialist depression treatment or treatment as usual. After 3 months of therapy, those with persistent insomnia were 3.5 times more likely to remain depressed at 12 months, compared with those without insomnia, showing how insomnia perpetuates depression (Pigeon et al., 2008). Similarly, in a 9-week RCT where depressed participants were treated with either 3 mg fluoxetine or placebo, participants with higher levels of insomnia experienced significantly greater intensity of suicidal ideation, indicating insomnia exacerbates depressive symptoms (McCall et al., 2010). After an RCT treating depression with interpersonal psychotherapy and/or pharmacotherapy, residual sleep disturbance was the strongest independent predictor of depression recurrence (Perlis, Giles, Buysse, Tu, & Kupfer, 1997).

Treatment Effects on Health

CBTI is currently the gold standard insomnia intervention. It is highly effective and has been extensively researched: it has a 70–80% success rate in efficacy studies for chronic insomnia

(Irwin, Cole, & Nicassio, 2006; Morin, Culbert, & Schwartz, 1994). Efficacy remains even when insomnia is comorbid with a range of other medical and psychiatric disorders (Geiger-Brown et al., 2015; Haynes et al., 2016; Mundt et al., 2016; Talbot et al., 2014; Trauer, Qian, Doyle, Rajaratnam, & Cunnington, 2015; Ye et al., 2015). Research consistently shows that CBTI is, at minimum, equally as effective as pharmacological treatment and has significantly longer duration of benefits after treatment ceases.

CBTI is a multimodal therapy, typically provided over a four- to eight-session course of treatment (Perlis, Benson-Jungquist, Smith, & Posner, 2005). It has two main foci: altering behaviors to improve sleep patterns (behavioral therapy) and altering the unhelpful and/or inaccurate thoughts, beliefs, and attitudes people hold regarding sleep (cognitive therapy). The ultimate goals of CBTI are to (a) consolidate sleep (behavioral), (b) break associations between sleep and anxiety and/or arousal (behavioral), and (c) to develop a more realistic picture of sleep and sleeping habits (cognitive). It is effective for reducing insomnia symptoms under many conditions, including when delivered in group settings, over the phone or internet, and in brief 1–2 session treatments, though different patient populations benefit most from different conditions (Cape, Leibowitz, Whittington, Espie, & Pilling, 2015; Ellis, Cushing, & Germain, 2015; Ho, Chung, Yeung, Ng, & Cheng, 2014; Norell-Clarke, Jansson-Fröjmark, Tillfors, Holländare, & Engström, 2015; Ye et al., 2015; Zachariae, Lyby, Ritterband, & O'Toole, 2016).

While experiencing insomnia, individuals report lower quality of life and many negative health outcomes (APA, 2013; Buysse et al., 1994; Foley et al., 1995; Fortier-Brochu, Beaulieu-Bonneau, Ivers, & Morin, 2010; Ohayon et al., 1998). Every health domain thus far studied improves significantly when insomnia is treated with CBTI (Manber et al., 2011; McCall et al., 2010). The direct impact on depression is discussed in detail.

Depression

While the relationship between insomnia and depression is bidirectional, when it comes to improving health, the effect is unidirectional: improving insomnia alleviates depression symptoms. An RCT of CBTI for comorbid insomnia and depression by Ashworth et al. (2015) found that depression scores dropped substantially more in the CBTI versus self-help control group. At 3-month follow-up, 61.1% of the CBTI group were in remission from both their insomnia and depression, compared with only 5.6% of the control group. These results are consistent within the broader literature: when patients are treated with CBTI, whether individually or in group format, both insomnia and depression symptoms improve, and remission rates for depression are higher in CBTI than in control groups (Bei, Ong, Rajaratnam, & Manber, 2015; Manber et al., 2011; Manber et al., 2008; Norell-Clarke et al., 2015; Trockel, Manber, Chang, Thurston, & Tailor, 2011).

Importantly, these therapeutic effects are not bidirectional. When depression is treated with CBT or with antidepressants, while depressive symptoms improve, sleep problems are not consistently alleviated (Carney, Segal, Edinger, & Krystal, 2007). In essence, once insomnia develops, it must be treated in its own right. This is also true for other mental health disorders, including PTSD, bipolar disorder, and substance use disorders (Belleville, Guay, & Marchand, 2011; Brower, Krentzman, & Robinson, 2011; St-Amand, Provencher, Bélanger, & Morin, 2013; Zayfert & De Viva, 2004), indicating the importance for treating insomnia symptoms independently and early. These findings also underscore the reason "secondary insomnia" is no longer considered a valid diagnosis. Even when another health condition is the precipitating event initially triggering the insomnia, once chronic, the insomnia has developed into its own disorder.

Sleep-Disordered Breathing

SDB refers to a range of sleep disorders characterized by insufficient or abnormal ventilation during sleep. Importantly, disordered breathing is specific to the sleep state, with respiration during wake being normal. The most common form of SDB is sleep apnea whereby the individual suffers from repetitive episodes of reductions (hypopnea) or cessation (apnea) in airflow during sleep. Sleep apnea is typically divided into two main forms: (a) OSA, where apneas/hypopneas occur due to complete or partial collapse of the upper airway, or (b) central sleep apnea (CSA), where apneas/hypopneas occur due to a reduction in brainstem respiratory motor output (i.e., no effort is made to breathe). These repeated respiratory events are associated with reductions in blood oxygen saturation (hypoxemia), rises in blood carbon dioxide (hypercapnia), and surges in sympathetic activation. Unfortunately, regular breathing usually only resumes upon arousal from sleep. Individuals with a SDB diagnosis stop breathing at least 5 times an hour, with 30 or more events per hour considered severe. The cumulative impact of repeated respiratory events (i.e., reduction/cessation of breathing followed by an awakening) is significant sleep fragmentation and reductions in both deep stage N3 sleep and REM sleep (Lamphere et al., 1989; Quan et al., 2011; Waldhorn et al., 1990).

Of the two types of SDB, OSA is by far the most common, with prevalence rates as high as 10% in adults between the ages of 30 and 70 (Peppard et al., 2013). There are a number of factors that put people at higher risk for developing OSA. The most common risk factor is obesity, specifically central obesity. In both sexes, OSA is more prevalent with increasing age (Young et al., 1993), reaching very high rates in patients over 65 years (Ancoli-Israel, Klauber, Kripke, Parker, & Cobarrubias, 1989). Males appear to have a higher rate of sleep apnea than women, with a ratio of 2:1–10:1, depending on the study (Strohl & Redline, 1996). In addition, any condition resulting in a smaller airway can predispose toward the development of OSA. Finally, several studies demonstrated a higher risk of OSA with a positive family history, and risk increases with the number of affected relatives (Redline et al., 1995). There are also several environmental factors increasing the risk of developing OSA. For instance, use of alcohol or sedative medication can contribute to development OSA through their relaxant effect on the upper airway muscles (Issa & Sullivan, 1982). A longitudinal epidemiological study showed that smokers are at an increased risk for developing OSA with current smokers at greater risk than nonsmokers and heavy smokers having the greatest risk (Wetter, Young, Bidwell, Badr, & Palta, 1994). Cessation of smoking eliminated the increased risk.

By comparison, CSA is much less prevalent; however it is commonly found in certain populations such as in preterm and term infants, in patients with heart failure (~30%) (Sin et al., 1999), and in most adults when ascending to high altitude (Burgess, Johnson, & Edwards, 2004) and can also be a side effect of opioids. Given that this review will largely focus on OSA, a more detailed description of CSA can be found in a recent review by Edwards, Sands, and Berger (2013).

Sleep-Disordered Breathing and Health

One of the most commonly reported symptoms of SDB is excessive daytime sleepiness (AASM, 2014), and this may explain the increased risk of motor vehicles accidents seen in this population (Terán-Santos, Jiménez-Gómez, & Cordero-Guevara, 1999; Young, Blustein, Finn, & Palta, 1997). However, the relationship between crash risk and measures of sleep apnea severity and subjective sleepiness have not always been consistently demonstrated (Ellen et al., 2006).

Sleep apnea has also been associated with a range of cognitive impairments, most particularly in attention (Ayalon, Ancoli-Israel, & Drummond, 2010; Bedard, Montplaisir, Malo, Richer, & Rouleau, 1993; Bedard, Montplaisir, Richer, Rouleau, & Malo, 1991; Canessa et al., 2011), executive function (Canessa et al., 2011; Naëgelé et al., 1998; Saunamäki, Himanen, Polo, & Jehkonen, 2009), and memory (Canessa et al., 2011; Daurat, Foret, Bret-Dibat, Fureix, & Tiberge, 2008; Salorio, White, Piccirillo, Duntley, & Uhles, 2002). A number of recent systematic reviews and meta-analyses have confirmed the consistency of these findings (Beebe, Groesz, Wells, Nichols, & McGee, 2003; Olaithe & Bucks, 2013; Saunamäki & Jehkonen, 2007; Wallace & Bucks, 2013). These impairments in cognition are also consistent with imaging data showing significant cerebral gray matter loss in OSA patients (Yaouhi et al., 2009). Nonetheless, cognitive deficits are often not as extreme as one might expect given the severity of sleep disruption and hypoxia, as well as gray matter abnormalities experienced, suggesting that some compensatory mechanisms may be at work in these individuals (Ayalon, Ancoli-Israel, Klemfuss, Shalauta, & Drummond, 2006; Castronovo et al., 2009). Based on a range of converging evidence from animal and human studies, it would appear that sleep fragmentation, intermittent hypoxia, or both play causal roles in the pathogenesis of these cognitive deficits (Beebe & Gozal, 2002; Knoepke & Aloia, 2009; Verstraeten, 2007).

Cardiovascular and Metabolic Health

Population-based studies have demonstrated SDB to be associated with metabolic abnormalities including glucose intolerance and insulin resistance, with risk increasing with increasing hypoxemic and SDB severity indices (Punjabi et al., 2004). Furthermore SDB has been shown to be an independent risk factor for diabetes (Botros et al., 2009; Reichmuth, Austin, Skatrud, & Young, 2005; Wang, Bi, Zhang, & Pan, 2013).

Hypertension is extremely prevalent in SDB populations. Numerous data from animal models and cross-sectional studies have demonstrated significant associations between SDB and blood pressure (Brooks, Horner, Kozar, Render-Teixeira, & Phillipson, 1997; Fletcher, DeBehnke, Lovoi, & Gorin, 1985; Nieto et al., 2000; Stoohs et al., 1996). Prospective longitudinal studies have demonstrated patients with SDB have increased risk of developing hypertension, with increasing severity of SDB associated with increasing risk (O'Connor et al., 2009; Peppard, Young, Palta, & Skatrud, 2000). Although SDB has been shown to be an independent risk factor for hypertension, comorbid obesity has previously been shown to mediate some of this dose–response relationship (Nieto et al., 2000; O'Connor et al., 2009).

SDB has also been associated with a range of other cardiovascular morbidities including, but not limited to, atherosclerosis, atrial fibrillation, stroke, and heart failure (Gottlieb et al., 2010; Hoffstein & Mateika, 1994; Hung, Whitford, Parsons, & Hillman, 1990; Neilan et al., 2013; Redline et al., 2010; Shahar et al., 2001; Somers, Dyken, Clary, & Abboud, 1995; Wessendorf et al., 2000; Yaggi et al., 2005). Importantly, longitudinal studies have shown that untreated OSA patients are at increased risk of both fatal and nonfatal cardiovascular events compared with controls (Marin, Carrizo, Vicente, & Agusti, 2005), as well as an increased risk of all-cause mortality (Punjabi et al., 2009).

Treatment Effects on Health

The current gold standard treatment for OSA in adults is continuous positive airway pressure (CPAP) therapy, which works by producing a positive pressure in a patient's airway in order to "splint" the airway open such that obstruction is no longer possible. CPAP is exceedingly efficacious in reducing OSA severity and improving hypoxemic and sleep quality parameters

(Issa & Sullivan, 1986; Kakkar & Berry, 2007; Sullivan, Issa, Berthon-Jones, & Eves, 1981). However clinical effectiveness is mainly limited by its tolerability. Long-term usage studies suggest approximately half of patients continue to use therapy after 3 months. Approximately 30% of patients fail to even initiate treatment (Wolkove, Baltzan, Kamel, Dabrusin, & Palayew, 2008). The second major treatment modality for OSA is mandibular advancement splints (MAS) (also referred to as oral appliances). These devices reposition the tongue and protrude the mandible forward in order to tighten several soft tissue structures and so increase the overall size of the upper airway (Chan et al., 2010). A variety of surgical procedures are also utilized for OSA treatment; however these are typically undertaken as a last resort option, often when patients are unable to adhere to these noninvasive treatments. The treatment success of these surgical procedures varies considerably in the literature (Caples et al., 2010) although is generally considered to be quite low. Part of this variability is likely due to differences in the way treatment successes have been defined in such studies as well as differences in the way OSA severity/burden was assessed.

Although there is a high degree of variability between studies, meta-analyses show that treatment with CPAP can significantly reduce subjective sleepiness complaints and, to a lesser degree, reduce objective sleepiness parameters (Patel, White, Malhotra, Stanchina, & Ayas, 2003). These effects are typically stronger in patients with more severe SDB and those with a greater degree of baseline sleepiness. A reduction in motor vehicle crash risk as well as improved driving simulator performance has also been demonstrated after successful CPAP treatment (Antonopoulos, Sergentanis, Daskalopoulou, & Petridou, 2011; Tregear, Reston, Schoelles, & Phillips, 2010). While a number of studies have demonstrated the success of CPAP in normalizing various aspects of neurocognitive function (Borak, Cieślicki, Koziej, Matuszewski, & Zieliński, 1996; Canessa et al., 2011; Engleman, Martin, Deary, & Douglas, 1994), others have demonstrated enduring impairments in some cognitive domains after treatment (Bedard et al., 1993; Ferini Strambi et al., 2003; Kotterba et al., 1998). Available meta-analyses suggest that deficits in attention are most effectively resolved by CPAP treatment (Kylstra, Aaronson, Hofman, & Schmand, 2013), whereas improvements in executive functions and memory are less consistently reported (Aloia, Arnedt, Davis, Riggs, & Byrd, 2004; Sánchez, Martínez, Miró, Bardwell, & Buela-Casal, 2009).

Cardiovascular and Metabolic Health

In general there is a relative paucity of RCT examining the effect of treatment on the metabolic disturbances associated with OSA. As yet, meta-analytic evidence does not suggest that glucose metabolism or measures of insulin resistance improve with CPAP usage (Hecht, Möhler, & Meyer, 2011). Furthermore, a recent systematic review suggests that with the exception of a reduced sympathetic activity, there is little evidence that treatment of OSA is associated with an improvement metabolic and inflammatory indexes (Jullian-Desayes et al., 2015).

In terms of the effect of treatment on cardiovascular sequelae, two meta-analyses have demonstrated that CPAP usage significantly reduces blood pressure. However, the effect size is small in comparison with antihypertensive medications (Fava et al., 2014; Montesi, Edwards, Malhotra, & Bakker, 2012). Despite this, successful treatment with CPAP is associated with a reduced risk of fatal and nonfatal cardiovascular events (Doherty, Kiely, Swan, & McNicholas, 2005; Marin et al., 2005). While the majority of the treatment data currently available applies to the use of CPAP, treatment data from patients using a MAS device generally demonstrates improvement in health outcomes equivalent to those observed with CPAP (Bratton, Gaisl, Wons, & Kohler, 2015; Phillips et al., 2013).

Summary

This chapter has emphasized the critical importance of achieving healthy sleep for a diverse set of physical and mental health morbidities. The mechanisms linking sleep and health are often complex and bidirectional in nature; however treatment outcomes tend to be unidirectional. Insomnia and OSA can be highly effectively treated using psychological and medical treatments. These treatments then contribute to subsequent improvements in health problems. However, the unidirectionality of these improvements means that chronic sleep problems require direct treatment for improvement. This reflects the special role that sleep plays in health and the attention that needs to be paid to healthy sleep for overall physical and mental health.

Note

1 Experimentally induced short sleep duration is typically called "sleep restriction" and much of the literature cited here uses that term. For consistency, we will always use the term "short sleep" even when referring to experimentally induced short sleep.

Telepsychology

Shawna Wright and Eve-Lynn Nelson

KU Center for Telemedicine & Telehealth, University of Kansas Medical Center, University of Kansas, Kansas City, KS, USA

Telepsychology is defined as the provision of psychological services using telecommunication technologies. The term *telepsychology* falls underneath the umbrella term *telemental health*, also called *telebehavioral health.* Telemental health refers to all the names and types of behavioral and mental health services, including discipline-specific applications such as telepsychology that are provided via synchronous telecommunication technologies. Telemental health specifically refers to mental health assessment, treatment, education, monitoring, and collaboration (Bashshur, Shannon, Bashshur, & Yellowlees, 2012). Secure videoconferencing allows psychologists to communicate with a client and observe nonverbal behavior in real time to approximate the relationship developed through in-person therapy. The visual component in videoconferencing establishes a social presence and promotes familiarity, connectedness, and comfort for discussing complex topics. This type of social presence cannot be established with the use of the telephone alone. The rational for using televideo has remained consistent over the last two decades, with a focus on using telecommunication technology to bridge the gap between a high need for psychological services and limited or no access to a growing number of empirically supported and evidence-based interventions.

Telemental health saves telepsychologists the time and expense of travel and has been applied to both rural and urban settings. Additional benefits of this approach are found in connecting systems of care and enhancing care coordination. Supervised settings that include a telepresenter, such as clinics, hospitals, primary care practices, schools, daycare facilities, detention centers, and other settings, have been the most frequent sites of connection with clients and have been associated with reimbursement (Bashshur et al. 2012). Mobile devices are expanding the reach and consideration of expanding secure videoconferencing to unsupervised settings such as the home.

Telepsychology expansion is driven by increasing expectations for high-quality behavioral health services across geographies. Telepsychology is further advanced by the decreasing cost of secure videoconferencing options and increasing access to high-speed connectivity.

The Wiley Encyclopedia of Health Psychology: Volume 4: Special Issues in Health Psychology,
First Edition. General Editor: Lee M. Cohen. Volume Editor: Suzy Bird Gulliver.

Telemental health is a relatively low-cost technology solution because behavioral health interventions predominantly rely on verbal communication and observation and there is minimal need for more expensive peripheral devices.

Healthcare reform has increased interest in innovative solutions to increase accessibility to behavioral health services due to challenges associated with the shortages of behavioral health specialists, a maldistribution of available specialists, a shrinking behavioral health specialist workforce, and instability in behavioral health funding. Rural and frontier communities are particularly affected by difficulties accessing behavioral health treatment because of shrinking populations, declining economies, limited transportation options, and increasing poverty (Myers & Turvey, 2012). The burdens of traveling for services are often amplified by the frequent standard of care for regular sessions sustained over a period of time.

Telepsychology services build on a long history of moving mental healthcare from the distant mental health clinic to the community in order to increase access to care, decrease stigma, and increase adherence to treatment planning. Telepsychology offers the opportunity to enhance treatment effectiveness and care coordination in naturalistic settings. The provision of care in local community settings has the advantages of gathering information from multiple informants/supporters about the broad range of contextual factors that influences a client's behaviors and mental health needs.

Telepsychology services initially focused on rural settings, but they are increasingly offered in urban/metropolitan locations to bridge access gaps. Mental health centers may provide infrastructure that facilitates the implementation of telepsychology services. For example, many schools are seeking to understand their students' mental health needs and are willing to use existing videoconferencing systems to access telemental health services. Most behavioral health diagnoses across the developmental spectrum have been evaluated through videoconferencing consistent with clients in usual outpatient practice. The authors first summarize key considerations in establishing a telepsychology clinic and then describe telepsychology best practices.

Establishing a Telepsychology Clinic

In order to maximize telepsychology clinic success, psychologists are encouraged to consider outreach best practices when establishing a clinic. Taking time to consider the unique needs of the clinic and to extend relationships with the target community/communities will assist in building a sustainable, high-quality telepractice.

Needs Assessment

Psychologists considering telepsychology services are encouraged to complete a needs assessment within the identified community to evaluate perceived interest and availability of such psychological services (Nelson & Duncan, 2015). This assessment should include discussions and meetings across key constituents, including consumers and their families, local mental health professionals, primary care providers, consumer advocates, and other community leaders likely to be affected by telepsychology initiation. Telepsychology works best when seen as complementing or adding to the community's local care.

The needs assessment should also identify the population the telepsychology service will serve. The choice of who will be seen depends on clients' preferences, developmental and diagnostic considerations, personnel and other resources at the distant site, and the psychologist's comfort. Telepsychology may be especially suited for younger populations who are often already comfortable and accepting of the technology medium. However, there is no data suggesting client exclusion based on age. With telepsychology's extended reach comes the responsibility of the psychologist to follow all professional standards of cultural competence across ethnicities, languages, genders, religions, sexual preferences, geographies, and other competence areas, including an understanding of the impact of rural culture on the clinical presentation.

