Foreword

Until the 1970s, there were no books, journals, or university courses on health psychology. Although the field's intellectual roots stretch back to the beginnings of psychology more than a century ago, its formal emergence depended on a convergence of influences (Friedman & Silver, 2007), including psychosomatic medicine, social-psychological and socio-anthropological perspectives on medicine, epidemiology, and medical and clinical psychology. Today, health psychology is a principal area of significant social science research and practice, with vital implications for the health and well-being of individuals and societies. Understanding the explosive trajectory of health psychology is useful to appreciating the strengths of the field and to approaching this new encyclopedia, the *Wiley Encyclopedia of Health Psychology.*

What is the nature of health? That is, what does it mean to be healthy? The way that this question is answered affects the behaviors, treatments, and resource allocations of individuals, families, health practitioners, governments, and societies. For example, if it is thought that you are healthy unless and until you contract a disease or suffer an injury, then attention and resources are primarily allocated toward "fixing" the problem through medications or surgical repairs. This is the traditional biomedical model of disease (sometimes called the "disease model"). Indeed, in the United States, the overwhelming allocation of attention and resources is to physicians (doing treatments) and to pharmaceuticals (prescription drugs and their development). In contrast, health psychology developed around a much broader and more interdisciplinary approach to health, one that is often termed the biopsychosocial model.

The biopsychosocial model (a term first formally proposed by George Engel in 1968) brings together core elements of staying healthy and recovering well from injury or disease (Stone et al., 1987). Each individual—due to a combination of biological influences and psychosocial experiences—is more or less likely to thrive. Some of this variation is due to genetics and early life development; some depends on the availability and appropriate applications of medical treatments; some involves nutrition and physical activity; some depends on preparations for, perceptions of, and reactions to life's challenges; and some involves exposure to or seeking out of healthier or unhealthier environments, both physically and socially. When presented in this way, it might seem obvious that health should certainly be viewed in this broader interdisciplinary way. However, by misdirecting its vast expenditures on health care, the United States gives its residents mediocre health at high cost (Kaplan, 2019). To approach these matters in a thorough manner, this encyclopedia includes four volumes, with Volume 1 focusing on the biological bases of health and health behavior, Volume 2 concentrating on the social bases, Volume 3 centering around the psychological and clinical aspects, and Volume 4 focused more broadly on crosscutting and applied matters.

Key parts of health depend on biological characteristics and how they interact with our experiences and environments. So, for example, in Volume 1, there are articles on injury to the brain, alcohol effects on the brain, nutrition, drug abuse, psychophysiology, and the tools and key findings of neuroscience. Note that even individuals with the same genes (identical twins) can and do have different health and recovery outcomes, and the articles delve into such complexities of health. Of course humans are also social creatures, and people's growth, development, and health behaviors take place in social contexts. So, in Volume 2, there are articles on such fundamental matters as social support, coping, spirituality, emotion, discrimination, communication, psychosocial stress, and bereavement.

Because our approaches to and conceptions of health are heavily influenced by society's institutions and structures revolving around medical care, much of health psychology derives from or intersects with clinical psychology and applied behavioral medicine. Volume 3 covers such clinical topics as psycho-oncology, depression, drug abuse, chronic disease, eating disorders, and the psychosocial aspects of coronary heart disease. Finally and importantly, there are a number of special and cross-cutting matters that are considered in Volume 4, ranging from relevant laws and regulations to telehealth and health disparities. Taken together, the articles triangulate on what it truly means to be healthy.

What are the most promising directions for the future that emerge from a broad and deep approach to health? That is, to where do these encyclopedia articles point? One key clue arises from a unique opportunity to enhance, extend, and analyze the classic Terman study of children who were followed and studied throughout their lives (Friedman & Martin, 2012). These studies revealed that there are lifelong trajectories to health, thriving, and longevity. Although anyone can encounter bad luck, a number of basic patterns emerged that are more likely to lead to good health. That is, for some individuals, certain earlier life characteristics and circumstances help propel them on *pathways* of healthier and healthier behaviors, reactions, relationships, and experiences, while others instead face a series of contingent stumbling blocks. There are multipart but nonrandom pathways across time linking personalities, health behaviors, social groups, education, work environments, and health and longevity. The present encyclopedia necessarily is a compendium of summaries of the relevant elements of health and thriving, but one that would and can profitably be used as a base to synthesize the long-term interdependent aspects of health.

In sum, this encyclopedia is distinctive in its explicit embrace of the biopsychosocial approach to health, not through lip service or hand-waving but rather through highly detailed and extensive consideration of the many dozens of topics crucial to this core interdisciplinary understanding.

Preface Volume 1: Biological Bases of Health

The field of health psychology is a specialty area that draws on how biology, psychology, behavior, and social factors influence health and illness. Despite the fact that the formal recognition of the field is only about a half of a century old, it has established itself as a major scientific and clinical discipline. The primary reason for this is that there have been a number of significant advances in psychological, medical, and physiological research that have changed the way we think about health, wellness, and illness. However, this is only the tip of the iceberg.

We have the field of health psychology to thank for much of the progress seen across our current healthcare system. Let me provide some examples that illustrate the diversity of these important contributions. Starting with a broad public health perspective, health psychologists have been involved in how our communities are planned and how urban development has a significant and direct impact on our health behaviors. That is, if we live close to where we work, play, and shop, we are more likely to walk or bike to our destination rather than drive or take public transportation. Focusing on a smaller, but no less important, source of data, health psychologists are involved in using information obtained from our genes to help counsel individuals to make good, well-informed health decisions that could have an impact on the individual immediately or in the future. Being well-informed can direct a person toward the best possible path toward wellness, whether it be measures aimed at prevention, further monitoring, or intervention.

Of course, there are many other contributions. For instance, data indicates that several of the leading causes of death in our society can be prevented or delayed (e.g., heart disease, respiratory disease, cerebrovascular disease, and diabetes) via active participation in psychological interventions. Knowing that we can improve health status by changing our behaviors seems like an easy "fix," but we know that behavior change is tough. As such, it is not surprising that health psychologists have been involved in trying to improve upon treatment success by examining patient compliance. When we better understand what motivates and discourages people from engaging in treatment or pro-health behaviors, we can improve upon compliance and help individuals adopt more healthy lifestyles. Health psychologists have also played a role in shaping healthcare policy via identifying evidence-based treatments. This work has direct effects on how individuals receive healthcare as well as what treatments are available/reimbursable by insurance companies. Finally, there are also factors beyond medical care to consider (e.g., economic, educational) that can lead to differential health outcomes. Thus, health psychologists likewise examine ways to reduce health disparities, ensuring that the public and government officials are made aware of the impact of the social determinants of health.

I could go on and on, however, examples like this illustrate the significant impact this broad and exciting field has had (and will continue to have) on our understanding of health and wellness. Given the constantly changing nature of the field, it is not possible to be all inclusive; however, the aim of these four volumes is to provide readers an up-to-date overview of the field. Each entry is written to stand alone for those who wish to learn about a specific topic, and if the reader is left wanting more, suggested readings are provided to expand one's knowledge. Volume I, ***Biological Bases of Health Behavior,*** includes entries that cover topics in the broad areas of neuroscience and biopsychology relevant to health behavior. General topics include degenerative and developmental conditions, emerging methodologies available in clinical research, functional anatomy and imaging, and gene × environment interactions. Volume II, ***Social Bases of Health Behavior,*** addresses topics related to theories and concepts derived from social psychology. Specifically, topics related to the self, social cognition, social perception, attitudes and attitude change, perception, framing, and pro-health behaviors are included. Volume III, ***Clinical Health Psychology and Behavioral Medicine,*** covers the applied aspects of the field of health psychology including practical topics that clinical health psychologists face in the workplace, behavioral aspects of medical conditions, the impact of unhealthy behaviors, and issues related to the comorbidity of psychiatric disorders and chronic health concerns. Finally, Volume IV, ***Special Issues in Health Psychology,*** contains a wide array of topics that are worthy of special consideration in the field. Philosophical and conceptual issues are discussed, along with new approaches in delivering treatment and matters to consider when working with diverse and protected populations.

It is my sincere hope that the *Wiley Encyclopedia of Health Psychology* will serve as a comprehensive resource for academic and applied psychologists, other health care professionals interested in the relationship of psychological and physical well-being, and students across the health professions. I would very much like to thank and acknowledge all those who have made this work possible including Michelle McFadden, the Wiley editorial and production teams, the volume editors, and of course all of the authors who contributed their outstanding work.

Preface Volume 1: Biological Basis of Behavior

The chapters of this volume focus on the neural and molecular mechanisms of the biopsychosocial model of behavioral health. The work detailed herein is timely, as the scientific pendulum is shifting away from the long-standing research aimed at dismantling complex clinical phenotypes into biological components as the pathway to discover biological mechanisms. The common reductionistic approach has yielded no curative strategies for children and adults affected by the most vexing neuropsychiatric and neurodegenerative conditions. At the same time, a worsening incidence of behavioral health disorders and associated reductions in health-adjusted life expectancies worldwide raises concern that behavioral health conditions represent a looming global health crisis.