Technology Selection

Fortunately, televideo services have recently benefited from higher-quality technology paired with lower cost. Technological advances in personal computer-based videoconferencing systems have made inexpensive, user-friendly, reliable, secure videoconferencing more available and have promoted an increase in the use of clinical televideo.

The purpose of the psychological service should guide technology selection, which may or may not need more expensive or newest technology upgrades. When considering technologies and vendors, it is advisable to follow up with colleagues and resources such as the federally funded telehealth resource centers (see http://www.telehealthresourcecenter.org) in order to gain comprehensive information about the best fit. Psychological services require videoconferencing equipment, but do not generally require the more expensive peripherals associated with other specialties (e.g., digital otoscope, stethoscope). Similar to other equipment purchases, psychologists should communicate with technology vendors as well as with colleagues and peers who have used technology to deliver treatment. Regional telehealth resource centers may offer feedback and recommendations for matching the appropriate technology with the provider and service. While individual technology standards often facilitate interoperability with other sites, the use of consistent technologies (e.g., brand of equipment, level of equipment) across the televideo network may decrease difficulties with connections.

Successful implementation of videoconferencing services calls for the psychologist and distant site to assess the availability of (a) modern, well-functioning televideo equipment, (b) encrypted videoconferencing software, (c) secure clinical space for the equipment setup, and (d) consistent high-speed connectivity. For telepsychology consultations, serious consideration should be given to privacy and security. Most guidelines recommend use of point-to-point encrypted software, with transparent company information about transmission and encryption protocols. Some sites need to run an additional network line to support the additional bandwidth requirements associated with televideo services. It is important to address sustainability of maintaining and paying for equipment, software, and connectivity when establishing a telepsychology clinic. Initial and ongoing training in the technologies and access to technical assistance should be considered.

Televideo Clinic Room

Televideo brings together systems of care, linking the psychologist with schools, clinics, primary care offices, and other systems of care. Therefore, televideo sites should identify rooms large enough to accommodate many participants as well as strategies to manage the participants in and out of the televideo room. Lighting is also important to clearly see facial expressions and affective responses. The technology at the provider site may have some benefits not seen in the on-site setting, such as the ability to unobtrusively zoom in and note physical presentations such as tics, gait, or nonverbal gestures.

Telepsychology Protocols

Psychologists are encouraged to develop protocols for their telepsychology clinics and update protocols annually. Telepsychologists should consider maintaining protocols referral and scheduling, pre-consult preparation, televideo session, crisis intervention, and follow-up. Telepsychology protocols should identify who is expected to attend the appointment (client, family members, case managers, other community members) and who is expected to coordinate the appointment at the distant site (school nurse, clinic nurse, other clinic personnel, etc.). Telepsychology consults, other than in the home setting, most often include a telepsychology coordinator to assist during the consult. The coordinator at the client site facilitates telepsychology session and often serves as the telepsychology "champion." Psychologists must carefully consider the risks and benefits related to inclusion coordinator for their specific clinical purpose. Psychologists often work with coordinators who provide assistance with the technology, support for the client, and immediate help in the event safety or other emergent concerns.

Telepsychology Coordinator

A telepsychology coordinator, sometimes called a telefacilitator, is an individual trained in assisting clients throughout their videoconferencing experience. The telepsychology coordinator is responsible for promoting the psychological service, scheduling the consultation, compiling intake packets, socializing the client and family to the televideo equipment, assisting during the consultation, and helping the family follow up on recommendations (Shore & Manson, 2005). The telepsychology coordinator also assists the psychologist in confirming that telepsychology encounters are private because the psychologist has less direct control of the distant environment. The telepsychology coordinator alerts the psychologist concerning those present in the secure televideo room as well as monitors the physical environment to ensure that others cannot overhear the communication occurring in the televideo room. While the telepsychology coordinator facilitates clinic implementation, his or her attendance in clinical encounters differs from most on-site clinics.

Ethical and Regulatory Considerations

Careful consideration and planning around regulatory and ethical issues may affect when telepsychology programs are able to launch. Comparable with on-site clinical settings, the core ethical concern to protect the client remains paramount for videoconferencing settings (Nelson & Duncan, 2015). In addition, professional guidelines addressing telepsychology are emerging to inform reasonable steps for telepsychology practice across clinical, administrative, and technical considerations, including child-specific guidelines. Telemental health guidelines are available through the American Telemedicine Association and the American Psychological Association, as well as a growing number of related mental health professional organizations.

There is limited state and national guidance concerning regulation of psychological services over televideo, with only a few state regulations specifically addressing televideo practice. Without guidance, a circular situation is created in which the lack of guidance potentially limits psychological practice and the lack of practice volume makes guidance a low priority. State psychology leaders (e.g., Ohio, others) encourage best practices within the framework of existing regulations. In general, the psychologist must be licensed in the state of the client's clinic location and across state, national, and international boundaries. Credentialing should also be considered based on the service sites.

At the national level, the Joint Commission on Accreditation of Healthcare Organizations has regulations applicable to telemedicine. Federal, state, and local laws, as well as institutional requirements, must also be reviewed related to the following: (a) involuntary commitment and reporting child maltreatment, (b) teleprovider credentialing and privileging requirements, and (c) malpractice insurance specific to telemedicine.

Interstate licensure is a complex issue; the telepsychologist is encouraged to review state licensure requirements related to the teleprovider location and the client location. Other regulatory/ethical requirements to consider include verifying the client identity and confirming the location of the client; this is often more easily accomplished in supervised than in unsupervised settings (e.g., the home). It is equally important for the teleprovider to inform the client of the teleprovider's location and credentials.

Other important factors to consider when initiating a telepsychology service include the client's privacy and compliance of the videoconferencing transmission with the Health Insurance Portability and Accountability Act. State law regarding confidentiality of behavioral health information should be reviewed, and when applicable, school-specific confidentiality requirements as outlined in the Family Educational Rights and Privacy Act Regulations. Informed consent for treatment may include an additional consent to receive telepsychology services. A review of the potential limitations and acknowledgment of the clients' right to refuse treatment over videoconferencing is part of informed consent as well as clarification of whether the sessions will be recorded and/or stored in any way. Best practices in documentation and use of the electronic health record should also be followed.

Sustainability

Psychologists should consider the sustainability of their telepsychology service over time. The initial costs associated with starting telepsychology include equipment and software costs, connectivity/line charges, installation costs, costs of remodeling or adding space, telemedicine training for personnel, and costs with adding staff to assist with telemedicine or with changing workflow to meet telemedicine responsibilities. Costs typically decrease over time as client volume increases. Psychologists have used various funding for initial televideo implementation, including institutional seed money, community and foundational support, state grants, federal funding, billing reimbursement, and contractual agreements.

Reimbursement is an important step toward sustaining telepsychology services. States are increasingly implementing parity legislation requiring televideo services be reimbursed as on-site benefits. A growing number of third-party insurers reimburse televideo services, including Medicare, the majority of state Medicaid policies, and many private insurers (Gros et al. 2013). In addition to provider billing, some sites may be eligible for Medicare/Medicaid's originating site fee. There is variation in coverage based on insurer, provider type, and location, and telepsychologists must carefully consider their own setting. In general, many, but not all, current procedural terminology (CPT) codes may be covered for televideo services, with the addition of a GT telemedicine modifier to the billing code, which indicates audio or video service provision. Billing reimbursement is an important step in televideo sustainability, but the same challenges seen in on-site billing for mental health services remain over televideo. Some telepsychologists may utilize other business models, such as contractual agreements with sites to cover both the psychologist's time and related costs (e.g., line charges, office management, etc.).

Telepsychology services to primary care settings are anticipated to increase with national and state initiatives around the client-centered medical home. The medical home model advances coordination and communication between primary care and psychologists. Telepsychology is a viable strategy to increase access to psychologists in primary care settings. As in other telepsychology settings spanning systems of care, team building and good communication skills remain crucial for a successful delivery of service.

New telepsychology models continue to emerge, including videoconferencing directly to the consumer in the home. A range of technologies are used for home-based services, and psychologists should consider the risks/benefits of the videoconferencing technology, including security and reliability. While home-based televideo services increase access, there is less control over the environment in this unsupervised setting (e.g., without a telepsychology coordinator). Psychologists providing service to the home should continue to consider key telepsychology components including (a) informed consent for telepsychology service; (b) protocols concerning the expected process, including key components discussed in other videoconferencing settings above (e.g., scheduling, follow-up, secure environment, backup plans in the event that the technology fails to the home, etc.); and (c) safety plans in the event the client reports suicidal, homicidal, or other safety concerns. Telepsychology services to the home are generally fee-for service and not reimbursed by third-party payers. Mobile technologies (e.g., smartphones, tablets, etc.) with video capabilities expand accessibility further, but consideration must be given to the new benefits and risks for the client and their families.

Telepsychology in Practice

Telepsychologists

Due to the newness of the field, there are no established performance competencies specific to technology, but telehealth guidelines and overall professional ethics guidelines provide direction. Telepsychologists should consider practice with the technology as well as cultural competence with the population served by the telepsychology clinic. Ideally, psychologists observe other telemental health providers, seek out supervision specific to telehealth, and complete mock/practice sessions in order to build confidence working with the team and implementing the telepsychology protocols. The technology itself offers unique opportunities for telesupervision, with requirements varying across states and health professions.

Telepsychology Clients

Selection of clients to be seen over televideo is contingent upon client and guardian preferences, developmental and diagnostic considerations, personnel and other resources at the distant site, and the telepsychologist's level of televideo competence and comfort. Psychological services over televideo may be especially suited for youth who are often already comfortable and accepting of technological media. Some studies suggest that televideo offers unique advantages, including less self-consciousness and decreased confidentiality concerns, as the telepsychologist is outside of the local community.

Across telepsychology clinics, clients tend to present with the same concerns as seen in traditional clinic settings. No presentation or diagnostic category has been excluded from mental health services over televideo. However, the same careful consideration used in traditional clinics should be taken related to competence with the presenting concern as well as access to necessary resources, particularly for clients with severe symptoms and impairments. Research has demonstrated that televideo is equivalent to face-to-face assessment and treatment of psychosis and that televideo is well tolerated and accepted by this population.

The Client–Provider Relationship and Televideo Etiquette

Psychologists should strive to replicate the same client engagement and rapport building strategies to the telemental health session (Grady et al., 2011). Shadowing existing teleproviders, seeking supervision for telepsychological intervention, and consulting with colleagues may foster the telepsychologist's comfort level associated with strong therapeutic relationship building. Strategies used in on-site visits translate to the telepsychology environment, such as noting a child wearing a shirt from a favorite team or taking time to talk about local events. Some telepsychologists may use more animated gestures or attend more closely to nonverbal cues such as facial expressions, although overly exaggerated/fast movements/hand gestures should be kept to a minimum to avoid pixilation. Verbal communications may be more deliberate to adjust for the slight auditory lag and to clearly indicate when the telepsychologist has finished speaking in order to facilitate reciprocity in communication, although this is decreasing as a less frequent concern due increasing availability of high-speed connectivity.

Families may be apt to quickly accommodate to the technology setting due to previous experience in using videoconferencing for social purposes, such as connecting with friends or family members. Telepsychologists should consider providing clients with reminders of the clinical nature of the televideo interaction as well as the additional security of the videoconferencing systems.

Technological Factors Affecting the Clinical Encounter

A high-quality video signal is imperative to the success of the telepsychology session, with recommendations generally advising a bandwidth of greater than 384 kB per second. A high-quality audio signal also assists with identifying nuances of an individual's verbal communication. The secure televideo room should ideally be away from clinic and street noise because the microphones are very sensitive, and extraneous sounds can interfere with the session. Toys can produce uncomfortable levels of noise, and foam blocks, books, markers, and papers may be an alternative, depending on the client population and developmental stage.

Video quality and camera placement are important to the caliber of the televideo session as they allow the telepsychologist to clearly observe facial expressions, affect, relatedness, crying, and other nonverbal reactions. Considerations for video quality include minimizing shadows, positioning lighting to emanate from behind the camera, selecting rooms without windows or adequate window cover to control lighting, staging professional backgrounds consistent with typical office settings, and avoidance of clothing with high contrast (e.g., stripes, busy patterns).

Technicians should support telepsychologists with strategies to maximize the quality of the videoconferencing encounter. Current videoconferencing speeds have decreased the pixilation/tiling associated with earlier videoconferencing rendering fewer technical difficulties over time. Consideration should be given to camera angle, monitor selection, and positioning in order to better facilitate communication. Telepsychologists are encouraged to check in with clients to make sure clients can see and hear telepsychologists as expected. Even though many televideo platforms have the ability to record sessions, telepsychologists should inform clients that sessions are not videotaped or archived in any way without client knowledge and consent.

Referral and Scheduling

As in other outreach clinics, telepsychologists should identify office personnel responsible for scheduling across the client sites (e.g., clinics, hospitals, schools, home, etc.). This person is responsible for coordinating the telepsychologist's schedule, the client site schedule, and room availability. As in the in-person setting, it is helpful to obtain the referral for the new client and determine if the client meets the insurance requirements consistent with the practice. Generally, the same paperwork as in the in-person setting is utilized (e.g., psychology intake form; registration form, including insurer information; consent form, including telemedicine-specific language; HIPAA-related Notice of Privacy Protection [NPP]; previous medical history and documentation; requested lab or other tests prior to the telemedicine encounter; any other information requested by the telemental health team specific to the consult). Best practices related to the transmission of health-related information should be followed, and the client's designated medical record is maintained by the telepsychologist.

Pre-session Preparation

The same on-site guidelines are followed for quiet, safe, handicap accessible, client-friendly space for televideo encounters. The secure televideo room must be large enough to accommodate all participants. The connection at the remote site should be tested for compatibility and entered into the directory for easy dialing. The technician may assist the telepsychologist with videoconferencing basics (e.g., that the microphone is not muted, that the camera is focused on the provider, that microphones are placed away from the monitor's speakers, and that the client is aware of any other individuals in the room). Backup plans should be in place in the event of technology failure, usually telephone follow-up. The televideo coordinator should complete training with the psychology team before initiating services. This includes shared expectations concerning support of the client related to the televideo encounters and assistance to the provider during the encounters. Safety protocols should be reviewed in the event the client presents with immediate suicidal concerns and needs local emergency services.

Televideo Session

The session approximates all key elements of the on-site visit at initial and follow-up sessions. The same attention to process and rapport building is given in the televideo appointments as in on-site appointments. The telepsychologist has full discretion to advise the client to be seen on-site. Overall, research has supported the feasibility and accuracy of psychological diagnostic interview and the diagnostic rating scales over televideo. Neuropsychological testing over televideo has been shown to be feasible as a broad indication of impairment, although some hands-on neuropsychological tests are more difficult to translate to the televideo setting. To date, there is very little clinical or research data concerning personality tests over televideo. Programmatic descriptions and a growing number of controlled trials directly comparing in-person with telepsychology services are encouraging, although more research is needed across presenting concerns and across the lifespan.

As in on-site clinics, the telepsychologist gathers information about the presenting concern and the relevant history. The telepsychologist observes the client throughout the session and notes behavior as well as physical presentation (e.g., gait, tics, affect). The zoom feature of the televideo camera can assist with this and allow unobtrusive close-up observation of such features. The telepsychologist completes the same documentation and billing forms as in on-site clinics and maintains the file/medical record.

Post-session

The telepsychologist and televideo coordinator collaborate to assist the client in understanding and following treatment recommendations and referral recommendations. The telepsychologist advises the client about follow-up appointments via televideo or on-site. Billing considerations are followed as described above. The same follow-up correspondence between telepsychologist and referral source is completed. The protocol for on-site visits is utilized for between-session needs, and information is shared with the client regarding designation of local emergency services in the event of crisis.

Conclusion

When best telepsychology practices are followed, telepsychology holds much promise to extend evidence-based treatments to clients and families and improve access to quality care for rural and other underserved clients/families. Evaluation across client, provider, and system metrics has been promising, although additional research is needed. Psychologists considering utilizing this technology should complete a needs assessment at both the community and clinic level in order to address the feasibility of acquiring and using the technology, understand the demand for the telepsychology service, and develop a business plan for sustaining services. Many successful telepsychology services benefit from strong relationships with communities and telehealth champions and are supported by a collaborative outreach team (i.e., psychologist, technical and scheduling support, telepsychology coordinators, etc.).

Psychologists who acquire this technology should use it in accordance with their professional organizations' ethical standards for best practice and develop a working protocol in order to minimize client risks. Initial and ongoing training and consultation with the telepsychologist's colleagues/community of practice is strongly encouraged. The unique risks and benefits of supervised and unsupervised/home telepsychology settings should be carefully considered and shared within the informed consent process. New technologies (e.g., smartphones, mobile tablets) offer exciting potential to extend reach with secure videoconferencing, as well as emerging potential to pair telepsychology services with other health technologies in order to best meet the needs of the individual client.

Author Biographies

Shawna Wright, associate director of KU's Center for Telemedicine and Telehealth, is a licensed psychologist. She obtained her graduate training in clinical psychology at Texas Tech University. Dr. Wright worked for over a decade in community mental health and has been a practicing telepsychologist since 2011.

Through her experience with providing treatment to rural and underserved populations, Dr. Wright is acutely aware of the impact of the shortage of medical and mental health providers, and she sees the promise of telehealth for improving access to care. She has interests in advancing telehealth policy and engaging medical and mental health professionals and students in telemedicine education. Dr. Wright works with KUMC's Project ECHO as project facilitator and behavioral health content expert to assist Kansas health/mental health providers with increasing access to up-to-date research outcomes, best practices, and standards of care to reduce health disparities.

Dr. Wright is a member of the Rural and Frontier Subcommittee of the Governor's Behavioral Health Services Planning Council, the Kansas State Epidemiological Outcomes Workgroup, and the Kansas Prescription Drug and Opioid Advisory Committee. She works with these groups to understand gaps in access to care and to identify ways telemedicine can be leveraged to increase health equity in Kansas.

Eve-Lynn Nelson is a research advisor and supervisor for health psychology students conducting clinical research and offers GRA positions at KUMC in the area of telemedicine.

Dr. Nelson also teaches graduate courses in health psychology and supervises the telemedicine practicum at KUMC.

Traditional Healing Practices and Healers

Robert M. Huff

Department of Health Sciences, California State University, Northridge, Morgan Hill, CA, USA

Causes of illness, disease and death as well as how to prevent and/or treat these conditions have been and continue to be concerns that humankind has sought answers to since their earliest beginnings. Over the millennia, these questions have spawned a host of explanations for illness causality and treatment along with those who would become the carriers of this knowledge. *Traditional medicine* grew out of these early beginnings and continues to be utilized into the present all around the world. Traditional medicine is strongly influenced by the cultural/ethnic groups from which it has emerged with practices and practitioners often used as a first choice for care before or in tangent with Western medical modalities. Traditional medicine is sometimes preferred for three reasons: (a) The cost of treatment tends to be lower than Western biomedicine, (b) the healer can come to the patient, and (c) the healer and patient come from the same cultural milieu with similar worldviews. Traditional medicine can be defined as the health beliefs, practices, and techniques used by indigenous healers to treat and cure the sick. These healing approaches may include herbal and animal-derived products, various minerals, prayer, shamanic journeying and related supernatural modalities, and other forms of alternative medical practices that are passed down through the family/culture from generation to generation. The term traditional medicine is often used interchangeably with the terms *folk medicine, complimentary medicine, or alternative medicine* to describe these non-western approaches to healing the sick (World Health Organization, n.d.).

Kleinman (1980) in his seminal work, looked at how individual patients and their healers defined health, illness, and disease and calls these *explanatory models.* He notes that the explanatory models of both patients and their health practitioners are important to the understanding of potential or real problems in a health care encounter. For instance, many cultural groups view health and disease as imbalances within the individual and their environment with factors such as ones' emotions, social interactions, physical behaviors, and spiritual or

---

The Wiley Encyclopedia of Health Psychology: Volume 4: Special Issues in Health Psychology,
First Edition. General Editor: Lee M. Cohen. Volume Editor: Suzy Bird Gulliver.

other metaphysical interactions contributing to these imbalances. Helman (2007) has identified four major categories of illness causality within a variety of cultural groups. These categories include: *the individual world*, *the natural world*, *the social world*, and *the supernatural world*. He notes that illness causality may be seen as emerging from one or more of these levels and in combinations of these. The individual level is concerned with personal behaviors (i.e., diet, exercise, tobacco use, etc.) over which the individual has some control. This also includes hereditary, social, economic and personality variables. The natural world is concerned with both animate and inanimate variables that can lead to illness, disease, and death. This level includes accidents, natural disasters, microbes, injuries from flora and fauna, toxins, weather, and other environmental factors. The social world encompasses interpersonal conflict such as bullying, gang violence, domestic abuse, war, and other similar causes. It should be noted that this level also is concerned with witchcraft, sorcery, evil eye, voodoo, and related practices. The supernatural world is concerned with a variety of entities including angry gods, ancestral spirits, soul loss, spirit possessions, and other metaphysical causes leading to illness and even death. At each of the four levels of disease causation, specialized healers may be necessary to help resolve the cause of a health problem. These may include a shaman, a root doctor, a curandero, spirit medium, herbalist, acupuncturist, or priest. Prayer, sweat lodge ceremonies, chanting, massage, a Western biomedicine practitioner, or combinations of any of these may also be utilized.