This volume summarizes the current state of science on the biological bases of behavioral health, with a focus on advanced conceptual models that prioritize the integration of numerous biological, psychological, and sociocultural interdependencies inherent to developmental conditions (e.g., autism spectrum disorder, Down syndrome, language-based learning disorder), contextual factors that alter neurodevelopmental trajectories (e.g., obesity, illicit drug use, psychosocial stress, traumatic brain injury, infectious disease), and age-related neurodegenerative conditions (e.g., cerebrovascular disease, Alzheimer's disease). Technological advances are reviewed, including neuroimaging methods capable of visualizing the anatomical and physiological basis of behavioral health disorders that have high potential to improve diagnostic classification and monitoring of patient care outcomes (i.e., precision medicine).

Technologies and computational innovations introduced during the past three decades following the "Decade of the Brain" in 1990 and completion of the Human Genome Project in 1993 offer a viable path to create much needed scientific breakthroughs that are difficult to achieve using traditional research methods designed more to confirm hypotheses than to foster new insights and discovery. Data science offers a new opportunity to identify nonlinear and linear patterns and highly dimensional interactions across explanatory variables that more accurately model the intrinsic features of the biopsychosocial determinants of behavior. Combined with new advances in diagnostic technologies (e.g., ligands for positron emission tomography) and intervention strategies (e.g., transcranial magnetic stimulation), the current scientific momentum has potential to transform behavioral health outcomes on a global scale.

Editor-in-Chief Acknowledgments

I would like to publicly recognize and thank my family, Michelle, Ross, Rachel, and Becca for being supportive of my work life while also providing me with a family life beyond my wildest dreams. I love you all very much. I would also like to note my great appreciation and thanks to the faculty and staff of the Doctoral Training Program in Clinical Psychology at Oklahoma State University for providing me with an opportunity to expand my education and for providing extraordinary training. In particular, I would like to thank my late mentor Dr. Frank L. Collins Jr., Dr. Larry Mullins, Dr. John Chaney, and Patricia Diaz Alexander. Further, I am grateful to the University of Mississippi and Texas Tech University (and the colleagues and students I have had the privilege to work alongside) for affording me excellent working environments and the support to do the work I am honored to be a part of. Finally, I would like to recognize and thank the volume editors for their vision and perseverance to this project as well as to each of the contributors for their excellent entries and their dedication to this very important field.

Brain Gray Matter and White Matter Development

The development of the central nervous system (CNS) begins approximately 17 days after conception. Arranged in a flat disk with three layers, the cells that comprise the topmost layer, the ectoderm, forms the neural plate and provides the foundation of the developing nervous system. Within 22–25 days after conception, the cells of this plate fold into a groove that forms the neural tube, the precursor to the brain and spinal cord. Subsequent development leverages a pool of undifferentiated cells that lack functional specificity until the cells migrate to predetermined regions. This process is guided by progenitor cells that release attraction molecules to guide the formation of new synapses. Beyond the first year of life, brain cells undergo ongoing refinement of existing connections (Institute of Medicine and National Academy of Sciences, 1992) and programmed cell death to eliminate connections that are not regularly activated.

In a comprehensive review, Sowell et al. (2003) describes the discordant pattern of gray and white matter development across the lifespan. Gray matter volumes increase exponentially during infancy until about 18 months after birth, when the rate continues to increase, albeit more slowly, until the late 20s. Peak gray matter volume is generally achieved in the third decade followed by progressive reductions in volume thereafter. By contrast, the volume of white matter increases into the fourth decade followed by progressive decline. Given the difference in developmental maturation of the gray and white matter, total brain volume is a poor index of brain integrity, especially during the third and fourth decade.

The brain accounts for 2–3% of total body mass while consuming 20% of total glucose needs. These demands are even greater from birth through late adolescence. The metabolic rate of glucose in the brain (CGMR) doubles from birth to 6 months, with a fourfold increase

from birth through the second year of life. Glucose needs remain high until adolescence, with peak levels accounting for almost half of the total energy needs of the body (Goyal & Raichle, 2018). These data underscore the high resource demands of the developing brain in children and adolescents (Kuzawa et al., 2014).