Archaeological evidence of *shamanic healing* practices date back thousands of years as seen in early burial practices, cave art, and related artifact materials. Injuries, illness, and death would have been common occurrences in these ancient human cultural groups and the need for someone to explain and treat these events fostered the rise of shamanic healing traditions that have persisted into modern times (Huff, 2002; Huff, Kline, & Peterson, 2015). A shaman is a man or woman capable of trance journeying into the spiritual dimension to seek knowledge regarding healing of the sick, communicating with the spirits of the dead, divining future events, and gaining the favor of the gods, spirit animals or other entities in the natural environment. They may be called upon to perform special ceremonies or rituals to keep a community safe, heal a community member, bring about a good harvest, or placate an angry god or spirit. They may be called to become a shaman as a result of a near death experience where they traveled to the spirit world and returned with new healing knowledge, songs, prayers, rituals, or other revelations given to them by teachers on the other side. A shaman may also be born into the shamanic role under certain circumstances such as being born under a veil (i.e., born with a portion of the amniotic tissue covering their face) or they may be trained if they seem to have special healing abilities (Eliade, 1964). Shamans may use rattles, drums, gongs, finger bells, dancing rituals, purification rites, or physical manipulation such as sucking (i.e., removing a stone, or other material from inside a person by sucking it out). Shamanism has seen resurgence in the United States, with training programs to prepare individuals to take on the role of a shaman in their personal lives.

In Latin American cultures a system known as *curanderismo* has evolved from a number of elements. These include spiritual, homeopathic and other indigenous and Western traditions, with specialized healers who use a variety of methods in their healing work. Medicinal plants are often used and include an extensive pharmacopeia of plants such as cat's claw and dragon's blood for arthritis; aloe vera and chamomile for asthma; camphor and kalallo bush for the common cold; anise, ginger, and mugwort for gastrointestinal problems; artichoke and wormwood for liver problems; and many others (DeStefano, 2001). Shops that sell herbals and other healing items can be found in Hispanic communities and are a ready source for medicines and healing advice. Other healers in the curanderismo system include spiritual healers (i.e., curandero/curanderas who use ritual, prayer and other approaches); those who use massage and physical manipulation; midwives; and others including those who practice the dark arts such as witchcraft and sorcery. Hot and cold illnesses, thought to result from an imbalance between these two humors, are a significant component of Hispanic health beliefs and practices (Ortiz, Shields, Clauson, & Clay, 2007). Cold illnesses are treated with a hot remedy (i.e., upper respiratory infections are considered a cold illness and would be treated with steam baths, hot compresses, cinnamon, and herbal teas); sore throat, a hot condition, would be treated with a cold remedy (i.e., a half and half mixture of honey and lemon juice). The objective is to balance the illness with an opposite treatment-hot with cold and cold with hot. The use of traditional medicine approaches is a common practice among diverse Hispanic populations and should be explored by Western health care providers when treating this population group.

Traditional Southeast Asian groups believe that illness can arise from physical, metaphysical, or supernatural causes. Treatment for any of these health problems may require the services of a Buddhist monk, an herbalist, a shaman, a spirit medium, astrologer, acupuncturist, physician, or other specialists. Traditional Chinese medicine, which has evolved over thousands of years, is based on the concept of Tao (the way or path). It is concerned with harmony and balance between and within the individual and his or her environment. The forces of yin and yang (representing a duality of the universe) must be in balance. Yin is the female side (i.e., the passive or negative female force; the front and inside of the body) while yang is the active male side (the outside and back of the body) of the yin/yang duality. It is represented by light, heat, and fullness. Should this balance be disrupted, illness may be one of its' consequences (Helman, 2007; Kagawa-Singer & Kho, 2015; Spector, 2013). In traditional Chinese medicine one may be treated using acupuncture, acupressure, herbs, moxibustion, cupping, meditation, and may also require a shamanic practitioner. Western biomedical practitioners may also be used in tandem with one or more of the traditional approaches noted above. Traditional Hmong (many who have settled in the United States in recent years) are oriented to animistic believes. That is, a belief that spirits inhabit rocks, rivers, ponds, trees, etc. and may, if angered, cause illness and even death. Soul loss, a belief that the soul can leave the body on its own or by being taken by an evil spirit is part of their belief system. Shamanic practitioners may be called in by the family should someone in the household become ill. The shaman may use a number of healing approaches including bells, rattles, herbs, and shamanic journeying to find a lost soul. Western biomedical approaches may be resisted because they are not understood as reported by Fadiman (1997) in her seminal study. Other Southeast Asian population groups vary in their use of traditional healers and beliefs in illness causation. These beliefs range from the natural world to supernatural causes and herbal treatments, prayer, magic, charms, medicinal potions, and Western biomedicine may be used for healing purposes.

American Indian health beliefs and practices revolve around the concept that health is strongly linked to spirituality and the interconnectedness of all things. As with a number of other cultural groups, traditional American Indian medicine is holistic in nature and concerned with maintaining one's balance in the mental, physical, emotional and spiritual domains of life (Hodge & Hodge, 2015). Illness results from an imbalance in any of these domains brought on by natural or supernatural forces. Traditional healers/medicine people may be called upon to perform healing ceremonies that may involve prayers, chanting, purification activities including smudging and sweat lodge ceremonies, herbal medicines, physical manipulations, and diagnosing emotional and spiritual disharmony. The medicine person (male or female) may also function as an arbitrator, psychiatrist, diviner, and spiritual advisor. Western biomedicine is also an accepted modality and hospitals and health centers can be found on reservations and in urban areas targeted specifically to American Indian and Alaska Native populations. In recent years there has been a trend in integrating traditional healers with Western biomedicine practice. That is, traditional healers work in tandem with Western health care practitioners in hospital settings to perform traditional healing ceremonies for patients while also receiving Western medical treatment modalities (Rhoades, 2009).

Black Americans for the most part share a greater belief in the Western biomedical model though traditional healing practices continue to a greater or lessor degree depending on regional differences, education, socioeconomic status, and related factors (Hopp & Herring, 2015; Mitchem, 2007). Immigrants from other areas of the globe are more likely to hold on to traditional health beliefs and practices that are associated with the cultural milieu from which they have come. For Black Americans, traditional folk medicine practices and practitioners were often their only recourse when formal health care services were not available to them. As with other groups discussed previously, the concepts of harmony and balance in ones' life are believed to help promote good health. Disharmony brings illness and poor health. Congress and Lyons (1992) note that Blacks tend to separate illness into two dimensions: *natural illnesses* that can result from stress, environmental factors, dietary habits, lack of moderation in daily activities, and as punishments from God for sins and other transgressions; and *unnatural illnesses,* which can be brought on by evil forces including bad spirits, witchcraft, spells, and magic. Traditional healers include spiritualists who may use ritual, prayer, magic, and other related activities, and herbalists (root doctors) who use botanicals (i.e., roots, herbs and teas) and may use magic also to bring about healing. Practitioners, who can be male or female, come to their calling by being apprenticed to a folk healer in the community or by being born with a veil (portion of the amniotic sac) over their faces. *Hoodoo* and *Voodoo* are two terms often used when describing healing traditions among Black Americans. Haskins (1990) describes hoodoo (or conjure) as the use of simple medicinal treatments as well as magical practices to bring about healing cures or to ward off or bring about evil. Voodoo is concerned with casting spells or hexes to bring evil and even death to the target of these processes. He notes that these terms are often used interchangeably and that the lines are frequently blurred between them. Folk healers don't necessarily advertise their practices, as they are typically already known in their communities. Spirituality, prayer, and the Church are also important themes in Black communities and many churches have health ministries where health promotion, health screening, counseling, and other health-related services are offered.

Euro-American folk medicine arrived with the first settlers into the New World. They brought with them health beliefs and practices reflecting the cultural areas they immigrated from. Doctors were not always available nor were they particularly well trained. These new colonists utilized what medicines they had from the areas they had come from but also medicines that were shared by the Indians living in close proximity to them. New plants and herbs found their way into the pharmacopeia of these early and later arrivals as they spread throughout the many geographical areas of what ultimately became the United States of America (U.S.) (Cavender, 2003). As these new groups spread across the American landscape, folk medicine practices began to change in the various geographical settings where people settled. Jarvis (1996), in his seminal writings about folk medicine in Vermont, discusses the impact of environment on the health and energy of those living there. He notes that Vermont folk medicine is focused on the entire body in an effort to prevent disease and other conditions of the body. Proper diet is a major key to good health as well as the impact of weather variability. Botanicals are a mainstay of Vermont folk medicine, as well as minerals, honey, and apple cider vinegar. For example, apple cider vinegar is used to treat dizziness, overweight, sore throat, impetigo, and a host of other medical conditions. Many Americans use a teaspoon of apple cider vinegar and honey as a daily tonic. Honey and honeycomb, alone or in combination with lemon juice or apple cider vinegar, is considered useful for a number of conditions including muscle cramps, burns, hay fever, sinusitis, bed- wetting and other health problems.

Cavender (2003) discusses the use of folk medicine healers and practices in Southern Appalachia from early settlement to the modern era. Many folk medicine practices were brought with these early settlers while botanicals in Southern Appalachia and healing practices learned from the Indians were added to this repertoire. Traditional healers included herb doctors; bloodstoppers; burn doctors; midwives; faith healers; prayer, and reading the Bible as psychological coping mechanisms; magic, and witchcraft. A rich pharmacopeia of medicinal plants utilized by healers in this region included such botanicals as apple cider vinegar for burns, colds, and cuts, black snakeroot for colds and cough and to cleans the blood, pine bark and sap for coughs, worms, and cuts, and sage leaf for nervousness and fever. In today's world, many of the old folk medicine practices are giving way to Western biomedicine. However, folk medicine practices may still be used in conjunction with formal healthcare modalities. Cavender (2003) also notes that a number of other alternative medicine practices including acupressure, Reiki, aromatherapy, massage, vitamin therapy and other modalities have also taken root in Southern Appalachia.

In any discussion of traditional healing practices and how these impact and may be integrated with modern biomedicine, the concept of *cultural competency* should be considered. That is, the need for the health care practitioner to become more knowledgeable about the cultural groups they may be treating. This involves not only looking into the culturally held beliefs and practices of the patient/culture(s) being treated but also ones' own biases and stereotypes and how these may affect the patient-provider encounter. Though the practitioner may not agree with their patient's health beliefs and practices, these must be respected just as the practitioner would expect this from their patient(s). This would seem to be particularly important when dealing with mental health problems that many people, no matter where they are from, are reluctant to talk about. Exploring the patient's use of traditional healing practices in a nonjudgmental manner can help illuminate a great deal about the patient that is being treated. Kleinman and Benson (2006) suggest that the practitioner seek to develop a "mini-ethnography" by questioning the patient as a way to determine their explanatory model for their illness. This would also include what they may have done to treat their problem. Huff, Kline, and Dobbins (2015) present a cultural assessment framework that in whole or part can help the health care provider develop the questions they might ask to help create this mini-ethnography.

Training in Health Psychology

Kevin T. Larkin

Department of Psychology, West Virginia University, Morgantown, WV, USA

Shortly after the Division of Health Psychology was recognized by the American Psychological Association (APA) in 1978 and the parameters for the specialty area defined (Matarazzo, 1980), the founding leaders of this emerging area of professional practice met to discuss and formulate training guidelines for those who desired to pursue careers as health psychologists. From its inception, there was a recognition that those psychologists desiring careers involving research and/or practice of health psychology needed to acquire competencies beyond those typically trained in existing doctoral programs. Founded on the biopsychosocial model of health (Engel, 1977), it was obvious to early leaders that additional competencies were required for psychologists who desired to function as health psychologists. Although knowledge of psychological theories and skills was a regular component of doctoral training programs in psychology for decades, expertise in the biological and social foundations of health was sorely absent in most doctoral programs training psychologists in the 1980s. To remedy this problem and develop training guidelines, 57 psychologists with a commitment to the emerging specialty of health psychology joined together to participate in the National Working Conference on Education and Training in Health Psychology held in May of 1983 at Arden House in Harriman, New York.

The Arden House Conference

The National Working Conference on Education and Training in Health Psychology, commonly referred to as the Arden House Conference, was a 4-day meeting that was funded largely through the support of the Carnegie Foundation, the MacArthur Foundation, and the Kaiser Family Foundation. The Conference was chaired by Stephen M. Weiss, one of the early leaders of the specialty of health psychology. Among the highlights from Arden House was the recognition that there were two types of training programs comprising the specialty area, scientist and scientist-practitioner (Miller, 1983; for comprehensive coverage of the Arden

---

The Wiley Encyclopedia of Health Psychology: Volume 4: Special Issues in Health Psychology,
First Edition. General Editor: Lee M. Cohen. Volume Editor: Suzy Bird Gulliver.

House Conference, see Stone et al., 1987). Both types of programs were based upon the biopsychosocial model of health that ensured broad-based training of the science regarding biological, psychological, and social determinants of health and health behaviors and the development of research skills that fostered discovery of new findings. Trainees emerging from scientist programs (or what are now called health psychology training programs) were prepared to launch research careers aimed at advancing the understanding of the multiplicity of factors that influence health and the treatment of health conditions. In contrast, trainees graduating from scientist-practitioner programs (or what are now called clinical health psychology training programs) received training in the application of this knowledge with patients seen in healthcare settings as well as acquiring the foundational research competencies. In this regard, a hierarchical model of competency acquisition was outlined, with (a) fundamental knowledge of psychological principles and theories commonly taught in existing doctoral programs at the base; (b) knowledge of biological, psychological, and social determinants of health and research skills to discover new information comprising the next level required for those entering the workforce as health psychologists; and (c) additional clinical skills to enable the competent application of the knowledge base of health psychology into healthcare practice at the final level for trainees with aims of becoming clinical health psychologists.

Although many recommendations voiced by participants of the Arden House Conference regarding the distinctive set of competencies associated with the specialty were adopted by consensus, one area of disagreement among meeting participants pertained to the level of training required to apply evidence-based training with patients seen in healthcare settings. On the one hand, it was argued that due to the vast amount of knowledge required for the competent practice of clinical health psychology, only doctoral psychologists should be credentialed to function as clinical health psychologists. In contrast, it was argued that properly trained behavioral healthcare providers from other training backgrounds could be credentialed to assess and treat patients presenting with specific healthcare problems to meet what would certainly be a rapidly expanding demand for these services. Indeed, the limited number of training programs available to train clinical health psychologists who delivered competent behavioral healthcare services has long been recognized as a problem for a healthcare system that claims to treat and prevent death and disability largely caused by problems humans have in developing and maintaining proper health behaviors (e.g., eating balanced diets, engaging in regular exercise, using safe sexual practices, moderating alcohol use, etc.).

Rather than meeting on a single occasion to devise and adopt recommendations regarding the training of health and clinical health psychologists, the Arden House participants envisioned the creation of a vehicle to promote the ongoing dialogue regarding education and training in health psychology that would monitor training guidelines that would certainly need to adapt to the changing healthcare environment. The body constructed to ensure this ongoing conversation was the Council of Health Psychology that was a nonprofit organization composed of training programs in health psychology at doctoral, internship, and postdoctoral levels. Representatives from these training programs met annually to discuss relevant issues regarding training the next generation of health and clinical health psychologists for over a decade before falling into a state of dormancy by the end of the twentieth century.

The Tempe Summit on Education and Training in Clinical Health Psychology

Recognizing the important role of behavioral factors in the etiology of many diseases and sources of disability, the APA redefined itself as a health profession (Anderson, 2003) by voting to add the objective “promoting health” to its vision statement. This event coincidently occurred as the importance of behavioral factors in the etiology, assessment, diagnosis, and treatment of a broad range of diseases and disorders was being recognized by professions long affiliated with healthcare (e.g., medicine, dentistry, nursing, etc.). As healthcare systems looked to psychology to assist in managing the behaviors at the root of most of the problems seen regularly in their clinics and hospitals, inadequate numbers of clinical health psychologists were readily available, so the healthcare system turned to other types of psychologists and then to other related professions (e.g., social work, health counselors) to provide behavioral healthcare in these medical settings. Unfortunately, many of these individuals lacked the requisite knowledge of the biological, behavioral, and social factors that influenced health and health outcomes and the clinical-applied competencies for functioning within the healthcare environment. Even those trained in the top doctoral clinical or counseling psychology programs learned that they lacked the essential competencies to meet the unique demands encountered in medical settings. It became quickly apparent that some additional work needed to be conducted to describe the parameters of knowledge and specify the skills required to identify as a clinical health psychologist capable of functioning competently within the modern healthcare environment.

Based upon the foundational work conducted at the Arden House Conference and the growing focus on articulating competencies within the broader profession of psychology, Division 38 (Health Psychology) of the APA planned and held the Tempe Summit on Education and Training in Clinical Health Psychology in 2007 (see France et al., 2008). The primary goal of this meeting of 20 leaders from the education and training community in clinical health psychology was to articulate the competencies required for entry-level practice of clinical health psychology in six areas: (a) assessment/diagnosis/case conceptualization, (b) intervention, (c) research/evaluation, (d) consultation, (e) supervision/teaching, and (f) management/administration. It is beyond the scope of this chapter to enumerate all of the competencies on the list here, but the interested reader is referred to France et al. (2008) for a depiction of the initial list and to Larkin and Klonoff (2014) for the most recent iteration of it. Representative examples of some of the competencies of clinical health psychologists that distinguish them from other types of practicing psychologists are shown in Table 1.

A quick perusal of Table 1 easily reveals some of the unique attributes of the modern healthcare environment in which health and clinical health psychologists operate. Unfortunately, many of these competencies are not acquired in traditional doctoral training programs and internships where mental health issues are given more attention than health problems generated by other organ systems in the body. Conversations among Tempe Summit participants acknowledged that the primary distinction between health and clinical health psychology was in the extensive list of competencies comprising the applications cluster (i.e., assessment, intervention, and consultation) and knowledge and skills essential for the practice of clinical health psychology, but not required for functioning as health psychologists.

An additional outcome of the Tempe Summit was the reestablishment of an active training council. In order to ensure that the next generation of clinical health psychologists acquired the requisite competencies for functioning in the rapidly evolving healthcare system, the training community recognized that they had to commit to meeting annually to keep up with new developments in medicine and healthcare. The Council of Health Psychology established at Arden House was revived, given a new name, and established a primary goal to ensure that behavioral healthcare providers identified as clinical health psychologists possessed all of the competencies required to function effectively in the changing healthcare environment. Composed of directors of all training programs in clinical health psychology across doctoral, internship, and postdoctoral fellowship programs, the Council of Clinical Health Psychology Training Programs (CCHPTP) (acronym pronounced “chip-tip”) was incorporated in 2007.

Table 1 Examples of some of the distinctive competencies of clinical health psychologists.

Competency cluster	*Clinical health psychology competency*	*Example of means of demonstrating competence*
Science	Knowledge of pathophysiology of disease and biomedical treatments specific to medical specialty or environment in which the practice will occur*	Earning an A or B in a human physiology class
Professionalism	Identification and ability to address the distinctive ethical issues encountered in clinical health practice, particularly if these are in conflict with the ethical code of other members of the healthcare team**	Ability to discuss ethical issues pertaining to making end-of-life decisions and/or determining capacity to consent for medical treatments
Relationships	Development of facilitative and collaborative relationships with professionals from a variety of healthcare disciplines including medicine, nursing, physical therapy, social work, etc.*	Completion of practice in which trainees interact regularly with other healthcare professionals
Applications	Ability to evaluate the presenting problem and to select and administer empirically supported biopsychosocial assessments appropriate for the patient's physical illness, injury, or disability*	Completion of practice in a hospital, clinic, or other healthcare setting
Education	Supervision of clinical health psychology skills, conceptualizations, and interventions for psychologists, psychology trainees, and behavioral health providers from other health professions*	Experience supervising others with less training in health psychology, including those in other disciplines
Systems	Leadership within an interprofessional team or organization in the healthcare setting*	Demonstration of effective leadership skills during research or clinical team meetings

The Council of Clinical Health Psychology Training Programs (CCHPTP)

Launched at the Tempe Summit, CCHPTP members have met twice annually for purposes of making sure that training programs in clinical health psychology are keeping up with the demands of the contemporary practice of clinical health psychology within the context of the modern healthcare environment. Based upon the spirit of collaboration and community observed at both Arden House and Tempe Summit conferences, CCHPTP sponsors working meetings that frequently result in published articles aimed at disseminating the most current information to the entire educational community (e.g., Kerns, Berry, Frantsve, & Linton, 2009; Larkin, 2009; Larkin, Bridges, Fields, & Vogel, 2016; Larkin & Klonoff, 2014; Masters, France, & Thorn, 2009; Nash & Larkin, 2012; Nash, McKay, Vogel, & Masters, 2012; Nicholas & Stern, 2011). Early CCHPTP meetings focused on refining the core list of competencies articulated at the Tempe Summit, but more recent meetings have focused on other extensions of education and training in this specialty area, including the enumeration of the distinctive competencies required for working in primary care medical settings, where flexibility is essential and rapid pace of healthcare is the norm.