Critical Time Windows of Brain Development

Development does not occur in a vacuum. Genetic, epigenetic, and environmental factors (Bale, 2015; Fox, Levitt, & Nelson, 2010) are potentially powerful moderators of neurodevelopment. During prenatal development, environmental factors can produce permanent damage to brain structure and connections. Preliminary research suggests that targeted interventions applied during the first years of life have potential to mitigate these deleterious abnormalities, but the durability of treatment outcomes remains unclear.

Many studies indicate that the prenatal environment strongly influences development, particularly maternal stress and immunity. A recent review by Lindsay, Buss, Wadhwa, and Entringer (2018) identifies associations between maternal anxiety, depression, elevated stress hormones, and alterations in both brain structure and function. Maternal diet may have a protective effect on prenatal development. Preliminary data indicate a link between certain high fat diets and reduced maternal stress. Additionally, an antioxidant-rich diet may also mitigate the effects of maternal stress on fetal brain development. Similarly, diets high in antioxidants, nutrients, and certain fatty acids (polyunsaturated), along with exercise and engagement in mental activities, can stimulate adult neurogenesis (Poulose, Miller, Scott, & Shukitt-Hale, 2017).

A sensitive developmental window also occurs around ages 5–7, a time when many children residing in resourced countries are exposed to new pathogens and social stressors at school. During puberty, a great deal of physical and chemical change is taking place in the body. Some brain regions are nearing maturity, whereas others are continuing to undergo dynamic change. Early adolescence is considered the end of a critical period for language acquisition. However, the frontal and prefrontal cortices that mediate reasoning and judgment are still developing. These structures are particularly sensitive to alcohol and drugs both in terms of damage and increased propensity for substance use disorders in adulthood. Early adulthood represents yet another sensitive period, as realized by the onset of chronic mental illness during the second to third decade of life (e.g., schizophrenia).

Moderating Factors of Brain Development

The impact of the gut microbial environment on brain health has been a fairly recent area of study. Research with germ-free mice suggests altered neurogenesis in a number of brain structures relative to a control group. In both the hippocampus and the amygdala, the resulting alterations consist of increased volumes as the result of increased neurogenesis; however, in the hippocampus, fewer dendritic spines were observed, whereas there were more spines evident in the amygdala of germ-free mice. Additionally, hypermyelination in the prefrontal cortex has also been reported in germ-free mice. In addition to effects on brain structure, some bacteria have the ability to synthesize neurotransmitters (NTs). As examples, *Lactobacillus* and *Bifidobacterium* are able to synthesize gamma-aminobutyric acid (GABA), and norepinephrine has been produced by species of *Escherichia*, *Bacillus*, and *Saccharomyces.* Other species, such as *Bifidobacterium infantis*, may indirectly influence serotonin levels by increasing the levels of precursor molecule, tryptophan. A strong empirical base is emerging that implicates the gut–brain axis in numerous brain disorders including anxiety, autism, schizophrenia, Alzheimer's disease, and Parkinson's disease (for review see Dinan & Cryan, 2017).

Another recent and active area of research examines the role of microglia in brain development and pathology. Microglia function as the immune cells of the nervous system, activating in the presence of injury or inflammation. Microglia facilitate the clearing of toxins and dying cells and support neurodevelopmental processes including modulation of neuronal apoptosis, cell proliferation, and synaptic activity. In studies of schizophrenia and autism, elevated levels of activated microglia have been observed, along with evidence of perturbations in brain development. As with numerous other factors, it is unclear whether this abnormal microglia activity is responsible for altered brain development or whether the microglia are responding to other insults that have negatively impacted neurodevelopment (Bilimoria & Stevens, 2015).

In this chapter we have reviewed the growth and development of the human brain, critical or sensitive periods in brain development, discordant gray and white matter maturation, and factors that influence neurodevelopment. The research literature in these areas is continuing to evolve to produce more complete explanatory models of brain development. Considerable research is needed on therapeutic targets to mitigate the negative effects of moderating factors on development to improve brain health across the lifespan.

Functional Anatomy: Types of Cells/Physiology

Neurons

Neurons are the primary fundamental unit of the central nervous system (CNS) and provide the infrastructure for all major communication within the brain. Grossly, typical neuron morphology consists of a cell body (soma), dendrites, and axons. The soma contains the nucleus and other organelles. Arising from the cell body is the arborization of dendrites, which act as the primary synaptic target from other neurons. The axon is a long projection from the soma that communicates integrated information from the dendrites and acts on a downstream synapse. In humans, neurons can be classified by the number of processes that extend from the soma: bipolar, multipolar, and pseudounipolar neurons. Bipolar neurons have one axon and one dendrite that extend from the soma and can be found in the visual pathway (e.g., retinal bipolar cells). Multipolar neurons (e.g., Purkinje cells in the cerebellum) have one axon and multiple dendrites; they are the most common type found in the CNS. Pseudounipolar neurons have one soma process that bifurcates into two branches. Most sensory neurons are pseudounipolar. Neurons can be further classified by their context-dependent structure determined by the neural circuit in which they participate. Interneurons, or local circuit neurons, have relatively short axons, whereas projection neurons have axons that extend to distant targets (Nicholls, Martin, Wallace, & Kuffler, 2001; Purves, 2008).

The Synapse

The interface between neurons where information is transferred is known as the synapse, which consists of the axon terminal of the presynaptic cell, the intermediate extracellular space (the synaptic cleft), and the postsynaptic cell. The axon of presynaptic cell is not limited to forming

synapses with only the dendritic projection of the postsynaptic cell. Instead, axosecretory (axon–bloodstream), axoaxonic (axon–axon), axodendritic (axon–dendrite), and axosomatic (axon–soma) are examples of alternative synaptic interfaces. Formed synapses are primarily classified by the mode of information transfer: chemical synapses and electrical synapses (Nicholls et al., 2001; Purves, 2008).

Synaptic Transmission

Electrical synapse

Electrical transmission at electrical synapses is mediated by gap junctions, which are channels that connect the intracellular space and cytoplasm of adjacent cells. Electrical synapses are inherently bidirectional, enabling the passage of electrical currents (carried by ions) as well as intracellular messengers to and from the postsynaptic cell. Each gap junction channel (connexon) is made up of a pair of hexameric connexin proteins (e.g., connexin 36 [CX36], CX50), with each cell providing one of the pair. These gap junctions allow passive ionic current flow, providing an almost instantaneous route of transmission (Nicholls et al., 2001; Pereda, 2014; Purves, 2008).

Chemical synapse

Chemical synapses are the most common type of synapse. Information transfer at chemical synapses is facilitated by presynaptic synaptic vesicles containing neurotransmitters. Action potentials, most often originating at the "neck" of the axon (known as the axon hillock) where it connects to the neuronal soma, propagate down the length of the axon to the axon terminals. Myelin sheaths provided by neighboring oligodendrocytes are insulating adipose tissue that improve conductance rate by constraining electrochemical gradient-associated depolarization to occur at the gaps between sheaths known as nodes of Ranvier; "white matter" is so named due to the white appearance of these myelin sheaths on axons. When the action potential arrives at the axon terminal, it activates voltage-gated calcium (Ca^{2+}) channels that are present along the presynaptic membrane. The subsequent influx of Ca^{2+} along its concentration gradient ($[Ca^{2+}]_e \approx 1–2\,\text{mM}$, $[Ca^{2+}]_i \approx 0.0001$) enables vesicle fusion to the presynaptic membrane. These vesicles contain neurotransmitters that can then be exocytosed into the synaptic cleft. Released neurotransmitters will diffuse across the synaptic cleft via Brownian motion to the postsynaptic membrane containing metabotropic and ionotropic receptors; information transfer via this mechanism is inherently probabilistic, in contrast to electrical transmission via gap junctions as occurs at electrical synapses (Nicholls et al., 2001; Pereda, 2014; Purves, 2008).

Synaptic vesicle exocytosis and recycling

SNARE (soluble *N*-ethylmaleimide-sensitive factor [NSF] attachment protein receptor) protein complexes at the vesicle (v-SNARE) and membrane (target-localized, t-SNARE) enable docking of the vesicle to the inner membrane surface following binding of Ca^{2+} to the Ca^{2+}-sensing vesicular protein synaptotagmin-1, enabling neuroexocytosis. The three-vesicle pool model describes a reserve pool consisting of 80–90% of the total pool of vesicles, a recycling pool with 10–15%, and the readily releasable pool (RRP) at the active zone, the portion of the presynaptic membrane where vesicle exocytosis occurs that faces the postsynaptic density, with only 1–2% of the total vesicle population. The vesicles in the RRP are docked and primed (i.e., SNARE complex has formed) and are ready for fusion and neurotransmitter exocytosis in $\ll 1\,\text{s}$ in the presence of Ca^{2+}. The vesicles of the recycling and reserve pools will release their neurotransmitter on the order of seconds to minutes and in response to moderate to intense (e.g., 5–10 Hz in frog neuromuscular junction or 30 Hz in *Drosophila* larval neuromuscular junction) stimulation frequencies. The synaptic vesicle cycle consists of the endocytosis and subsequent recycling of vesicles that have bound to the presynaptic membrane and released neurotransmitter. This endocytosis of incorporated synaptic vesicles can be clathrin mediated for fully fused membranes or can consist of direct retrieval and recycling for vesicles that did not fuse completely for exocytosis ("kiss and run" fusion) (Gundelfinger, Kessels, & Qualmann, 2003; Kavalali, 2015; Nicholls et al., 2001; Purves, 2008; Rizzoli & Betz, 2005).