Most recently, CCHPTP has focused on establishing a standard method for describing the range of clinical health psychology training programs that exist among doctoral, internship, and postdoctoral levels of training. By addressing this issue, prospective learners have informed consent regarding the depth and breadth of training in clinical health psychology to assure that the designated program matches their desired training objectives. Using the structural framework of the *Taxonomy for Education and Training in Professional Psychology Health Service Specialties* (APA, 2012), CCHPTP outlined criteria for academic programs at four levels of training (doctoral, internship, postdoctoral, and post-licensure) for designation as (a) a major area of study (e.g., an internship in which 50% of supervised practice is in clinical health psychology), (b) an emphasis (e.g., a doctoral program that offers two courses and two practicum experiences in clinical health psychology), (c) an experience (e.g., a doctoral program that offers one course and one practicum in clinical health psychology, and (d) exposure to the specialty area (e.g., 10–20% of a postdoctoral program is in clinical health psychology). The complete taxonomy of clinical health psychology training programs is available on the CCHPTP website (see http://cchptp.org).

The Specialization of Clinical Health Psychology

Periodically, specialty areas are reviewed by the Commission for the Recognition of Specialties and Proficiencies in Professional Psychology (CRSPPP) of the APA to ensure that they continue to meet the requirement of providing advanced, specialty-specific scientific knowledge. Clinical health psychology last underwent this scrutiny in 2011, and its status as a specialty was reconfirmed (see APA, 2011). Part of the documentation for the redesignation as a specialty area requires that the area state whether specialty training occurs at the doctoral level, the postdoctoral level, or both. Although the specialty practice of psychology in most areas was historically conducted during postdoctoral training, the specialization of clinical health psychology reported in their petition that training was now done at both levels. In full recognition of the growth of specialization within the profession of psychology, trainees interested in pursuing advanced, specialty-specific training now start acquiring specialty competencies during their doctoral training years alongside the acquisition of broad and general competency acquisition (Nash & Larkin, 2012). In the past, students had opportunities to secure internships and postdoctoral fellowships in clinical health psychology with very little exposure to the specialty area during their doctoral training years. This is no longer the case. Entrance into most accredited internships and postdoctoral training programs in clinical health psychology is so competitive that some exposure and experience in clinical health psychology is almost a requirement for advanced specialty training. To fulfill the need to produce trainees who had acquired some specialty competencies during their doctoral training years, more doctoral programs began offering tracks or areas of emphasis in specialty areas, and clinical health psychology or its related discipline of behavioral medicine is one of the most popular tracks among all accredited doctoral programs (Perry & Boccaccini, 2009).

Although the specialty area of clinical health psychology acknowledges that training is conducted at both doctoral and postdoctoral levels, accreditation of clinical health psychology programs is only recognized for postdoctoral programs in the specialty area. This is largely done because most of the doctoral programs that offer opportunities to acquire specialty competencies in clinical health psychology are embedded in existing clinical or counseling psychology training programs (Larkin, 2009). As such, some, but not all, trainees in these programs acquire specialty-specific competencies in clinical health psychology. That said, there are now several programs that exclusively train clinical health psychology students at the doctoral level of training and ensure that all graduates of these programs acquire coursework, practicum, and research experiences relevant to clinical health psychology. This same state of affairs exists at the internship level, where over 500 internship sites provide rotations in clinical health psychology (Masters, France, & Thorn, 2009).

The foundational work on articulating entry-level competencies of the clinical health psychologist was cited prominently in the petition to CRSPPP for re-recognition as a specialty area. Most formidably, competencies in conducting research were highlighted as credentials of clinical health psychologists that make them stand out among all other professions represented in the modern healthcare environment. As such, clinical health psychologists become natural leaders of interdisciplinary research programs and quality improvement evaluation efforts. The fact that the Affordable Care Act, once fully implemented, will require demonstration of positive treatment outcomes in order to obtain optimal compensation for services will position clinical health psychologists as indispensable members of staffs of academic medical centers and hospitals.

Expansion of Clinical Health Psychology Specialty Training

It is clearly recognized that expertise in behavioral healthcare is highly valued in the modern healthcare arena. The extent to which these services will be provided and/or supervised by specialists in clinical health psychology has yet to be known. The dilemma confronting Arden House participants, whether adequate numbers of doctoral clinical health psychologists to provide these services exist, continues to confront the field. Naturally, cost–benefit calculations also enter into these equations as healthcare organizations consider the value of hiring doctoral level clinical health psychologists. In this regard, it is clear that clinical health psychologists of the future will not be hired only as frontline behavioral healthcare providers. Their value becomes truly recognized through their extensive training in research, consultation, team management, and clinical supervision.

Regardless of how specific hospitals and healthcare systems resolve the workforce decisions associated with hiring doctoral level clinical health psychologist and their research-oriented health psychology peers, the domain of health psychology has been expanding. For example, pediatric psychology reflects a somewhat newer specialty area that certainly has its roots in clinical health psychology and those psychologists who chose to provide behavioral healthcare and conduct research in pediatric clinics. Likewise, early clinical neuropsychologists applied their solid behavioral assessment skills acquired in traditional clinical or counseling training programs with patients visiting neurology clinics and rehabilitation hospitals. More recently, considerable attention has been given to psychologists who integrate the provision of behavioral healthcare and practice-based research into the daily medical practice in primary care settings (e.g., McDaniel et al., 2014; Nash et al., 2012). The unique set of interdisciplinary systems, practice management, and supervisory skills with which clinical health psychologists are equipped makes them highly competitive for these types of positions. As the field becomes more specialized, even more subspecialty areas that have their roots in clinical health psychology can be envisioned (e.g., psycho-oncology, cardiac psychology, pain psychology).

Although the addition of health promotion to APA's vision statement accurately acknowledged the fact that mind and body are interconnected, it has, in some respects, blurred the distinction between clinical health psychology and other types of professional psychology. Nowhere is this more apparent in the decision to replace the term "professional psychology" with "health service psychology" (Health Service Psychology Education Collaborative, 2013).

Health service psychology should not be confused with clinical health psychology. Health service psychology refers to psychologists who are licensed to provide services within the scope of their competencies and to offer and bill for these services through various health plans. In this regard, a clinical health psychologist is one type of health service psychologist. The inverse statement, however, is not true. Not all health service psychologists possess the competencies to practice as clinical health psychologists and should not attempt to practice beyond the scope of their competencies. To the extent that the enumeration of clinical health psychology competencies has informed the construction of the competencies of all health service providers, it has become clear that all practicing psychologists, clinical health psychologists included, will need to learn more about interdisciplinary healthcare provision, biological diseases and treatments that influence human functioning, and practice management within healthcare systems.

Clinical health psychologists are well positioned to play critical roles in the healthcare teams of the future. They possess the knowledge of behavior change that should be at the root of almost all treatment plans of patients seeking care from all health professionals today. They are uniquely suited for developing and testing interventions in healthcare settings, training and supervising those who use them, leading interdisciplinary research teams, and consulting with other members of the healthcare teams regarding patients with complicated medical presentations. Educators comprising professional training programs have long been committed to working with trainees to ensure that the next generation of clinical health psychologists possess the competencies needed to practice effectively in the modern healthcare arena.

Author Biography

Kevin T. Larkin, PhD, ABPP, is a professor and department chair in the Department of Psychology at West Virginia University. As a board certified clinical health psychologist, he also holds an appointment in the Department of Behavioral Medicine and Psychiatry at the Robert C. Byrd Health Sciences Center in Morgantown, WV. His primary works of scholarship focus on applied psychophysiology and cardiovascular behavioral medicine. He served as the chair of CCHPTP during its first 6 years and has written extensively on the training and education of clinical health psychologists.

Training Non-psychologists in the Healthcare Settings

Cesar A. Gonzalez[1], Kristine M. Diaz[2], and Richard J. Seime[1]

[1]*Mayo Clinic Minnesota, Rochester, MN, USA*
[2]*Walter Reed National Military Medical Center, Bethesda, MD, USA*

Historical Context of Psychology in the Healthcare Setting

In the United States, psychology first began to hold a prominent role in healthcare settings around 1945 through the development of the Department of Veterans Affairs' psychology program. The inclusion of psychologists into the Veterans Affairs promoted the advancement of multisite and interdisciplinary research and facilitated the inclusion of behavioral treatments in healthcare settings. In 1977, George L. Engel published *The Need for a New Medical Model: A Challenge for Biomedicine* and introduced the biopsychosocial model into medicine, which, in addition to the biological determinants of disease, also included the psychological and social determinants in the contribution to the development and progression of disease (Engel, 1977).

The World Health Organization describes determinants of health as being the context in which individuals are born, develop, live, work, and age that influence the shape and trajectory of health and mortality (WHO, 2010). An individual's behavioral and sociocultural context is estimated to account for 10–50% of the cause of chronic diseases and early mortality. Health psychology uses the scientific method to generate and apply knowledge related to the interplay between the determinants of disease in the biopsychosocial model in order to prevent, treat, rehabilitate, and maintain the health and well-being of individuals, communities, and populations. Since the 1990s, in the United States, there has been a movement toward integrated care characterized by colocation and deliberate collaboration among healthcare professionals with the goal of integrating the biopsychosocial model into patient care to optimize the trajectory of care and health.

The Wiley Encyclopedia of Health Psychology: Volume 4: Special Issues in Health Psychology,
First Edition. General Editor: Lee M. Cohen. Volume Editor: Suzy Bird Gulliver.

Given the rapidly changing healthcare system, psychologists are uniquely positioned to serve as behavioral health experts; health educators and consultants; and researchers across primary, secondary, and tertiary healthcare settings. In addition to training licensed health professionals in these settings, psychologists train undergraduate, graduate, and postgraduate learners.

Psychologist as Educators With Non-psychologists

While psychologists hold specialized training to provide direct patient care, the role of the psychologist in healthcare settings is likely to shift to one that is focused on the delivery of training and supervision for other healthcare professionals. In 2014, the "Competencies for Psychology Practice in Primary Care" published in the *American Psychologist* (McDaniel et al., 2014) identified teaching and supervision as a competency of psychologists in these settings, serving as educators in faculty and staff development as well as educating and supervising health trainees. Working with various health professionals, finding a common language and focus contributes to successful education and training goals with non-psychologists.

Family medicine is one field of medicine that has demonstrated success in the integration of psychologists as educators with non-psychologists in primary care, utilizing accreditation standards in the provision of behavioral health in primary care. With identified core competencies and training milestones, emerging physicians, attending physician faculty members, and allied health providers are able to treat patients with complex medical histories. In fact, the triumph of the integration of psychology into family medicine serves as an educational model for psychologists working with non-psychologists. Accreditation-driven graduate medical education in family medicine has contributed to a system-based approach to the inclusion of psychologists in traditionally physician-dominated areas of medicine, and family medicine is one of the first specialty areas of medicine to demonstrate interprofessional collaborative clinical practice.

With the innovation of family medicine to embed educational requirements of non-psychologists in their field through accreditation standards, the field has created an inclusive learning environment, building a common language for the sustainability of psychology as integral to the practice of family medicine.

Enhancement of Learning Environment in the Education of Non-psychologists

The American Psychological Association published the *2015 Survey of Psychology Health Service Providers*, which suggested that over half of psychologists engage in collaboration with at least four different healthcare professionals: 60% of psychologists reported collaboration with physicians and surgeons, 50% reported collaboration with nurse practitioners, and 45% reported collaboration with nurses. Moreover, the survey found that approximately 24% of psychologists in the United States identified their primary work setting to be in a hospital setting or organized human service settings (American Psychological Association, 2015).

In 2016, the US-based Interprofessional Education Collaborative, which is inclusive of 60 health professional fields, identified four fundamental domains and competencies that aim to promote interprofessional collaboration in order to improve individual and population health outcomes:

1. *Values/Ethics for Interprofessional Practice:* Work with individuals of other professions to maintain a climate of mutual respect and shared values.
2. *Clarity around Roles/Responsibilities:* Use the knowledge of one's own role and those of other professions to appropriately assess and address the health care needs of patients and to promote and advance the health of populations.
3. *Interprofessional Communication*: Communicate with patients, families, communities, and professionals in healthcare.
4. *Engage in Teams and Teamwork*: Apply relationship-building values and the principles of team dynamics to perform effectively in different team roles to plan, deliver, and evaluate patient/population-centered care and population health programs and policies that are safe, timely, efficient, effective, and equitable. With the increase in team-based interprofessional healthcare, psychologists' skills are well matched to facilitate and deliver the core competencies across healthcare settings and disciplines (Interprofessional Education Collaborative, 2016).

The expanding role of psychologists within the healthcare systems demands standards of practice and guidelines for the integration of behavioral health. However, there remain limited resources for using a common set of competencies in the integration of behavioral health into integrated care. To address this gap, the Substance Abuse and Mental Health Services Administration and the Health Resources and Services Administration Center for Integrated Health Solutions (CIHS) developed the *Core Competencies for Integrated Behavioral Health and Primary Care* as a resource for integrated practice relevant to behavioral health and primary care providers (Hoge et al., 2014). CIHS seeks to advocate for the advancement in the treatment of patients with mental health and substance use issues in either integrated primary or behavioral health settings. Published in January 2014, the *Core Competencies for Integrated Behavioral Health and Primary* serves as a resource for educators in curriculum development and training in integrated care using the following competencies: (a) interpersonal communication, (b) collaboration and teamwork, (c) screening and assessment, (d) care planning and care coordination, (e) intervention, (f) cultural competence and adaptation, (g) systems-oriented practice, (h) practice-based learning and quality improvement, and (i) informatics. This framework serves as an opportunity to unite all health providers under a shared mission and values.

Behavioral anchors allow the educator to identify specific educational topics and medical knowledge to address in curriculum development. The Institute of Medicine (IOM) identified a lack of educational resources to identify relevant behavioral and social science curriculum content, instructional strategies, and educational research in undergraduate medical education (Institute of Medicine [US] Committee on Behavioral and Social Sciences in Medical School. Curricula, 2004). Thus, IOM identified 26 educational topics in the following 6 behavioral and social science knowledge domains in *Improving Medical Education: Enhancing the Behavioral and Social Science Content of Medical School Curricula*: (a) mind–body interactions in health and disease, (b) patient behavior, (c) physician role and behavior, (d) physician–patient interaction, (e) social and cultural issues in healthcare, and (f) health policy and economics. The use of behavioral anchors (or short-term objectives) will lead to an increase in positive outcomes in obtaining long-term training goals (achieve core competencies).

The use of a comprehensive behavioral and social science curriculum and core competencies in the education and training of non-psychologists serves an opportunity to highlight the psychologist's expertise. The additional role as an educator within healthcare will demonstrate the utility of a psychologist in the education and training of non-psychologists in integrated care. Education and training to further one's competency in behavioral and social science curriculum development and interprofessional education exists in various medical specialty areas and health psychology.

Conclusion

The ever-changing culture of healthcare has contributed to an evolving role of psychologists in medicine. Psychologists historically have served a dual role within healthcare systems providing clinical education and training and psychological services. The current emphasis of behavioral health integration in primary care has contributed to psychologists' responsibilities for integrating mental health, substance abuse, and health behavior change to meet the community's needs. Within the context of integrated care, there are resources available to help psychologists translate their psychology expertise into obtainable educational learning goals for non-psychologists, furthering the integration of psychology into medicine.

Transgender Health

DeAnna L. Mori[1,2], Colleen A. Sloan[1,2],
Heather Walton Flynn[1,3], and Claire Burgess[1,2,3]

[3]*Department of Psychiatry, Harvard Medical School, Boston, MA, USA*

Social Context

Within the past two decades, transgender lives and experiences have received more attention within sociocultural–political contexts and relatedly within healthcare. Transgender is a term used to describe people whose gender identity (sense of maleness, femaleness, or other non-binary identities) or gender expression (how one communicates their gender) differs from that typically associated with their sex assigned at birth, although not all people who have this experience will identify themselves as transgender. Regardless of how they label themselves, transgender people collectively have unique experiences and healthcare needs, which are greatly impacted by social context and issues of stigma. Stigma, defined as the shame or disgrace attached to something regarded as socially unacceptable, manifests both via negative attitudes and treatment toward transgender people and within transgender people via internalization of negative beliefs and feelings. These effects impact physical and mental health and contribute to well-documented health and healthcare disparities for transgender people. Moreover, some transgender people experience identity-specific distress (known as gender dysphoria) and may choose to alter their bodies and expressions to be more consistent with their identities, a process usually termed "transitioning" and which may also involve utilization of specific healthcare services. Of note, not all gender transitions involve medical interventions. Some transgender people may opt to socially transition by altering their gender expression and gender role to be more consistent with their self-identified gender identity. Regardless of the intervention or change employed, the goal is to reduce distress and to promote congruity with physical body and sense of self.

The Wiley Encyclopedia of Health Psychology: Volume 4: Special Issues in Health Psychology,
First Edition. General Editor: Lee M. Cohen. Volume Editor: Suzy Bird Gulliver.

Understanding of transgender stigma and associated consequences within the larger social context is necessary to fully comprehend transgender health disparities. Stigma regarding transgender identities and experiences manifests systemically, at multiple levels—within legislation, media, communities, environments of care, and via interpersonal and intrapersonal processes—and therefore is experienced as chronic and pervasive. Consequently, transgender people are at risk of experiencing a specific type of chronic stress, termed *gender minority stress* (Hendricks & Testa, 2012), an extension of *minority stress* (Meyer, 2003). Such stress increases vulnerability to health problems, which are elevated within the transgender population. The US Transgender Survey (USTS) conducted in 2015 is the largest survey of transgender people in the United States, with over 27,000 participants in all 50 states and US territories (James et al., 2016). Survey respondents endorsed experiencing mistreatment, discrimination, harassment, and violence in all areas of life including housing, employment, education, personal/family life, health and healthcare, and experiences with the criminal justice system. Moreover, results revealed transgender individuals experienced mistreatment in these areas at a higher rate than cisgender (i.e., self-identified gender is congruent sex assigned at birth) individuals. One of the most alarming findings is the high rates of violence and victimization perpetrated by family, employers/coworkers, law enforcement officials, and even healthcare providers. Relatedly, results revealed elevated rates of unemployment and homelessness and decreased rates of health insurance coverage, all of which are compounded by absence of legal protections for transgender people in many of these areas. For example, anti-discrimination policies may or may not include gender identity as a protected component of identity. Lastly, one of the most notable findings from this survey is the strikingly high rates of suicide for transgender people. While the USTS only surveys transgender people, other sources have demonstrated that these suicide rates are significantly higher than rates for cisgender people. Collectively, these findings highlight the pervasiveness of transgender stigma and its profound impact on physical and mental health and general well-being. Additionally, these disparities highlight an apparent dilemma with respect to health and healthcare—limited to no access to healthcare may lead to solicitation of care that is of poor quality (e.g., traveling surgeons, "doc in the box"), which in turn contributes to poorer health.

Access to Healthcare

Regarding healthcare in particular, specific and unique disparities have been indicated for transgender people. According to USTS, roughly one-fourth reported having experienced at least one problem with their insurance related to transgender identity, with over 50% being denied for transition-specific surgical procedures and 25% being denied for hormone therapy. Additionally, over one-third of those who sought care from a healthcare professional during the past year reported having had a negative experience including refusal of care, verbal harassment, or experience of physical or sexual assault, all of which were higher for transgender people of color and/or with disabilities. Likewise, almost one-fourth of respondents reported avoiding healthcare due to fear of mistreatment based on transgender identity, which further perpetuates health disparities. Negative experiences notwithstanding, healthcare providers often do not have adequate education and training regarding transgender health, as this area is not reliably included in medical or mental health curricula. Inadequate education and training leads to lack of knowledge and competency, which in turn can negatively impact provision of care (or lead to lack of care). For example, transgender people often use pronouns that differ from the ones typically associated with sex assigned at birth. When others refer to transgender people using incorrect pronouns, an example of "misgendering," this may communicate both a lack of knowledge and a lack of respect, both of which negatively impact provision of care and general interaction. Relatedly, healthcare facilities rarely have visual cues and/or other materials (e.g., intake forms, reading material) that depict or communicate directly to the transgender population. These types of issues contribute to concern in transgender individuals about the availability of competent and respectful care and sometimes lead to avoidance of healthcare. Collectively these factors highlight the multifaceted nature of transgender disparities within healthcare.