The action potential

The electrical signals that propagate over distances within the CNS and enable neurotransmitter release are called action potentials. Action potentials are an all-or-nothing event that are a consequence of the transmembrane electrochemical gradient of local sodium (Na^+) and potassium (K^+) ions. Prior to the evocation of an action potential, when the cell is at rest, resting membrane potential is ~–65 mV (range: ~–40 to –90 mV). At equilibrium, there is higher extracellular Na^+ concentration than intracellular ($[Na^+]_e \approx 145$ mM, $[Na^+]_i \approx 5$–15 mM) and higher intracellular K^+ concentration than extracellular ($[K^+]_e \approx 5$ mM, $[K^+]_i \approx 140$ mM). The resting membrane is most permeable to K^+ compared with other ions, underlying the resting membrane potential being close to the equilibrium potential of K^+ (~–58 mV).

When a threshold potential is reached that is depolarized relative to rest (~–50 vs. ~–65 mV), an action potential is triggered. Voltage-gated Na^+ channels open, allowing an influx of Na^+ into the cell along its electrochemical gradient; this is the primary depolarization phase of the action potential. Spike amplitude will peak at around ~+25 mV before the repolarization phase begins, in which voltage-gated Na^+ channels are beginning to inactivate and voltage-gated K^+ channels are opening. This efflux of K^+ repolarizes the membrane potential to resting potential and overshoots it due to the slow closing of these channels. The shape and timing of action potentials can vary considerably across cell types, but the typical total duration of an action potential is 2–5 ms. Finally, Na^+/K^+-ATPase, an active transporter pump that relies on energy from the hydrolysis of ATP, actively pumps 3 Na^+ out of the cell for every 2 K^+ brought in to return the cell to steady-state resting potential and establish the electrochemical gradients necessary to facilitate subsequent action potentials (Bean, 2007).

Following an action potential, the neuron enters a refractory period, in which it is either impossible (the absolute refractory period, initial ~1 ms following action potential) or more difficult (the relative refractory period, ~2–4 ms following the absolute refractory period) to attain threshold. This is due to the initial depolarization causing in the delayed action of K^+ channels and inactivation of Na^+ channels. This period of enforced silence limits the highest frequency of action potential occurrence (Nicholls et al., 2001; Purves, 2008).

Excitatory and inhibitory postsynaptic potentials

Small induced potential differences at the individual synapse level are known as postsynaptic potentials and are defined by the manner in which they affect the probability of action potential production. Excitatory postsynaptic potentials (EPSPs) increase the likelihood of action potential occurrence, whereas inhibitory postsynaptic potentials (IPSPs) decrease it. Generally, EPSPs and IPSPs can be differentiated by where their reversal potential, the potential at which current polarity is reversed, is relative to action potential threshold. For example, a net flow of cations causing depolarization (e.g., flow of Na^+/K^+) upon activation of an *N*-methyl-D-aspartate (NMDA) glutamate receptor will have a reversal potential that is depolarized relative to resting membrane potential (e.g., 0 mV compared to –60 mV), inducing a depolarization that increases the probability of threshold being achieved. Alternatively, a hyperpolarizing inward flow of anions (e.g., chloride [Cl^-]) due to a reversal potential that is more negative than resting potential will drive an IPSP and a reduction in likelihood that threshold will be achieved. It should be noted that a depolarizing flow of ions will still drive an IPSP if its reversal potential is negative relative to threshold potential, despite being positive relative to resting potential. It is the cumulative contribution of incident EPSPs and IPSPs from all synapses received by the postsynaptic cell, integrated spatially and temporally, that determines if membrane potential threshold is achieved and an action potential evoked (Nicholls et al., 2001; Purves, 2008).

Ionotropic and Metabotropic Receptors

Ionotropic receptors across the synaptic cleft at the postsynaptic membrane serve as ligand-gated ion channels. These allow for direct synaptic transmission driven by the binding of released presynaptic neurotransmitters. Metabotropic receptors, on the other hand, typically act through second messenger systems such as GTP-binding proteins (G-proteins) and are thus considered “slow” and indirect. These receptors are not themselves ion channels, as in the case of ionotropic receptors, and instead can modify the activity of ion channels or receptor proteins. G-protein-coupled receptors (GPCRs) can also commonly act at the level of gene expression, modulating transcription through, for example, the cyclic AMP-protein kinase A pathway (Nicholls et al., 2001; Purves, 2008).

Neurotransmitters

The chief low-molecular-weight (non-peptide) CNS neurotransmitters can be delineated in three ways: the biogenic amines, amino acids, and acetylcholine. A single neuron can release multiple neurotransmitters, often at least one low-molecular-weight neurotransmitter as well as neuropeptides. Among the biogenic amines or monoamines include the catecholamines, which are derived from tyrosine and defined by the possession of a benzene ring with two adjacent hydroxyl groups: dopamine, norepinephrine (NE, noradrenaline), and epinephrine (adrenaline). Another class of biogenic amine is the tryptophan-derived 5-hydroxytryptamine (5-HT, serotonin), an indoleamine (containing a benzene ring fused with a pyrrole ring). Relatively few neurons in the CNS release these biogenic amines, and most are localized to nuclei in the brain stem. The amino acid neurotransmitters include glycine, glutamate, and γ-aminobutyric acid (GABA). A key component of synaptic transmission via neurotransmitter is clearance of transmitter from the synaptic cleft. This can be done by diffusion, degradation (e.g., acetylcholinesterase is an enzyme that hydrolyzes ACh to choline and acetate), or reuptake by glia or nerve terminals (Nicholls et al., 2001; Purves, 2008).

Glutamate

Glutamate is an amino acid that serves as the primary excitatory neurotransmitter of the CNS. The four classes of glutamate receptors are NMDA, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), kainate, and metabotropic glutamate receptors (mGluRs). The ionotropic channels are all nonselective cation channels, which enable consistent production of excitatory postsynaptic responses. The mGluRs are slower and can either increase or decrease postsynaptic excitability. Increased glutamate concentrations have been associated with depression and bipolar disorder. Elevated glutamate at the synaptic cleft, for example, following neural injury such as status epilepticus, trauma, or ischemic stroke, can be excitotoxic and lead to the destruction of postsynaptic neurons (Nicholls et al., 2001; Purves, 2008; Raiteri, 2006).

GABA

GABA and glycine are amino acids that are the principal inhibitory neurotransmitters in the CNS. The primary target receptors of GABA are $GABA_a$ receptor ($GABA_aR$) and metabotropic $GABA_bR$. $GABA_aR$ preferentially permits flow of Cl^- ions (anions). Extracellular Cl^- concentration is greater than intracellular concentration ($[Cl^-]_e \approx 110\,mM$, $[Cl^-]_i \approx 4–30\,mM$), so Cl^- enters and consequently hyperpolarizes the cell, decreasing the likelihood of threshold potential being achieved and an action potential produced. Presynaptic $GABA_bR$ receptors suppress the activity of voltage-gated Ca^{2+} channels, while postsynaptic $GABA_bR$ receptors activate inward rectifier K^+ channel. $GABA_aR$ is unique in that it is sensitive to allosteric modulation. These receptors have binding sites that act as targets for anti-anxiety benzodiazepines (e.g., diazepam [Valium] and chlordiazepoxide [Librium]) and anticonvulsant barbiturates (e.g., phenobarbital) (Nicholls et al., 2001; Purves, 2008; Raiteri, 2006).

Dopamine

Dopamine is both an excitatory and inhibitory (dependent on target receptor) catecholamine with five identified metabotropic receptors ($D_{1–5}$). Dopamine-containing nuclei and their projections are involved in regulating selection and execution of motor behaviors, problem solving, regulation of emotion, response to reward, and motivation. It is because of the influence of these pathways that antipsychotics for treating schizophrenia and bipolar disorder target dopamine receptors (e.g., aripiprazole [Abilify], a partial agonist of the D_2 receptor, and olanzapine [Zyprexa], a D_2 antagonist). Furthermore, the degeneration of dopaminergic neurons in the pars compacta of the substantia nigra is the defining feature of Parkinson's disease. A reduction of presynaptic dopaminergic axon terminals drives a loss of dopamine in the basal ganglia, leading to downstream motor disorders such as difficulty in initiating movement and tremor at rest. L-DOPA, the precursor for dopamine, can be used pharmacologically to improve dopamine concentrations and reduce associated motor deficits (Nemeroff & Owens, 2002; Nicholls et al., 2001; Purves, 2008; Raiteri, 2006; Schatzberg & Nemeroff, 2009).