Health-Related Issues

Transgender individuals are at increased risk for certain types of health-related problems, diseases, and mental health problems. This is largely impacted by the issues discussed above, including but not limited to minority stress, poor access to healthcare, and lack of culturally competent providers (Makadon, Mayer, Potter, & Goldhammer, 2015). The following are key health problems for which transgender individuals are at increased risk.

Alcohol and Substance Use Disorders

Results of observational studies in the United States show that alcohol and substance use (both marijuana and illicit substances) in this population is high. A recent empirical study found that gender dysphoria was significantly associated with excessive alcohol use for transgender women, cannabis use among both transgender women and men, and illicit (non-cannabis) drug use among transgender women (Gonzalez, Gallego, & Bockting, 2017). Gender minority stressors were independently associated with excessive alcohol use among transgender men and cannabis use among transgender women, suggesting that minority stress partially accounts for the increased use. Transgender individuals should be screened for problematic alcohol and drug use and should be referred to appropriate resources for achieving recovery and learning healthy coping skills.

Cancer

There is little information on cancer outcomes for transgender people because of an absence of large-scale prospective studies investigating cancer incidence and mortality in lesbian, gay, bisexual, and transgender people. Anecdotal evidence and case reports suggest that transgender individuals' rates of cancer may be higher than that of the general population. Transgender men continue to have a risk of developing breast, ovarian, or uterine cancer if those parts of their body have not been removed. Similarly, transgender women still have a risk of prostate cancer. It is important to note that while transgender individuals should be treated and addressed according to their self-identified gender, they also need to receive screenings that align with their sex assigned at birth to detect any problems related to the anatomy with which they were born as well as any organs they have at present. These screenings may not occur because transgender individuals or their providers may not realize the need for them, because of problems with healthcare access, or due to discrimination. Having culturally competent, sensitive care available can help individuals realize the need for these screenings and address the barriers that often interfere with receiving this care.

Cardiovascular Disease

Transgender persons are often at higher risk for heart disease. Several factors may contribute to this disparity, including higher rates of tobacco use, obesity, and reduced physical activity. Transgender individuals should be encouraged to follow up with routine physical exams that include blood pressure and cholesterol checks and to engage in healthy behaviors that can protect against cardiovascular disease. Due to the increased risk, transgender individuals also should be educated about the signs and symptoms of heart disease and stroke.

Depression and Suicidality

Transgender individuals have higher rates of depression and anxiety compared with cisgender individuals, including an increased risk for suicide. These problems can be exacerbated in those who lack social support or feel unable to "come out" and express their gender identity. Transgender individuals should be screened for depression and suicidality and referred for treatment. Untreated depression can also interfere with engagement in healthy behaviors and medical care, which further contributes to the development of health problems and medical illness.

Sexually Transmitted Infections (STIs)

Transgender individuals, especially women of color, are at high risk for sexually transmitted infections (STIs), including those for which there are effective cures (e.g., chlamydia, gonorrhea, pubic lice, or syphilis), as well as those for which treatments are more limited (e.g., hepatitis, HIV, human papillomavirus). This risk may be related, in part, to higher rates of alcohol and drug use. In addition, given the high rates of homelessness and unemployment, transgender individuals are more likely to support themselves by engaging in underground economy activities, such as sex work, which increases risk for STIs. Transgender individuals who are sexually active should be encouraged to be screened for sexually transmitted diseases.

Smoking/Tobacco Use

The limited information that exists regarding transgender individuals and tobacco use suggests that transgender adults smoke cigarettes and use tobacco products at a higher rate than the general population of adults. Transgender individuals should be screened for tobacco use and offered tobacco cessation treatment or resources. Identification of factors that contribute to tobacco use (e.g., depression, minority stress) and treatment to address the underlying stressors may help reduce tobacco use in this population.

Weight

Although the data regarding transgender individuals' weight and exercise habits are limited, current findings suggest that transgender individuals are more likely to be either underweight or obese compared with cisgender individuals. Obesity may be impacted by other co-occurring risk factors, such as depression and minority stress. On the other end of the spectrum, a subset of the transgender population may be underweight in an attempt to achieve a body type that is more consistent with their gender identity. Transgender individuals may benefit from providers approaching discussions about their weight in a manner that is supportive and affirming of gender identity while also promoting the importance of healthy diet and exercise.

Transition-Related Health Issues

In addition to being at disproportionately high risk for the health issues described above, some transgender individuals experience health-related issues related to medical treatments for gender dysphoria or discomfort or distress that is caused by a discrepancy between a person's gender identity and sex assigned at birth (Coleman et al., 2012). A range of medical treatment options are available that can help individuals move toward achieving changes that are more consistent with their self-identity and reduce or alleviate their gender dysphoria (Coleman et al., 2012). These treatments range from hormone therapy and hair removal to a number of surgical interventions that include feminizing procedures such as vaginoplasty, breast augmentation, or facial alteration or masculinizing procedures that include phalloplasty, scrotoplasty, metoidioplasty, chest surgery, or liposuction. Transgender people make highly individual decisions about which procedures or steps to pursue to achieve their gender transition needs. Some individuals do not pursue any medical interventions, while there are others who may pursue many.

The World Professional Association for Transgender Health (WPATH) is a multidisciplinary organization whose mission is to "promote evidence-based care, education, research, advocacy, public policy, and respect for transgender health" (Coleman et al., 2012). Consistent with this mission, the WPATH draws from current research and expert opinions to develop *Standards of Care (SOC) for the Health of Transsexual, Transgender, and Gender Nonconforming People* (Coleman et al., 2012). Importantly, the WPATH has determined that medical treatments, including hormones and surgical interventions, are medically necessary to treat gender dysphoria in many people.

There are many health-related implications of these treatments that must be considered. It is important to ensure that individuals who are pursuing these medically necessary treatments for gender dysphoria are well informed about the procedure and course of treatment, have a good understanding of the associated risks, have realistic expectations regarding outcomes, and have the ability to adhere to their medical regimen In addition, given the individualized and complex nature of each person's treatment plan, having a good working relationship with an interdisciplinary, culturally competent team of providers can help transgender individuals achieve their treatment goals while prioritizing their overall health and well-being, thus enhancing outcomes.

Hormone Therapy

Gender-affirming hormone therapy is a commonly sought medical intervention, and it allows individuals to develop secondary sex characteristics that are more with consistent with their gender identity and can help to minimize some characteristics that are associated with sex assigned at birth.

There are a number of risk factors associated with hormone use. For feminizing hormones, the most prominent side effects are venous thromboembolic disease, gallstones, elevated liver enzymes, weight gain, and hypertriglyceridemia. There is also a risk of cardiovascular disease, particularly in the presence of other risk factors. For masculinizing hormones, the most significant side effects are polycythemia, weight gain, acne, balding, and sleep apnea. Promoting healthy behaviors and good medical adherence can help to minimize some of these risks. Some individuals may also be reluctant to report side effects if they are concerned that they will be taken off of hormones. As noted above, having a trusting relationship with a culturally competent provider who promotes open communication can help minimize this risk.

Surgical Procedures

While many transgender and gender-nonconforming individuals do not desire or pursue surgical interventions, for many others, the modification of their primary and/or secondary sex characteristics is medically necessary to address their gender dysphoria. As many of these surgical interventions are irreversible, surgeons often require careful decision making. While a mental health evaluation is not always required to initiate hormone treatment, the WPATH recommends that an appropriate mental health assessment is conducted prior to genital and chest surgeries, and criteria for each different surgical intervention are provided in the SOC. For all procedures, evidence of persistent gender dysphoria is recommended, and for some surgeries, criteria include being on hormone therapy (unless medically contraindicated) and living in the gender role that is consistent with their gender identity for a specified period of time.

Unregulated Treatments

Some individuals who are not able to obtain gender-affirming medical treatments by qualified providers or those who are worried that they will not meet criteria may attempt to obtain treatments in an unregulated manner. For example, these individuals may buy hormones without a prescription from pharmacies online or from other unregulated sources without appropriate medical oversight. There are multiple risks associated with this approach: the hormones purchased may be unsafe or counterfeit, and use of hormones without appropriate medical monitoring could lead to health-related issues that go undetected or untreated.

Injectable silicone is another treatment that is sometimes pursued by transgender women who want to achieve feminizing body changes rapidly. While injectable silicone can be used safely when administered by a trained healthcare professional for more minor enhancements, it can be dangerous and potentially lethal when used by unqualified individuals. The FDA warns against the use of silicone for larger-scale body contouring, which includes injecting large quantities of silicone in hopes of quickly achieving a more feminine body type. When silicone is obtained through unregulated methods, there is also the risk that the silicone used is contaminated or not FDA approved. Ideally, individuals should only receive care from qualified licensed providers and be skeptical if the treatments are offered in nonmedical settings (e.g., private homes or hotel rooms).

Transgender individuals may opt to travel long distances, even overseas, to obtain gender-affirming surgeries. While cost and other barriers to care may drive these decisions, it is important that individuals understand the medical, psychological, and legal risks associated with traveling out of country to obtain care. Facilities may have varying quality of care, their promotional claims may be unregulated, and it can be difficult to assess outcomes from some of these facilities. For continuity of care and to maximize positive outcomes, it is important that individuals return with a comprehensive postoperative plan and treatment providers whom they can enlist to provide follow-up care. Facilitating communication between providers and facilities (e.g., carrying medical records in both directions) may also allow for smoother transition of care.

Future Directions

In order to promote health and enhance care for transgender people, a number of actions can be taken. Most vital to this effort is for healthcare providers to be educated about best practices to ensure well-informed and culturally competent care. The importance of competence in provision of care is highlighted by the finding that more than 70% of psychology graduate students and psychologists reported unfamiliarity with transgender patients' experiences (American Psychological Association Task Force on Gender Identity and Gender Variance, 2009). To address this need, the American Psychological Association (APA) Council of Representatives on the Resolution on Transgender, Gender Identity, and Gender Expression Non-Discrimination called upon psychologists to provide appropriate nondiscriminatory treatment and to take an active role in leading work against discrimination toward transgender individuals.

WPATH is a leader in providing evidence-based standards of care that can be used as a guiding resource for both providers and patients, providing comprehensive recommendations for transgender health considerations. In addition, the APA has published *Guidelines for Psychological Practice with Transgender and Gender Nonconforming People* (APA, 2015), which were written in accordance with Endocrine Society and WPATH guidelines. These guidelines were developed with the purpose of promoting culturally competent, developmentally appropriate, and trans-affirmative care.

Healthcare systems can also enhance care for transgender individuals by ensuring that affirmative standards of care are mandated. Large healthcare systems can also receive certification through the Human Rights Campaign on the Healthcare Equality Index (HEI) if they demonstrate that they are competent to provide transgender care and promote affirmative workplace practices.

Although there is increasing awareness of the health issues that transgender individuals experience, the research is at a nascent stage. While there has been debate about the inclusion of transgender individuals and their health needs in broad-based surveys, it is notable that Healthy People 2020, the national health promotion goals set by the US Department of Health and Human Services, recommended an increase in the number of surveys that collect information on transgender health outcomes. The number of national representative surveys of transgender individuals has remained unchanged since 2008. Furthermore, much of the transgender health research has been based on convenience samples that do not necessarily represent the diversity of the transgender population within the United States (APA, 2015). Future studies using broader representative samples will provide a more complete understanding of the health-related issues and experiences of the transgender population.

In order to advance knowledge about healthcare needs of the transgender population, research funding by governmental and other large mechanisms is critical. In the United States, NIH funding of research dedicated to transgender health outcomes has historically been low: less than .04% of NIH funding from 1989 to 2011 (Coulter, Kenst, Bowen, & Scout, 2014).

Broad-based surveys that identify the healthcare needs and barriers to treatment of the transgender population can be used to highlight the necessity of greater funding to address the healthcare needs and disparities of this marginalized population.

Veterans' Health Issues

Cynthia J. Willmon

Reno VA Sierra Nevada Health Care System, Reno, NV, USA

Military Background Information

In order to understand issues concerning veterans, it may be helpful to briefly review contextual information pertaining to the military. In the United States, there are five active duty branches of the military or armed forces: the Army, the Navy, the Air Force, the Marine Corps, and the Coast Guard (US Military, 2017). Each branch has its own specified focus areas and eligibility requirements. Additionally, a person can join the military as an enlisted member or as an officer, depending upon one's experience and qualifications, and the person is typically employed full time with one's branch for a specified time period. It is likely that the differences in stated missions and cultures of the branches factor into which branch a person chooses to join along with other motivations for being in the armed forces (e.g., family legacy, to see the world, get away from home, avoid legal problems, path to citizenship, etc.). There are also National Guard and Reserve units connected to the military branches, and individuals who choose to go into the guard or reserves typically have civilian jobs, and they may be called into active duty military service if needed. Moreover, a person's military experience can often include initiation into the military (i.e., boot camps, basic training), specialized training in one or more occupations, multiple duty station assignments, and possible deployments to different countries or combat zones. How one leaves the military also matters and the type of military discharge a person receives can impact if he or she receives post-military benefits or services, such as qualifying for care through the Department of Veterans Affairs (VA) (Szymendera, 2016).

Definition of Veteran and Other Demographic Information

To a layperson, a veteran can generally be defined as a person who served in the military. According to national statute, a veteran is defined as a "person who served in the active

First Edition. General Editor: Lee M. Cohen. Volume Editor: Suzy Bird Gulliver.

military, naval, or air service, and who was discharged or released therefrom under conditions other than dishonorable" (Szymendera, 2016, p. 1). Additionally, to qualify to receive VA benefits, a veteran must meet specific criteria, including having been in active service, meet minimum length of service requirements (especially if one joined the military on or after September 8, 1980), and not have had a dishonorable discharge (Szymendera, 2016). Veterans represent a small percentage of the US population. In 2014, it was estimated that there were 251.4 million adults ages 17 and above living in the United States and Puerto Rico and 19.4 million of these adults were identified as being veterans (US Department of Veteran Affairs, National Center for Veterans Analysis and Statistics [NCVAS], 2016). The vast majority of veterans are male, with only about 1.6 million of the 19.4 million veterans being female (NCVAS, 2016).

Veterans' Health Issues

Veterans face unique health concerns based upon their military experiences. Some of these concerns may be associated with events occurring during the era in which a person served (Fontana & Rosenheck, 2008; Olenick, Flowers, & Diaz, 2015), and these concerns often include a combination of mental and physical health problems (Frayne et al., 2010; Fredricks & Nakazawa, 2015; Olenick et al., 2015; Spelman, Hunt, Seal, & Burgo-Black, 2012). Additionally, although a significant number of veterans qualify to receive healthcare from a VA facility, veterans do seek out healthcare services through the community or private sector (Fredricks & Nakazawa, 2015; Olenick et al., 2015; Taylor et al., 2012), and it is important for VA and non-VA providers alike to be aware of issues that may be common or prevalent in the veteran population (Spelman et al., 2012).

Chronic Pain

Pain is a common presenting problem for people seeking medical care (Kaur, Stechuchak, Coffman, Allen, & Bastian, 2007; Kerns, Otis, Rosenberg, & Reid, 2003), and this finding is consistent in the veteran population. Research in a primary care setting found that 48% of veterans reported having pain on a regular basis, and these veterans rated their health during the past year as being significantly worse than those who had no pain (Kerns et al., 2003). Additionally, chronic pain can be defined as pain that persists after the amount of time it takes for one's body to heal from an acute injury (Kaur et al., 2007), and 90% of veterans in a primary care setting had pain conditions lasting longer than 6 months (Reid, Crone, Otis, & Kerns, 2002). Some of the most common chronic pain conditions found within the veteran population include joint pain, back pain, headaches, abdominal pain, and limb pain (Kaur et al., 2007), and the prevalence of low back pain in veterans increased about 5% annually from 2000 to 2007 (Sinnott & Wagner, 2009).

Age and gender differences have been found with regard to chronic pain. In a study comparing pain experiences in younger veterans (i.e., ages 64 and below) vs. older veterans (i.e., ages 65 and above), significant differences were found pertaining to the location of the worst experienced pain (Reid et al., 2002). Specifically, 32% of younger veterans experienced the most discomfort from low back pain, whereas 32% of older veterans identified leg pain as being the most uncomfortable. This study also found that older veterans report experiencing more consistent or constant pain, whereas younger veterans rated their intermittent pain levels as being more intense. Additionally, gender differences in chronic pain exist. Specifically, female veterans experience significantly more headaches, abdominal pain, and limb pain than males, while male veterans have higher rates of back and joint pain than females (Kaur et al., 2007). Female veterans with chronic pain also have higher rates of comorbid mental health conditions than male veterans (Kaur et al., 2007).

Problems with physical, emotional, and other functioning are associated with chronic pain (Kerns, Sellinger, & Goodin, 2011). A significant number of veterans were found to be service-connected for pain-related conditions (Reid et al., 2002), and one of the requirements for VA service connection includes significant impairment in physical, occupational, or social functioning. Chronic pain was also found to be associated with reductions in veterans' performance of their roles at home and at work (Helmer et al., 2009). Additionally, veterans experiencing pain attend more outpatient medical appointments than veterans without pain (Kerns et al., 2003), and women veterans with chronic pain attended a higher number of medical visits than male veterans with chronic pain (Kaur et al., 2007). Moreover, high comorbidities have been found between chronic pain and multiple mental health disorders, including depression and posttraumatic stress disorder (PTSD) (Helmer et al., 2009; Kaur et al., 2007; Otis, Keane, & Kerns, 2003). Having a mental health diagnosis was associated with veterans' higher attendance of medical appointments for pain concerns, and these were especially true for veterans diagnosed with chronic pain and depression or PTSD (Kaur et al., 2007). Another group of researchers cited a study that found about 10% of veterans referred to a pain clinic had symptoms consistent with PTSD, and these researchers hypothesized that the comorbidity of chronic pain and PTSD is likely higher than this, especially in cases where one's pain is associated with one's experience of trauma (Otis et al., 2003). Furthermore, a recent study of OEF/OIF veterans (i.e., veterans who were deployed to Iraq and Afghanistan) in a VA polytrauma clinic found that about 72% of the sample met criteria for PTSD, about 88% experienced significant pain, and 65% had comorbid PTSD and pain (Lang, Veazey-Morris, Berlin, & Andrasik, 2016). This study found that diagnosis was related to healthcare utilization, with veterans with PTSD symptoms participating in significantly higher numbers of both mental and medical healthcare visits, while veterans with significant pain had high rates of attendance of medical appointments. Finally, associations were hypothesized between substance use and chronic pain. Specifically, veterans who experience regular pain have higher rates of tobacco use than veterans without pain (Kerns et al., 2003), and this could lead to the exacerbation of other health problems. Interestingly enough, the presence of pain was not found to be related to excessive alcohol use (Kerns et al., 2003) or alcohol misuse (Helmer et al., 2009).

Numerous recommendations have been made about how best to approach treatment with veterans who experience pain. Specifically, treatment should include a thorough assessment of one's pain, psychological assessments for all reporting pain, and the use of integrative interventions (Kerns et al., 2003). Integrative approaches can include a combination of treatments, including pharmacology, behavioral interventions, and complementary or alternative treatments (Spelman et al., 2012). Additionally, psychological treatments of pain may include self-regulatory approaches (e.g., biofeedback, relaxation training, hypnotherapy, or mindfulness), behavioral approaches (e.g., operant behavioral therapy or fear avoidance), cognitive behavioral therapy, or acceptance and commitment therapy. Finally, veterans with comorbid mental health diagnoses may benefit from participation in mental health services in additional to pain-focused treatments.

Sleep Problems

Disturbed sleep is an important area for consideration when working with veterans. The prevalence of problems related to sleepiness, snoring, and risk for sleep apnea is higher in veterans compared with those for nonveteran populations (Mustafa, Erokwu, Ebose, & Strohl, 2005). Specifically, 50% of veterans in a primary care setting reported problems with falling asleep, staying asleep, or sleeping too much during the past year, while 35% reported insomnia during the past week (Shepardson, Funderburk, Pigeon, & Maisto, 2014). In a different primary care study using different sleep measures, 40% of veterans reported symptoms consistent with a diagnosis of insomnia (Mustafa et al., 2005). High rates of sleep apnea have also been found, with 76% of veterans referred to a specialty sleep clinic for possible sleep problems being diagnosed with obstructive sleep apnea and 47% of those with this disorder had severe sleep apnea (Samson, Casey, Knepler, & Panos, 2012). Veterans also report receiving insufficient sleep more often than nonveterans, and they are more likely to get less than 7 hr of sleep each night (Faestel, Littell, Vitiello, Forsberg, & Littman, 2013). Additionally, OEF/OIF veterans with and without mental health diagnoses were found to experience significantly more sleep impairments, nightmares, and distressing dreams than nonveterans (Ulmer, Van Voorhees, Germain, Voils, & Beckham, 2015).

Sleep problems are associated with problems with health and functioning. Insufficient sleep in veterans was found to be significantly related to factors, including younger age, lower income, inability to work, frequent mental distress, current tobacco use, and binge-drinking behaviors (Faestel et al., 2013). Similarly, veterans who reported sleeping 5 hr or less per night had higher rates of PTSD, major depressive disorder (MDD), panic disorder, and risky health behaviors, including drug misuse, alcohol misuse, and suicidal ideation, than veterans sleeping between 7 and 8 hr per night (Swinkels, Ulmer, Beckham, Buse, & Calhoun, 2013). High rates of comorbidities exist between insomnia and other disorders, including depression, anxiety, PTSD, chronic pain, and traumatic brain injury (TBI) (Bramoweth & Germain, 2013). Sleep disturbance may also play a role in completed suicides in veteran populations (Pigeon, Britton, Ilgen, Chapman, & Conner, 2012). Additionally, insomnia has been found to be related to increased severity of PTSD and depressive symptoms in combat veterans, and insomnia can be viewed as a chronic condition, especially since insomnia symptoms in these veterans persisted over time, even after reductions in PTSD and depressive symptoms occurred (Pigeon, Campbell, Possemato, & Ouimette, 2013). Moreover, veterans who do not have diagnosable mental health problems were found to experience poorer sleep quality, shorter sleep duration, and more severe insomnia than nonveterans (Ulmer et al., 2015). Finally, veterans identified as sleeping too much (i.e., sleeping 9 hr per night or more) had higher rates of PTSD and MDD diagnoses and increased tobacco use than those identified as being average sleepers (Swinkels et al., 2013).

Given the prevalence of sleep problems in the veteran population, the following treatment recommendations are suggested. Assessment of sleep problems in primary care settings is recommended (Mustafa, 2015), and it is important to address sleep problems with all veterans with and without mental health diagnoses (Ulmer et al., 2015). Additionally, insufficient sleep and insomnia should be viewed as chronic conditions deserving of clinical attention, assessment, and referral for appropriate treatment (Faestel et al., 2013), and assessing for sleep duration (especially in regard to getting too little or too much sleep) could help identify other potential comorbid mental health conditions or risky health behaviors (Swinkels et al., 2013). Veterans can also be referred to specialty sleep clinics for further diagnostic testing if warranted. Moreover, the use of sleep-focused cognitive behavioral treatments and the medication prazosin have resulted in significant reductions in sleep complaints, including insomnia (Trockel, Karlin, Taylor, & Manber, 2014) and frequency of nightmares (Germain et al., 2012). Furthermore, Shepardson et al. (2014) researched veterans' treatment preferences for insomnia and veterans identified trying to deal with sleep problems on their own or talking to their primary care provider about their problems as being their preferred treatment methods. Veterans were less likely to want to meet with a behavioral health provider or be prescribed a sleeping medication. Finally, veterans expressed a preference for individualized treatment as opposed to participation in group treatments for sleep problems (Shepardson et al., 2014).

Traumatic Brain Injuries

TBI within the veteran population has been a focus of attention in recent years. Aspects of military service including training situations and deployment to combat zones place veterans at risk for TBI (King & Wray, 2012), and blast-related TBIs may be unique to combat service, especially when exposed to improvised explosive devices (IEDS) (Elder, 2015). Additionally, OEF/OIF veterans are more likely to survive events causing TBIs due to improvements in military protective gear than veterans serving in previous conflicts (Vasterling, Verfaellie, & Sullivan, 2009), and it has been estimated that 20% of OEF/OIF veterans have experienced a TBI (Tanielian & Jaycox, 2008). Rates of deployment-related TBIs have also been found to be similar between male and female veterans (Iverson et al., 2011). Moreover, TBIs vary in level of severity from mild to severe (King & Wray, 2012). Morissette et al. (2011) cited that about 77% of the TBIs identified in a military sample were rated as being mild, and mild TBIs (mTBIs) often go undetected when they occur (Elder, 2015). Various symptoms (e.g., headaches, dizziness, irritability, disturbed sleep, concentration problems, light sensitivity, etc.) may develop following an mTBI, and these symptoms typically resolve within a few months for the vast majority of people (King & Wray, 2012). However, a recent study of OEF/OIF veterans with a history of TBI found that 85% experienced post-concussive symptoms (including headaches, balance problems, and/or memory problems) persistently longer than expected for an mTBI, and these symptoms likely result in ongoing problems in social and occupational functioning (Morissette et al., 2011). Female OEF/OIF veterans also had more severe somatosensory (e.g., pain, headaches, nausea), cognitive (e.g., poor concentration, decision-making problems, forgetting), and vestibular (e.g., loss of balance, dizziness, and coordination problems) symptoms than male veterans (Iverson et al., 2011).

Furthermore, TBI appears to be related to emotional and cognitive problems. A review of research found that veterans with a past history of TBI are at higher risk of attempting and completing suicide (King & Wray, 2012). Comorbidities have also been found between TBI and mental health problems, including depression and PTSD (Elder, 2015; King & Wray, 2012). Researchers note that there has been some difficulty determining comorbidity rates of TBI and PTSD due to overlap in diagnostic criteria and post-concussive symptoms, although one study found that about 44% of soldiers had both mTBI and PTSD (King & Wray, 2012), whereas another study found 75% had both disorders (King, Wade, & Wray, 2013). Additionally, there are gender differences in prevalence rates of veterans with TBI and other comorbid mental health disorders (Iverson et al., 2011). Specifically, female veterans had higher rates of diagnoses of depression, anxiety disorders, and comorbid depression and PTSD. Male veterans were more likely to be diagnosed with PTSD and substance use disorders. Moreover, moderate and severe TBIs have been associated with chronic cognitive problems, and veterans with a history of these TBIs may be at risk for developing dementia and chronic traumatic encephalopathy (Elder, 2015). Finally, veterans with a history of TBI were found to utilize healthcare more frequently, and they were more likely to be referred for specialty care than those with no TBI (King et al., 2013). Veterans also attended significantly more behavioral health appointments if they had both TBI and PTSD than if they were diagnosed with only PTSD or only TBI.

King and Wray (2012) offer multiple treatment recommendations for providers seeing veterans with a history of TBI, especially in primary care settings. Specifically, they encourage all veterans to be screened for TBI, and a current assessment of a veterans' current cognitive, emotional, and somatic symptoms be done. They also recommend that veterans be informed about the likely course and recovery of symptoms associated with TBI and about other factors that could impact their symptoms, such as comorbid mental or physical health problems. Moreover, King and Wray (2012) suggest veterans be encouraged to develop coping skills, avoid future brain injuries if possible, and be referred for specialty care when needed (such as cognitive rehabilitation, polytrauma, mental health services, substance use programs, and pain clinics).

Posttraumatic Stress Disorder (PTSD)

PTSD is a mental health disorder that is often associated with veterans, and PTSD is believed to be more common in veteran than nonveteran populations. Recent studies estimate the lifetime prevalence rate of PTSD in veteran populations is between 6.3 and 8% (Smith, Goldstein, & Grant, 2016; Wisco et al., 2014), and it is estimated that 5% of veterans likely have current PTSD (Wisco et al., 2014). Lifetime prevalence rates have also been found to be significantly higher in female veterans and in younger veterans (especially those under the age of 30; Smith, Goldstein, et al., 2016; Wisco et al., 2014). Additionally, the majority of veterans experience at least one traumatic event during their lifetimes, and the most common traumatic events reported were death of a close friend or family member (61.3%), witnessing a sudden death or bad injury (37.7%), combat exposure (34.3%), and natural disasters (33.9%; Wisco et al., 2014). A recent study found that about 86% of OEF/OIF veterans were exposed to a life-threatening event during their recent deployment (Asnaani, Reddy, & Shea, 2014). Lifetime prevalence rates for PTSD were high for veterans who were sexually abused as an adult (37.3%), had heavy combat exposure (34.9%), or reported sexual abuse as a child (25.9%) (Wisco et al., 2014).

PTSD within the veteran population has been associated with numerous problems. Veterans with reexperiencing symptoms have been found to have more problems with pain and physical health functioning, while those with hyperarousal symptoms have lower energy and poorer reports of mental well-being (Asnaani et al., 2014). Trauma exposure and PTSD symptoms also were associated with poorer physical health in women veterans (Smith, Tyzik, & Iverson, 2015). Additionally, sleep problems are common in veterans with PTSD. A recent study found that 76% of recent combat veterans with PTSD have persistent insomnia, while more than half of these veterans report having distressing nightmares (Pigeon et al., 2013). This study also found that veterans with insomnia had more severe symptoms of PTSD and depression than those without, and the insomnia symptoms tended to persist, even after PTSD and depressive symptoms reduced or resolved. Moreover, exacerbation of PTSD symptoms has been found to occur in about 10% of veterans as they age, and this may be due to exposure to a greater number of traumas, increased cognitive difficulties, loneliness, lower social support, and increased stress (Mota et al., 2016). Lifetime prevalence of PTSD also was associated with current suicidal ideation and past history of suicide attempts (Wisco et al., 2014). Finally, veterans with PTSD often have other comorbid mental health problems, including depressive disorders (e.g., MDD, dysthymia, etc.), anxiety disorders, substance use disorders, and personality disorders (Smith, Goldstein, et al., 2016; Vojvoda, Stefanovics, & Rosenheck, 2014; Wisco et al., 2014).

Given the increased prevalence of PTSD in veteran populations, it may be helpful for providers to regularly assess for PTSD when working with veterans. Additionally, PTSD can develop in response to numerous different types of trauma, with sexual assault and heavy combat exposure being the most common. Some of the most effective evidence-based treatments for PTSD include prolonged exposure (PE) and cognitive processing therapy (CPT) (Hamblen, Schnurr, Rosenberg, & Eftekhari, 2017). In addition, treatments to enhance coping skills and/or other identified problems, such as anger, pain, and physical health concerns, may be beneficial, and referral for appropriate medical care may be warranted. Moreover, insomnia was found to persist, even after PTSD symptoms resolve (Pigeon et al., 2013), and referral for insomnia treatment is likely appropriate. Finally, veterans should continue to be assessed for PTSD over time, given that about 10% experience an exacerbation in symptoms as they age.

Military Sexual Trauma (MST)

Military sexual trauma (MST) refers to threatening sexual harassment or sexual assault that occurred while an individual is in the military (US Department of Veterans Affairs, 2004). MST can include unwanted sexual attention (e.g., touching, sexual comments, cornering, or pressure for sexual favors) or being threatened with the use of force and/or actually being forced into sexual contact without consent (Klingensmith, Tsai, Mota, Southwick, & Pietrzak, 2014). In a brief review of the literature, Suris et al. (2013) reported that about 20% of female veterans and 1% of male veterans receiving care in the VA healthcare system experienced MST, and these rates are similar to the lifetime prevalence rates of sexual assault in nonveteran populations. Of note, MST only occurs during the time one is in the military as opposed to across one's lifetime, which suggests individuals in the military are at an increased risk for sexual assault compared with civilians (Klingensmith et al., 2014; Suris et al., 2013). Additionally, a recent national survey study found that approximately 7.6% of US veterans likely experienced MST, with female veterans having higher rates (32.4%) than male veterans (4.8%; Klingensmith et al., 2014). Another interesting finding is that the number of male and female veterans experiencing MST is actually pretty similar; however, MST impacts a larger percentage of female veterans given that the military is predominantly male.

MST has been associated with numerous problems within the veteran population. While both men and women can experience MST, the majority of research has focused on female veterans with MST, and it is believed that men and women experience similar mental health outcomes related to sexual assault (Suris & Lind, 2008). Specifically, MST is linked to increased mental health problems, including PTSD, depression, generalized anxiety, social phobia, eating disorders, and substance use disorders (Klingensmith et al., 2014; Pavao et al., 2013; Suris & Lind, 2008). One study of female veterans found that 76% of the women who met criteria for PTSD experienced MST (Kintzle et al., 2015), whereas a different study found that male veterans with MST were more likely to have mood disorders than those without MST (Mondragon et al., 2015). MST also has been linked to worse quality of life, poorer emotional and cognitive functioning, increased risks for current suicidal ideation and history of suicide attempts, and interpersonal difficulties (Klingensmith et al., 2014; Mondragon et al., 2015). Additionally, reviews of the research literature indicate that MST is associated with physical health problems, including cardiovascular disease, pain, genitourinary conditions, gastrointestinal problems, headaches, fatigue, and chronic pulmonary and liver disease (Suris et al., 2013; Suris & Lind, 2008). Finally, high rates of MST have been found in both female and male homeless veterans (Pavao et al., 2013).

It has been recommended that all female and male veterans be assessed for MST (Klingensmith et al., 2014). Identifying individuals with MST and getting them engaged in appropriate care in a timely manner is important (Suris et al., 2013). Additionally, the vast majority of veterans do not seek treatment immediately after their MST experience; however, these individuals tend to utilize higher rates of healthcare services (including mental health services) presently, which demonstrates the ongoing impact MST may have on their lives (Kintzle et al., 2015; Klingensmith et al., 2014; Pavao et al., 2013). Moreover, educating veterans about the availability of treatment for problems associated with their MST is important, and veterans and non-VA providers alike may not be aware that mental and medical care associated with MST experiences is free at VA facilities (Suris et al., 2013). Finally, providing veterans with MST with integrated clinical care is important, given the mental, physical, and cognitive difficulties often associated with MST (Klingensmith et al., 2014).

Suicide

Suicide is a problem found in both veteran and civilian populations. Recent estimates indicate that 20 US veterans commit suicide each day (Shane & Kime, 2016), and the research literature is unclear about whether the prevalence of suicide in veterans is higher than that found in the American nonveteran population (Katz, McCarthy, Ignacio, & Kemp, 2012). Suicidal ideation is likely associated with suicide attempts. A national cohort study found that about 10% of veterans reported suicidal ideation within the past 2 weeks, and it also found that rates of suicidal ideation vary over time (Smith, Mota, et al., 2016). Specifically, about 5% of veterans experienced chronic suicidal ideation over a 2-year period, about 4% of veterans no longer had suicidal ideation after 2 years, and about 5% of veterans developed suicidal ideation over this time period. Additionally, a recent study found that about 9% of veterans in primary care setting have suicidal ideation (Magruder, Yeager, & Brawman-Mintzer, 2012), and increased suicidal ideation was associated with deployment-related TBI, mental health diagnoses (e.g., depression, PTSD, generalized anxiety disorder, and substance use disorders), head and musculoskeletal pain, and poorer physical, psychological, and social functioning (Gradus et al., 2015; Magruder et al., 2012; Smith, Goldstein, et al., 2016). Psychiatric distress and physical health problems were associated with the development and chronicity of suicidal ideation (Smith, Goldstein, et al., 2016), and pain-related functioning played a more significant role in suicidal thoughts than pain severity (Magruder et al., 2012). A qualitative study of OEF/OIF veterans also found suicidal ideation to be associated with aspects of military culture, difficult deployment experiences, and challenges adjusting to life after deployment (Denneson et al., 2014).

Multiple studies have been conducted examining people who completed suicide to better understand factors that may have contributed to these deaths, including veteran status, gender, age, presence of psychiatric symptoms, and healthcare utilization. The majority of veteran suicides are via firearms (Kaplan, McFarland, Huguet, & Valenstein, 2012), and suicide rates for male veterans are significantly higher than for female veterans (Katz et al., 2012). Male veterans age 64 and younger were found to have a higher risk of suicide than nonveterans (Kaplan et al., 2012). Age differences were also found in veterans who completed suicide (Kaplan et al., 2012). Specifically, younger male veterans had more occupational, financial, legal, and intimate relationship problems prior to their deaths, they had a higher number of past suicide attempts, and they were more likely to be intoxicated at their time of death compared with older veterans. Male veterans age 65 and older had more health problems, and they also had higher rates of firearm-related suicides than younger veterans (83.5 vs. 61%; Kaplan et al., 2012).

Suicide rates were also found to differ in veterans based on their healthcare utilization. Katz et al. (2012) found that suicide rates were higher for male veterans who utilized care through the VA than those who did not, and it was hypothesized that this may be due to VA users having more problems resulting in them being at increased risk for suicide. However, a decline in suicide rates from 2005 to 2008 was found for male veterans under the age of 30 who utilized VA care compared with those who did not, and this decline may be related to an enhanced focus on suicide prevention within the VA (Katz et al., 2012). In a study examining characteristics of veterans who committed suicide while involved in VA care, 68% of veterans had clinician-documented psychiatric symptoms within the past year compared with 32% of veterans with none of these symptoms (Britton et al., 2012). Veterans with identified mental health symptoms had higher rates of reported suicidal ideation and plans, mental health treatment participation, sleep disturbance, and stressors, including occupational, relationship, legal, and housing problems. These veterans also had higher rates of death within 60 days of their last VA visit, and death rates of veterans who reported suicidal ideation within the past year were twice as high within 30 days of their last VA visit than those with no suicidal thoughts (Britton et al., 2012). Similarly, a different study found that veterans with sleep problems committed suicide more quickly after their last VA visit than those without disturbed sleep (on average 75 vs. 174 days; Pigeon et al., 2012). Veterans with and without psychiatric symptoms who committed suicide were found to have similar rates of chronic pain, and this suggests that pain may be a risk factor for suicide regardless of mental health status (Britton et al., 2012).

Given the prevalence of suicidal ideation and suicide within the veteran population, the following treatment recommendations are encouraged. All veterans should be periodically monitored for suicidal ideation because veterans at risk for suicide may not be easily identified (Britton et al., 2012) and suicidal ideation can change over time (Smith, Goldstein, et al., 2016). Additionally, identified risk factors for suicide in veterans include pain, sleep problems, health problems (especially in older veterans), life stressors, relationship problems (especially in younger veterans), and mental health diagnoses (Britton et al., 2012; Kaplan et al., 2012; Magruder, Kassam-Adams, Thoresen, & Olff, 2016). Suicide prevention strategies would likely benefit from being tailored to veterans' individual concerns (Denneson et al., 2014), and intervention strategies would likely include development of appropriate coping skills (Kaplan et al., 2012). Moreover, planning for safety (including restricting access to weapons) is important in veteran populations, and non-VA providers should be educated about this (Kaplan et al., 2012).

Conclusion

Overall, US veterans experience a number of physical and mental health concerns that may be associated with their military experience, including chronic pain, sleep problems, TBI, PTSD, MST, and suicidal ideation and/or attempts. Although many of these problems are not unique to the veteran population, many of these health concerns have been found to occur at higher rates in veteran populations and with significant impact on one's level of functioning. Additionally, it is important for VA and non-VA providers alike to be informed about issues experienced by veterans, given that a large number of veterans participate in healthcare through the private or community sector (Fredricks & Nakazawa, 2015; Olenick et al., 2015; Spelman et al., 2012; Taylor et al., 2012).

Department of Preventive Medicine, Northwestern University, Evanston, IL, USA

The Science and Praxis of Team Science: Definitions

Team science (TS) is the study and application of principles about how to assemble, optimize, and lead groups of people who collaborate on a shared endeavor. A science team in particular is composed of two or more individuals who have different roles and who work interdependently to accomplish a common research goal. In unidisciplinary teams, researchers from a single discipline work together to solve a shared problem. In multidisciplinary teams, researchers from different disciplines work separately on different parts of a research problem, each applying their own discipline specific expertise. The parts are then integrated at the end in an additive manner. Finally, interdisciplinary/transdisciplinary teams work in a more integrative, interactive manner. Team members work jointly to understand each other's disciplinary frameworks. They develop new language and a shared mental model that enables them to approach the shared research problem from a more deeply integrated perspective.

Two aspects of TS are of great contemporary interest: the science of TS and the praxis of TS. A 2015 report from the National Academy of Science (NAS) defined the science of TS as a new interdisciplinary field that empirically examines the processes by which scientific teams organize, communicate, and conduct research to achieve scientific breakthroughs that would not be attainable by either individual or simply additive efforts (NAS, 2015). To date, the science of TS has been largely concerned with describing features that appear to facilitate or hinder high impact research. Most of this research has been correlational in nature, concerned with identifying conditions that covary with bibliometric indicators of scholarly impact (i.e., citations). In parallel, research on the praxis of TS examines how to apply the TS knowledge base pragmatically so as to optimize the assembly, launch, and maturation of interdisciplinary research teams. Research on TS praxis includes not only observational studies characterizing the sociopsychological processes that successful teams display but also experimental studies of interventions aiming to improve team functioning.

First Edition. General Editor: Lee M. Cohen. Volume Editor: Suzy Bird Gulliver.

The Emergence of Team Science

Throughout much of history, the dominant image of a scientist has been a lone individual secluded away in a lab, single-handedly trying to solve the most pressing scientific problems. This romantic notion of the lone scientist as "Renaissance person" (i.e., someone very accomplished at many different things) has a few prototypic exemplars. Consider Leonardo da Vinci who, alongside painting the Mona Lisa, made important scientific discoveries in engineering, weapons design, flight, and the understanding of human anatomy. Or contemplate Galileo Galilei, another Renaissance era polymath, whose studies of sunspots, planetary motion, temperature, gravity, and inertia contributed not only to astronomy and mathematics but also to physics. Jumping ahead to the seventeenth century brings to mind philosopher-architect Robert Hooke, who discovered and coined the term for "cell" while solving major problems in mechanics and potential energy, gravitation, astronomy, and paleontology. A few solo "Renaissance" scientists can even be identified in the nineteenth century. An example is the English physician Thomas Young, who lived from 1773 to 1829 and who has been called "the last man who knew everything." In addition to deciphering Egyptian hieroglyphs on the Rosetta Stone, Young made significant contributions to the fields of vision, solid mechanics, energy, physiology, language, and musical harmony.

By the mid-twentieth century, however, the social ecology of scientific knowledge production had fundamentally changed, as the paradigm of the solo scientist lost ground. Discovery of the DNA double helix, unarguably one of the most significant breakthroughs of the twentieth century, emerged from a group effort between two English crystallographers (Rosalind Franklin and Maurice Wilkins), an American biologist (James Watson), and an English physicist (Francis Crick), albeit that Franklin's main contribution to the collaboration occurred unknowingly when her discovery was shared without her consent. Another prominent TS example that occurred during WWII was the top secret Manhattan Project, which engaged physicists, mathematicians, and chemists from 19 different locations to collaborate on producing the first atomic bomb.

By 1955, 50% of science and engineering publications were authored by two or more individuals; by 2015, the percent of papers that were co-authored reached 90% (NAS, 2015). A 2007 analysis of nearly 20 million papers published over 5 decades and 2.1 million patents demonstrated that research is increasingly being done by teams in all branches of science (Wuchty, Jones, & Uzzi, 2007). Only in the arts and humanities does the solo author remain prevalent. Moreover, teams produce more frequently cited research than individuals do, and this team advantage has increased over time. The same growing dominance of teams that is observed in the physical sciences and engineering also is evident in the basic biological and social sciences, medicine, and health. Also consistent is the finding that National Institutes of Health (NIH)-funded extramural research produces primarily multi-authored papers (Lauer, 2018). Moreover, research teams are growing larger. The number of authors per paper is increasing over time in all areas of science, including health (Guimera, Uzzi, Spiro, & Amaral, 2005; Lauer, 2018). Finally, collaboration is becoming more geographically distributed across institutions, and, at least among relatively high-tier universities, the scholarly impact of multi-institution projects is higher than single-institute ones (Jones, Wuchty, & Uzzi, 2008).

What was true of the twentieth century is even more so in the twenty-first century. More and more, major scientific discoveries are made by larger teams. Mega-team authorship has become the norm in some research areas, such as genetics. For example, the initial report of the human genome sequence had more than 1000 authors. The Human Genome Project involved collaboration between scientific and medical communities from 20 institutions in

6 countries. The Large Hadron Collider at CERN, the world's biggest and most powerful particle accelerator, is a collaboration involving more than 10,000 scientists and engineers from over 100 countries, as well as hundreds of universities and laboratories.

Why Team Science?

As the body of scientific knowledge has grown, it has become increasingly difficult for a lone researcher to maintain deep expertise in more than one area. More than 50 million scientific papers have been published since the mid-1600s, at a current rate of about 2.5 million new scholarly publications every year. The pace of knowledge growth also has increased exponentially since the 1600s when it was still feasible for some Renaissance scientists to become both proficient in the arts and expert in several scientific disciplines. Moreover, the rate of knowledge proliferation continues to rise to a current state at which global scientific output doubles every 9 years (Bornmann & Mutz, 2015).

To keep up, science and scientists became more specialized, acquiring deeper knowledge of a more circumscribed domain. By the twentieth century, the growing specialization in science forced research to be carried out largely in disciplinary silos. Because of the time and resources involved in developing expertise, young scientists were encouraged to master a very narrow and specific subset of topics, identifying a unique niche from which they could contribute the deepest possible domain expertise. In consequence, as the volume of scientific knowledge expanded, it became increasingly difficult for one researcher to have a deep understanding of all the parts involved in any one problem. Slowly, the realization dawned that addressing the major unresolved research questions would require scientists from a variety of different fields and diverse expertise to collaborate. The lone scientist sitting in his isolated lab no longer possesses all the knowledge needed to single-handedly lead scientific discovery, and the most famous discoveries are no longer attributable to a single name.

In 2005, 2014, and 2015, the NAS produced several reports attributing the twenty-first-century surge of interest in TS to several powerful drivers (NAS, 2005, 2014, 2015). The first driver is the increasing impossibility for any individual to remain expert in multiple scientific disciplines. The second driver concerns the complexity of pressing unresolved societal and natural problems (e.g., poverty, global warming, violence, cancer) that command global policy attention. The knowledge and skills needed to address these outstrip the domain expertise of any single scientific discipline. Instead, such complex problems call for collaborative efforts that leverage the strengths and expertise of professionals trained in different fields. Whereas traditional single-investigator driven approaches suffice for solving well-defined problems of circumscribed scope, complex social problems with multiple causes call for coordinated teams of investigators with diverse skills and knowledge. A third driver of interest in TS is the availability of powerful but expensive new technologies whose use is optimally shared.

The 2005 NAS report on Facilitating Interdisciplinary Science sounded a clarion call signaling an urgent need to stimulate a more interdisciplinary research climate in the nation's universities (NAS, 2005). The goal was to advance fundamental understanding or to solve problems whose solutions are beyond the scope of a single discipline or field. Interdisciplinary research was defined as an approach integrating information, data, techniques, tools, perspectives, concepts, and theories from two or more disciplines or bodies of specialized knowledge. The 2005 NAS report opened eyes to the fact that academia lagged far behind industry and government laboratories in familiarity with and commitment to interdisciplinary research. Both industry and government research facilities had a track record of agile problem-driven research whereby scientists could assemble in interdisciplinary teams and move flexibly between laboratories as the research problem and professional development needs warranted it. In contrast, even though the greatest density of scientific talent exists in the nation's universities, entrenched institutional customs in academia create a persistent "drag" on researchers who would like to do interdisciplinary research and teaching.

Interdisciplinary Team Science Initiatives

The major increase in federal funding for TS research that has occurred during the past four decades strongly incentivizes universities to encourage the formation of interdisciplinary research teams. The most recent NAS report on TS (NAS, 2015) highlights this trend. Both the National Science Foundation (NSF) and the NIH have increased the proportion of funding they award to research overseen by more than one principal investigator (PI). The number of NIH multiple PI (MPI) grants increased from 3 in 2006 (when such grants were first allowed) to 1,098 in 2013, or 15–20% of major grants awarded. Beginning in the mid-1980s, both NIH and NSF also increased their funding of research centers, which involve multiple related research projects and more loosely linked "U" networks of topically related grant projects.

Some NIH Center grant initiatives have been very large, and analysis of their productivity outcomes provides much of what is known about the science of funding TS. One example is the Transdisciplinary Tobacco Use Research Centers (TTURC), a group of seven university-based centers and a coordinating center co-funded in 1999 by the National Cancer Institute, National Institute on Drug Abuse, and the Robert Wood Johnson Foundation to advance understanding and reduce use of tobacco. A subsequent NCI initiative, the Transdisciplinary Research on Energetics and Cancer Centers (TREC) supported eight research centers and a coordination center in two separate funding cycles, 2005–2010 and 2011–2016, with aim of accelerating progress toward reducing cancers associated with obesity, physical inactivity, and poor diet. An even more expansive and international collaboration was the Human Genome Project, which aimed to determine the DNA sequence of the entire human genome. Launched 1990 and declared complete in 2003, this highly interdisciplinary project identified 22,300 genes in the human genome, ultimately yielding 2,000 genetic tests for adverse health conditions and 350 biotechnology products in clinical trials.

A major currently ongoing transdisciplinary NIH initiative is the Brain Research through Advancing Innovative Neurotechnologies (BRAIN) Initiative. Launched in 2014 with an initial annual allocation of $100 million, this large-scale undertaking expanded to a budget of $434 million for fiscal year 2017. The extensive interagency collaboration, involving 15 NIH institutes and centers, NSF, Defense Advanced Research Projects Agency (DARPA), Intelligence Advanced Research Projects Activity (IARPA), the Food and Drug Administration, and the Department of Energy (DOE), aims to develop tools to create a new dynamic picture of the brain that shows how individual cells and complex neural circuits interact in time and space.

Practical Challenges of Interdisciplinary Team Science

Mastering the praxis of TS sufficiently to optimize team performance is of great importance, especially given sizeable federal investment in large-scale interdisciplinary research. A group of individuals needs to progress through the series of developmental stages needed to function well as a team. Bruce Tuckman described the team development sequence as forming–storming–norming–performing (Tuckman, 1965). Members of a new interdisciplinary team need to become oriented to who is on the team, what knowledge and skills they possess, and, on that basis, who will be responsible to undertake which tasks. Particularly because team members come from different disciplinary training backgrounds as well as having different personalities and demographic characteristics, the getting-acquainted process takes time, requires conversation, and is impeded by distance. In the late 1970s, research by Robert Allen identified a principle known in communication theory as the Allen curve. Allen found a strong negative correlation between physical distance and the frequency of communication between workers. He found that collaboration effectiveness declines when coworkers are more than 30–50 m apart, because they do not interact regularly. Although one might wonder whether the same principle holds true today in this era of easier virtual communication, Allen has argued in the affirmative, finding that we are more likely to telephone or use additional communication channels to contact those whom we often see in person (Allen & Henn, 2007).

To reach the next level of productivity, team members need to dialogue openly enough to earn each other's trust, a process that may initially cause the conflict that Tuckman characterized as storming. Teams can struggle between the application of their own knowledge and the willingness to listen to other points of view and discover new approaches. One discipline's efforts to adhere to standards of practice in their field can cause dispute with group members encouraging adoption of another discipline's methods and values. Eventually, to engage in productive problem solving about their shared project, teams need to progress toward generating a shared language and mental model of the problem at hand. Productive collision of viewpoints fosters the constructive disagreement needed to challenge conventional ways of thinking. It is defined as "a process by which parties who see different aspects of a problem can constructively explore their differences and search for solutions that go beyond their own limited vision of what is possible" (Gray, 1989).

Once a shared image has emerged of who knows what and how team members think differently, teams can progress to the next stage. During norming, team members become more open to each other's ideas and less inclined to take criticism personally. The team collaborates on establishing rules of conduct, values, standards, and methods. These shared normative expectations help the team to function more efficiently, segueing into the next stage of optimal performance when team members work collegially toward their shared objective.

Now try to imagine facilitating this stage-wise developmental progression for a very large team representing multiple disciplines and whose members are dispersed across multiple universities. Even though such cross-institutional teams can produce very high impact research (Jones et al., 2008), there is also evidence that the more universities involved in a collaboration, the fewer are the project outcomes such as patents, grant awards, and publications (Cummings & Kiesler, 2007). The discrepancy between these two apparently contradictory findings can be explained by variation in the team's degree of investment in coordination activities. Time allocated to communication and discussion among team members is as essential, if not more so, in distributed teams as it is in colocated ones. Substantial investment in coordination activities and tools is necessary to help cross-institutional teams establish a shared vision, divide responsibilities, and communicate effectively. Project management tools, regular teleconferences, in-person meetings, student exchanges, and co-authored manuscripts are all effective approaches to maintain coordination. Another essential ingredient is patience. That truism was well demonstrated in a longitudinal analysis that Kara Hall and colleagues conducted to compare the scientific productivity and impact of very large NIH transdisciplinary research center grants versus traditional investigator-initiated NIH R01 grants in the same area. The results showed that although productivity initially lagged for the center grants, it eventually outstripped that for R01 grants both because of a higher rate of publication and a larger number of co-authors per paper (Hall et al., 2012).

Training Team Science Competencies

A number of training resources have been developed to facilitate skills development for those interested in working on interdisciplinary teams. One freely available online training resource is the COALESCE online learning modules available at https://www.teamscience.net. This web tool created by Bonnie Spring, Arlen Moller, and Holly Falk-Krzesinski at Northwestern University's Clinical and Translational Science Institute includes four modules. One provides an overview of the science of TS through animations and short videos featuring many of the experts who contributed to the NAS's 2015 volume on TS. The other three interactive modules present case scenarios that enable learners to practice foundational TS skills as applied to problems in clinical medicine, basic biological science, and behavioral science while assuming the roles of a junior scientist, a senior scientist, and a research development officer. Comparison of pretest with posttest scores of those completing the modules indicates that the training increases knowledge, attitudes, and self-efficacy about implementing TS practices (Klyachko et al., 2018).

A different training approach, sponsored by NSF, is the Toolbox Project (see http://toolbox-project.org) developed by philosophers Michael O'Rourke, Steven Crowley, and their colleagues. This facilitated in-person 2-hr group workshop prompts attendees to engage in philosophical dialogue about their fundamental assumptions regarding science, ways of knowing, values, and the nature of the world. Although the Toolbox Approach has not been formally evaluated, anecdotal evidence suggests that the workshop meets its goal of encouraging participants to thoughtfully consider other points of view.

Alternative training models take the approach of training TS competencies implicitly by embedding young investigators in the TS context most relevant to their research aspirations. Bill Ameredes and colleagues at the University of Texas Medical Branch took this approach to train early career investigators in interinstitutional collaboration (Ameredes et al., 2015). Self-report survey responses gathered from a subset of trainees suggest that participating in a multi-institutional science team increased participants' confidence in specific research competencies, including research design and statistical analysis. Another frequently used format is the weeklong immersive training experience. Trainees attend a retreat where they are grouped into teams to develop an interdisciplinary research proposal. They hear didactic lectures in relevant content areas and collaborate with project team members who have complementary skills in the other disciplines needed to design the research successfully. One such training experience is the very well-subscribed NIH-sponsored mHealth Summer Training Institute held at UCLA (see https://mhealth.md2k.org/mhealth-training-institute). The institute receives more than 300 applicants annually for its 30 positions. Pre–post comparison of self-reported knowledge, attitude, and skill changes reported by participants shows positive changes in appreciation of interdisciplinary science and confidence about working in teams.

Institutional Culture

The risks and the rewards of engaging in interdisciplinary TS have been well described for the individual investigator (Rhoten & Parker, 2004). In their 2014 report on Convergence, the

NAS went on to consider institutional barriers that impede integrative transdisciplinary science (NAS, 2014). The department-based budgeting structure of most universities is one tradition that has discouraged research and mentoring collaborations from crossing disciplinary lines. University departments compete to acquire their allocation of faculty positions, laboratory and office space, and seed funding from their school's central administration. Departments seek to justify their resource allocation by being credited for the grant funding, teaching, and service accomplishments contributed to the university by their departmental faculty. Even today, many years after recognizing and trying to correct institutional barriers to cross-disciplinary work, not all universities have figured out how to allocate shared credit and resources for research grants, teaching, and mentorship accomplished by faculty from more than one department. In such settings, university faculty may feel subtly discouraged from pursuing collaborations with colleagues in other departments. On a more positive note, most research-intensive universities have by now implemented sharing policies that support cross-departmental implementation of research grants.

The residual TS barrier that has remained most challenging to resolve exists at the level of the academic promotion and tenure system (Klein & Falk-Krzesinski, 2017). Because interdisciplinary science inherently occurs at the boundary of adjoining fields, but most distinguished senior scientists were trained as specialists, it can be a daunting task for review committees to acquire requisite letters of endorsement from external authorities who fully appreciate a candidate's interdisciplinary science. Augmenting that difficulty is the multi-authored nature of multidisciplinary publications, coupled with the promotion committee's historic bias to downgrade the importance of contributions other than first, last, and, in some communities, second authorship.

Optimizing Institutional Culture to Support Team Science

The National Center for Advancing Translational Sciences (NCATS), founded in 2011 as 1 of 27 institutes and centers at the NIH, is a major national driver for interdisciplinary TS. Broadly, NCATS's goal is to transform the translational process so that new treatments and cures for disease can be delivered to patients faster. NCATS regards TS as integral to its mission because of the need to "encourage partnerships that cross many scientific disciplines and research sectors in pursuit of translational success." Consequently institutions applying for CTSA designation are required to describe the mechanisms they have put in place to foster interdisciplinary science collaborations as well as engagement of researchers with community stakeholders.

A few institutions are changing institutional policy to facilitate TS. For example, in 2011, Northwestern University's Feinberg School of Medicine created a faculty track for team scientists. To quote from the University's handbook, the track is designed for "non-clinical faculty who make substantial contributions to the research and/or educational missions of the medical school. Faculty members whose primary activity is in research will typically engage in team science. Their skills, expertise and/or effort play a vital role in obtaining, sustaining and implementing programmatic research.… Typically such faculty provide critical expertise to a program or group of research teams as a co-investigator with contributions that do not necessarily require or result in independent grant funding, but some faculty on this track may serve as principal investigator on related research. Faculty on this track do not perform clinical work but do contribute to the education and service missions of the medical school.… For candidates on the Team Scientist track engaged in research and related academic activities, Feinberg recognizes the critical importance of collaboration in research and scholarly activity and that the contributions of middle authors in multi-authored publications are often seminal and of the highest quality. It is an expectation that faculty on this track who choose the research domain will generally be members of a research team and that their contributions to publications will often be as middle authors. When research and/or scholarship is pursued in a collaborative fashion and results in multi-authored publications, the specific contributions of the candidate should be made clear. The school also recognizes the critical contributions of collaborators in the acquisition of grant funding to collaborative research projects." Initiatives like the creation of the TS faculty track pave the way for institutions to support and reward the collaboration that is integral to TS.

Conclusion

Burgeoning government investment in interdisciplinary research reflects an urgent need to improve the public's health by pressing forward the frontiers of transdisciplinary science. On one hand, an association between multiple cross-institutional authorship and citation impact has been documented, and it has become rare for scientific research to be conducted by single investigators. On the other hand, the existing evidence base gives scant guidance regarding best practices to follow when assembling, launching, and optimizing a science team. For now, the policies followed to assemble large cross-institutional interdisciplinary research teams must inevitably outstrip the science base about TS praxis. On the other hand, the process of iteratively trying to improve these teams' performance affords a rich learning lab to enhance the knowledge base about how to optimize team performance. A first priority is to develop rigorous metrics that can track teams' short-term and long-term team performances, making it feasible to understand how well and poorly performing teams evolve over time and the patterns that predict superior scientific productivity and impact. Having a grasp of how outstanding teams evolve should point to critical team development processes that can potentially be optimized. A bright future for interdisciplinary TS rests upon progressing the science of TS from descriptive to interventional studies that build a practical knowledge base translatable into high impact collaboration.

Author Biographies

Sasha Cukier graduated from Emory University where she majored in neuroscience and behavioral biology and minored in predictive health. Sasha worked as a research study assistant in the Spring Laboratory at Northwestern University, Feinberg School of Medicine, on the Opt-IN, SMART, and Sense2Stop studies exploring her research interests in preventive medicine and behavioral interventions. While working with diverse groups and teams spanning multiple institutions across the country, Sasha became interested in the science of team science and engaged in projects exploring what constitutes effective team-based research.

Dr. Ekaterina Klyachko is the team science program administrator at the Northwestern University Clinical and Translational Sciences Institute where her primary role is to support researchers in the development of multidisciplinary research teams. Prior to joining the TS program, she organized and managed multidisciplinary research programs and grant applications in the Northwestern University Feinberg Cardiovascular Research Institute. Katya holds a PhD in Microbiology from University of Illinois and a master's in clinical research and regulatory administration from Northwestern University. Dr. Ekaterina Klyachko has been the recipient of multiple grant awards, and she has published numerous peer-reviewed manuscripts.

Dr. Bonnie Spring is professor of preventive medicine, psychology, psychiatry, and public health at Northwestern University and director of the Center for Behavior and Health – Institute for Public Health and Medicine. She also serves as team science director for NUCATS, Northwestern's CTSI, and co-leader for the Cancer Prevention Program. She studies technology-supported interventions to promote healthy change in multiple chronic disease risk behaviors (particularly poor quality diet, overeating, physical inactivity, and smoking), and her research has been funded continuously for more than 30 years. Current mHealth trials ongoing by her group involve the use of wearable sensors to predict and preempt relapse to smoking, MOST factorial, SMART, and JITAI designs to optimize treatment for obesity and a cluster randomized trial to prevent loss of cardiovascular health among college students. A past president of the Society of Behavioral Medicine (SBM), she is a recipient of SBM's Distinguished Research Mentor, Research to Practice Translation, and Distinguished Leadership awards and founding editor of its journal, *Translational Behavioral Medicine: Practice, Policy, Research.* A winner of The Obesity Society's e-Health Pioneer Award and past chair of American Heart Association's Behavior Change Committee, she chairs the NIH Psychosocial Risk and Disease Prevention standing study section. An original member of APA's Advisory Steering Committee to establish Practice Guidelines and past chair of its Board of Scientific Affairs, she was awarded an American Psychological Association Presidential Citation for Innovative Research and Leadership in Health Psychology and for Vision in Incorporating Technology into Practice and Training. She has served as primary mentor for 42 training awards. Her NIH-funded learning modules on evidence-based practice (www.ebbp.org) and the science of team science (www.teamscience.net) are freely available online and have been used by more than 50,000 learners worldwide.

Family and Health

Brittany N. Sherrill[1], Janet Deatrick[2], and Keith Sanford[1]

[1]*Department of Psychology and Neuroscience, Baylor University, Waco, TX, USA*
[2]*Department of Family & Community Health, University of Pennsylvania School of Nursing, Philadelphia, PA, USA*

There are many ways in which family characteristics are associated with physical health. Family structure, family relationships, and family behaviors are associated with physical health behaviors and physical health outcomes. Also, the medical condition of a family member can place demands on other family members, and this in turn can influence the well-being of other family members and influence family functioning. Conversely, if a family member has a medical condition, family coping can influence the medical and emotional sequela of the medical condition. Before considering links between family characteristics and physical health, it is necessary to clarify the scope of the topic by defining both physical health and families. First, although there are many dimensions to health, it is useful to delimit the scope of physical health to include areas of well-being or disease that are defined primarily in terms of body organ systems. This definition makes a somewhat artificial distinction that excludes dimensions of mental–behavioral health, which pertains to areas of well-being or disease defined primarily in terms of behavior, emotion, and cognition. Second, although there are many diverse types of families, researchers have commonly defined families to include at least one of two basic components: intergenerational provision of care (such as between parents and children) and/or committed domestic partnerships (such as marriage or cohabitation relationships).

When considering ways that family and health are related, four overarching questions are salient. First, how are family-related variables associated with health behavior and health outcomes in the general population? Second, how does having a family member with a medical condition influence the health and well-being of other members of the family unit? Third, what types of family interaction behaviors help or hinder a family's ability to cope when one member has a medical condition? Fourth, what types of family interventions are effective in improving outcomes when one member has a medical condition? Each of these questions will be considered in detail below.

The Wiley Encyclopedia of Health Psychology: Volume 4: Special Issues in Health Psychology,
First Edition. General Editor: Lee M. Cohen. Volume Editor: Suzy Bird Gulliver.

Associations Between Family Characteristics and Health Variables

The first overarching question pertains to correlations between family characteristics and health variables within a general population. This question is unique in that it is best addressed in studies of the general population and not in studies that focus exclusively on families that have a member with a medical condition. There is a large body of research investigating how health is related to family structure, such as being married or having children. There is also a body of research specifically investigating the effects of family conflict on health, as well as research specifically investigating how family relationships may predict outcomes that involve health behavior. In general, people tend to be the healthiest when they have supportive family relationships characterized by low levels of family conflict and when they live with other family members who engage in healthy behaviors.

Marriage

Research indicates that married individuals enjoy better physical health outcomes throughout their lifespan compared with their unmarried counterparts. Morbidity and mortality reduction in married individuals includes reduced levels of heart attacks, cancer, and surgery. This effect may be partially due to selection effects of healthy individuals getting married, as well as due to protective benefits of marriage related to access to resources, reduced stress levels, less engagement in risky health behaviors, and reduced social isolation. By reducing stress levels, marriage indirectly acts physiologically to improve health benefits by reducing cortisol levels, improving immune function, and reducing risk for cardiovascular disease. Although evidence of a link between marriage and health has been found across different economic status and culture groups, the link appears to be stronger in men than in women. A possible explanation for this trend is that men may tend to have narrower social networks outside of marriage; therefore, the effects of being married might be especially consequential.

Family Structure and Aging

Both marital status and having children are associated with health-related variables in aging populations. Marriage is associated with a lower disease risk as well as fewer functional limitations as individuals age. Additionally, a lack of children in old age is associated with riskier health behaviors due to a lack of the social control functions of parenthood. The presence of a single grandchild increases contact between parents and grandparents, which may mitigate the health effects of social isolation. There are also associations between family structure and the provision of healthcare to aging parents by their adult children. Research suggests that divorce and formation of stepfamilies reduce the extent to which children will provide healthcare for aging parents.

Conflict

Although marriage is generally associated with positive health outcomes, people in highly conflictual or distressed relationships are at greater risk for negative outcomes. While the health effects of simply being married may tend to be stronger for men, the effects regarding relationship conflict and distress tend to be stronger for women. This might reflect a tendency for women to be more attentive than men to issues regarding relationship quality. A large body of research on relationship conflict and health has focused on physiological stress responses that occur when people experience relationship conflict. Recalling past conflicts has been shown to elevate blood pressure, while spouses who report low levels of cohesion in their marriage experience higher blood pressure simply from being in contact with their spouses (Baker et al., 1999). Both correlational and experimental research have found that exposure to relationship conflict is associated with impaired immune system functioning and prolonged inflammation responses. In part, this physiological response may be a direct consequence of the stress associated with relationship conflict. It also may be an indirect outcome of a mediated pathway that includes other variables associated with relationship conflict-such as depression, poor sleep, decreased physical activity, and unhealthy diet (Kiecolt-Glaser, Gouin, & Hantsoo, 2009). The physiological effects of family conflict are not limited to those family members who are directly involved in a conflict. Relationship conflict between parents is often noticed and a source of stress for their children. For instance, research has found that adolescents experience increased cortisol production at times when their parents report relationship conflict.

Family Influence on Health Behaviors

Family members also have the potential to influence the health behaviors of one another. Children's health beliefs and lifestyle behaviors are influenced by parent modeling, including parent involvement in exercise and healthy eating. These modeling effects last even beyond adolescence (Norton, Froelicher, Waters, & Carrieri-Kohlman, 2003). Negative parent health behaviors are often emulated by children. A case in point is children of parent smokers, who have an increased risk of becoming smokers in adolescence. Married partners also tend to share similar health behaviors pertaining to smoking, drinking, and exercise. Research suggests that this similarity is both due to people selecting similar partners to marry and to partners becoming more similar to each other after getting married. This type of pull toward partner similarity is also evidenced in the fact that former smokers are more likely to relapse in the presence of a partner who smokes. Research also finds that family structure is related to health behavior. Merely having a partner is associated with a decreased likelihood of smoking. Finally, childbirth is associated with changes in health behaviors in new parents. Physical activity tends to decrease in new parents and tends to remain low even several years after the birth of a child.

Family Outcomes When One Member Has a Medical Condition

The second overarching question relates to how families are influenced by having a member with a medical condition. This question is unique in that it is best answered with research comparing families where all members are healthy with families having one member with a medical condition. Research in this area has focused on two general types of family variables that may be affected when one member has a medical condition. These include (a) increases in feelings of stress among family members and (b) changes in the ways that family members interact with each other. The literature suggests that when one family member has a health condition, other members sometimes experience increased stress, while family interactions are sometimes also characterized by increased understanding toward the member with the health condition. However, research on this particular question sometimes produces results that are inconsistent across different studies or that are nonsignificant. This likely reflects the fact that there are substantial differences between types of medical conditions and between families in how they cope and respond to medical conditions. Compared with other questions regarding families and health, it may be especially difficult to draw strong generalizations about how families are typically influenced by having a member with a medical condition.

Family Stress When One Member Has a Medical Condition

When one member of a family experiences a significant adverse health event, there is sometimes an increased risk that other family members will report feelings of stress, anxiety, or depression. When one member of a couple is diagnosed with cancer, it is common for the patient's partner to experience a similar level of psychological distress to the patient. Several studies have also investigated the extent to which parents experience stress when their children have medical conditions. Mothers and fathers of children who experience serious burn events report significant stress reactions. Posttraumatic stress disorder symptoms have been noted in parents of survivors of childhood leukemia (Kazak et al., 1997). These symptoms have also been observed in parents of children diagnosed with other types of cancer, as well as type 1 diabetes. It is important to note, however, that strong stress reactions are not consistently observed across studies or across medical conditions: one study found that the presence of juvenile rheumatoid arthritis had only small effects related to parents worrying about children's health. The intensity of the stress reaction is likely moderated by other variables. Some studies find that mothers report higher stress compared with fathers.

Family Interactions When One Member Has a Medical Condition

Research has found only a small number of consistent results regarding ways that family interactions may be influenced when one member has a medical condition. Compared with parents of healthy children, parents of children with medical conditions tend to be more excusing toward their children and to have more positive affective responses to child behavioral and academic problems. Along this line, one study found that, among children with phenylketonuria, the higher the phenylalanine levels were in the child, the more likely parents were to attribute child behavior and academic problems to external sources (Antshel, Brewster, & Waisbren, 2004). Aside from research showing that parents make excusing attributions for children with medical conditions, research has been mostly inconclusive regarding other possible ways that families typically respond when a child has a medical condition. Studies investigating this issue often fail to find significant results. One study comparing families with and without a child with juvenile rheumatoid arthritis found only minimal differences between families. In another study of families of children with a variety of health conditions including cystic fibrosis, sickle cell anemia, and epilepsy, no significant differences related to family functioning were observed.

Notably, it is sometimes suggested that having a child with a medical condition can lead to increased levels of family conflict. Along this line, one study found that among parents of children with epilepsy, the presence of recent seizures in the child was associated with high levels of expressed emotion in the parent, a type of interaction characterized by criticism and emotional over-involvement. However, there are few other studies suggesting this type of negative effect. Moreover, general research on married parents of children with disabilities has often (though not always) failed to find associations between child disability status and relationship satisfaction between parents. In sum, it is difficult to draw clear conclusions about how families typically respond when a child has a medical condition. Given differences between medical conditions and diversity in family experience, it may be especially difficult to make meaningful generalizations about the ways in which families typically respond to medical stressors.

It is also important to consider how couple relationships change when one partner has a medical condition. This association may be especially salient when a medical condition causes changes in areas that are relevant to the relationship, such as changes in physical appearance, sexual functioning, self-care ability, cognitive ability, and ability to perform previous responsibilities. However, as with research on families of children with medical conditions, it is difficult to draw clear generalizations regarding how couples respond. Studies investigating levels of relationship satisfaction often find that couples facing medical conditions have similar levels of satisfaction to couples that are not; however, this is not always the case. For example, one study of stem cell transplant cancer patients and their caregiving partners found that relationship satisfaction tended to decline over the course of treatment for female caregivers, but not for male caregivers or for patients (Langer, Yi, Storer, Syrjala, 2010). In general, the divorce rate for couples when one partner has a serious medical condition is similar to that of the general population. However, divorce rates are substantially higher when women have serious medical conditions, compared with when men have serious medical conditions. Thus, in infrequent situations where partner abandonment occurs, it is most likely to involve a healthy man abandoning a woman with a medical condition.

Family Interaction Behavior That Helps or Hinders Family Coping

The third overarching question involves examining research that identifies types of family interaction behaviors that help or hinder a family's ability to cope with a member's medical condition. Researchers investigating this topic have focused on three basic goals: (a) identifying the important dimensions of family interaction behavior, (b) investigating correlations between family interaction behavior and other dimensions of family functioning, and (c) investigating correlations between family interaction behavior and aspects of well-being outside of family functioning. As discussed below, this research finds that when a family member has a medical condition, positive family behavior and negative family behavior are not opposites and that negative family behavior may be especially consequential in predicting outcome variables regarding feelings of stress and well-being.

Key Dimensions of Family Interaction Behavior

Researchers have proposed many different models identifying types of family interaction behavior that are important when one member has a medical condition. A commonly used model of social support makes a distinction between the provision of emotional support (such as providing comfort to a family member) and instrumental support (such as completing a task to assist a family member with medical care). In another model focused on dyadic coping in couples, Bodenmann (1997) identifies four important components: common coping (behaviors that two partners do together), supportive coping (behaviors that one partner does to comfort, encourage, or advise the other), delegated coping (tasks that one partner completes at the request of the other), and negative coping (behaviors that are hostile, ambivalent, or superficial). Coyne and Smith (1991) identified a distinctive and potentially problematic type of behavior called "protective buffering" where one family member attempts to shield another family member from negative information. Other models have emphasized variables such as congruence between family members' preferred coping styles, the ways in which a family communicates about medical issues, and the ways in which family members may lead each other to have specific types of thoughts about or emotional reactions to a member's medical condition. Other more general models that are not specific to families facing medical conditions suggest that important types of family interaction may include overall levels of family conflict, cohesion, and adaptability.

Despite the widely varied number of models put forth, recent research suggests that the types of family interaction described in these models can be understood as reflecting just two basic dimensions. One dimension involves the presence of positive behavior, and the other involves the absence of negative behavior. This research suggests that most types of *negative* family behavior are similar in function and most types of *positive* family behavior are similar in function, but there are important differences between the function of negative and positive behavior, respectively. In other words, they do not function as mere opposites.

According to the mobilization–minimization hypothesis (Taylor, 1991), it is adaptive for people to respond strongly and quickly to threatening events (such as negative family interactions). In comparison with positive events (such as positive family interactions), negative events elicit more intense affective, cognitive, and behavioral responses. Thus, negative family behavior may be most important because it elicits immediate stress responses that are memorable and distressing. This type of stress response is evident in the fact that interpersonal conflict is associated with physiological stress symptoms such as impaired immune system functioning and prolonged inflammation responses. In contrast, the function of positive behavior may be to facilitate the gradual building of relationship cohesion, which in turn is useful for emotion regulation. According to relational regulation theory, people are best able to regulate their emotions in the context of positive interpersonal interactions that include ordinary, routine conversations and shared activities with other significant people in their lives (Lakey & Orehek, 2011). In sum, negative interactions may function as stressors, whereas positive interactions may function to help members build cohesion and closeness.

Consistent with this model, a line of research suggests that when families face medical stressors, family members perceive their family interactions in a way that makes clear distinctions between the presence of positive interaction and the absence of negative interaction (Sanford, Backer-Fulghum, & Carson, 2016). This research began with a study that identified a large pool of different relationship behaviors that people naturally notice and experience in their relationships during a range of stressful life events. This pool included most of the behaviors previously identified as being important in models of family resilience and dyadic coping. Subsequently, a series of factor analytic studies indicated that this pool of behaviors reflects two basic underlying dimensions: first, a positive behavior dimension that includes family members providing support and companionship, contributing skills, and helping each other feel optimistic and second, a negative behavior dimension that includes family members being irritable, withdrawn, or avoidant, or failing to engage in expected positive behaviors. This research found high correlations between all the different types of positive behavior and high correlations between all the different types of negative behavior, while the correlation between positive and negative behavior was close to zero. This means that the presence of positive behavior is not necessarily associated with the absence of negative behavior, and vice versa. In fact, when families face stressful medical situations, there is a possibility that members may increase the use of both positive and negative behavior—such as being both more comforting and more irritable.

Family Interaction Behavior and Other Dimensions of Family Functioning

A large body of research covering a wide variety of medical conditions has investigated associations between different types of family coping behavior and other aspects of family functioning. In general, this research finds that variables measuring different aspects of family functioning are correlated. In couples that have a child with a medical condition, and in couples where one partner has a medical condition, the use of positive couple coping behavior is strongly correlated with couple relationship satisfaction. Other research on families with a child with a medical condition finds that when families report low levels of family hardiness, the parents are likely to view their children as engaging in negative coping strategies. However, this line of research is difficult to interpret because it is mostly based on studies where people complete questionnaires asking about different aspects of family functioning. Due to a process called "sentiment override," family members sometimes rely upon their global, overall feelings regarding family quality as a basis for how they respond to all self-report questionnaires measuring different aspects of family functioning. If people respond to all the questionnaire scales in a study on the basis of sentiment override, then all the scales will be correlated. Thus, it is not clear if this research tells us about the effects of family coping or if it merely shows us the extent to which responses to questions about family functioning are influenced by sentiment override.

Family Interaction Behavior and Well-Being

Research on families facing medical stressors has found that family interaction patterns are associated with emotional well-being. Several studies have investigated samples of couples where one partner is facing a serious medical condition such as breast cancer, lung cancer, prostate cancer, or a cardiac event. These studies have found that dimensions of couple interaction behavior are correlated with measures of emotional well-being ranging from depression and social dysfunction to illness-related distress. Other research with couples has specifically distinguished between positive and negative interaction behavior. In samples of couples where one member has a medical condition, as well as in samples of parents of a child with a medical condition, research has found that negative couple behavior is correlated with perceived stress, reduced well-being, and reduced quality of life. Notably, this negative behavior tends to be more important than positive behavior in predicting these outcomes. This is consistent with the mobilization–minimization hypothesis (discussed above) suggesting that negative and positive behavior have different functions and that negative behavior elicits particularly strong stress reactions.

In addition to research on couples, studies investigating parent–child relationships have also found links between family coping and well-being. In families of children with type 1 diabetes, children who rated their mothers as being uninvolved tended to be less likely to take recommended medications and to report poorer quality of life. In families of children with juvenile rheumatoid arthritis, mothers that describe their families as low in supportiveness and high in conflict are at greater risk of high levels of mental health symptoms.

There is also a large body of literature regarding family interactions when a family member experiences chronic pain. Several models of pain focus on the concept of pain behavior, in which a person verbally or nonverbally expresses or displays his or her pain, for example, by verbal complaint or facial expressions indicating pain. If a family member engages in pain behavior and this behavior is reinforced or supported by other family members, it can lead to increased pain behavior and, ultimately, higher levels of pain. This pattern has been observed in couples where one partner experiences chronic pain and in parent–child interactions where the child experiences pain. Additionally, research finds that parent reinforcement of their children's pain behavior is related to school absences and that parent use of symptom-related talk is associated with increases in child somatic complaints. While reinforcement of pain behavior is typically regarded as maladaptive, research with couples suggests that it is also beneficial for partners to be able to have intimate conversations about pain. Specifically, conversations characterized by discussion of emotions, as well as provision of empathy, are associated with less pain and less pain-related distress (Cano & Williams, 2010).

Family Interventions

The fourth overarching question has to do with identifying types of family interventions that improve outcomes when one member has a medical condition. These interventions include programs designed to help patients and their families cope with and manage medical conditions, and they fall into two broad categories. First, couple-based interventions are intended for couples where one partner has a medical condition and they target both members of the couple. Second, parent-based interventions are intended for families where a child has a medical condition and they include a substantial parent component. All these family interventions may target a range of different goals such as decreasing symptoms of the medical condition, improving adherence to a treatment plan, improving emotional well-being in the patient and in family members, and improving family relationships overall. In general, research in this area is still in its early stages. As might be expected for a new line of research seeking to develop effective treatments, the number of initial studies is still quite limited, and these initial studies often produce treatment effects that are small or nonsignificant.

Although several different types of couple-based interventions have been developed, many of these interventions are designed to address five different areas (for a review, see Baucom, Porter, Kirby, Hudepohl, 2012). First, they have an educational component where both members of a couple are provided with medical information. Second, they build intimate and clear communication in which partners share their thoughts and feelings regarding the medical condition. Third, they help partners negotiate the process of making medical decisions together. Fourth, they help partners make adjustments in their relationships to accommodate changes that may have been caused by a medical condition, including changes in physical ability, appearance, and sexual functioning. Fifth, they help couples improve their general relationship functioning.

At this point, evidence supporting the effectiveness of these types of interventions remains sparse. One small pilot study of women with early-stage breast cancer suggested that a couple-based relationship intervention might be beneficial in several areas, including increased acceptance and relationship satisfaction, as well as decreased pain and fatigue. In contrast, a randomized clinical trial of a caregiver-assisted cognitive skills training program for couples with a partner with lung cancer failed to find significant treatment benefits for emotional distress, quality of life, and caregiver stress. One of the largest randomized clinical trials for a couple-based intervention tested a partner-assisted emotional disclosure program for patients with gastrointestinal cancer. This study found that the treatment had nonsignificant effects on emotional variables but did have a small positive effect on relationship satisfaction. A follow-up analysis suggested that this effect was primarily noticeable in couples that initially did not talk about cancer-related concerns and emotions before treatment. As it stands, there remain many unanswered questions about which types of interventions will be most effective for which types of people.

Research regarding the effectiveness of parent-based interventions is also in its early stages. A meta-analysis identified three types of parent-based interventions that have been tested in randomized clinical trials (Law, Fisher, Fales, Noel, & Eccleston, 2014). First, cognitive behavioral approaches teach all family members to change thoughts and behaviors that may exacerbate symptoms of a medical condition or feelings of distress. Second, problem-solving approaches focus on helping family members develop problem-solving skills related to the illness. Third, systemic approaches help family members alter potentially problematic patterns of interaction. This meta-analysis found a small but significant effect (.25 standard deviations of difference between treatment and control groups) indicating that, in general, parent-based interventions produced positive changes in parent behavior. However, this meta-analysis failed to find significant effects for other important outcomes such as parent and child mental health, family functioning, and child medical symptoms. Other reviews of parent-based interventions have suggested that cognitive behavioral approaches may reduce medical symptoms and improve family functioning in youth with chronic pain and that systemic approaches may reduce medical symptoms and improve family functioning in youth with diabetes. In sum, although some results are promising, there remains a need for further research and development of parent-based approaches for families of children with medical conditions.