Serotonin

Serotonin is a predominantly excitatory monoamine (indoleamine) neurotransmitter. All serotonin (5-HT) receptors except for the cation-selective ionotropic $5\text{-}HT_3$ receptor are metabotropic. Serotonin receptors can act broadly and influence activity across the cortex by modulating the release of many neurotransmitters (e.g., glutamate, GABA, ACh) through inhibition, facilitation, or stimulation of specific neurotransmitter exocytosis by a postsynaptic neuron. Serotonin projections originate at the raphe nuclei of the midbrain. Serotonergic neurons are involved with arousal and the sleep–wake cycle, mood, aggression, and the establishment of social dominance. The monoamines, including 5-HT, are the primary neurotransmitters implicated in depression. Pharmacotherapy via antidepressants acts by either inhibiting monoamine oxidase, which degrades monoamine neurotransmitters and excites or inhibits pre-/postsynaptic receptors that regulate neurotransmitter release and neuronal firing rates, or by blocking presynaptic monoamine transporter proteins (which remove neurotransmitter from the synaptic cleft). Examples of this final class of antidepressants include selective serotonin reuptake inhibitors (SSRIs) (e.g., fluoxetine [Prozac] and citalopram [Celexa]) and serotonin–norepinephrine reuptake inhibitors (SNRIs) (e.g., duloxetine [Cymbalta] and venlafaxine [Effexor]) (Nemeroff & Owens, 2002; Nicholls et al., 2001; Purves, 2008; Schatzberg & Nemeroff, 2009).

Acetylcholine

Acetylcholine (ACh) is an excitatory small-molecule neurotransmitter that is involved with memory, learning, and cognitive performance. Cholinergic neurons project from the basal forebrain nucleus and innervate most of the cortex. Cholinergic receptors are classified based on their responsiveness to nicotine ("nicotinic" acetylcholine receptor [nAChR]) or muscarine ("muscarinic" acetylcholine receptor [mAChR]). nAChRs are cationic ionotropic receptors, whereas mAChRs are metabotropic. nAChRs are preferentially impacted by amyloid-beta plaque deposition in Alzheimer's disease (AD) (compared with mAChRs), more so than the effects seen due to normal aging, providing a potential therapeutic target for AD-associated cognitive decline. AD patients are currently often prescribed drugs that are acetylcholinesterase inhibitors (e.g., donepezil [Aricept]), thus increasing the concentration of ACh (Nicholls et al., 2001; Purves, 2008; Raiteri, 2006; Sadigh-Eteghad, Majdi, Talebi, Mahmoudi, & Babri, 2015).

Norepinephrine and Epinephrine

Norepinephrine (noradrenaline) and epinephrine (adrenaline) are excitatory catecholamines that share metabotropic noradrenergic receptors (α and β receptors). The primary source of norepinephrine in the brain is the locus coeruleus in the brain stem. Norepinephrine is involved with dysphoria, fatigue, apathy, and cognitive dysfunction. It regulates circadian patterns of melatonin synthesis in mammals. Epinephrine has the lowest concentration in the brain among the catecholamines and is found in the fewest neurons. No plasma membrane transporter specific for epinephrine has been identified. Epinephrine plays an important role in driving a sympathetic response in autonomic nervous system, but it also is involved in memory consolidation within the CNS (Cahill & Alkire, 2003; Nicholls et al., 2001; Purves, 2008; Raiteri, 2006; Schatzberg & Nemeroff, 2009).

Glia

In addition to neurons, a family of non-neuronal support cells, called glia, are present in the CNS. In the combined cortical gray and white matter, glia are more numerous, outnumbering neurons by >3.5 : 1 (Azevedo et al., 2009). Additionally, they lack axons and have more negative resting potentials (–90 vs. ~–65 mV) compared with neurons. Glia are involved with maintaining ion concentrations in the neuropil, regulating the uptake of neurotransmitters at or near the synaptic cleft, and controlling rate of action potential propagation among other support roles. Also, glial cells react to neuronal injury by replication and will propagate and occupy the injured area after all cellular debris has been removed. They can then secrete the extracellular matrix glycoprotein laminin to encourage neurite outgrowth or neoangiogenesis, for example, after ischemic stroke (Ji & Tsirka, 2012). The primary glial cell types are oligodendrocytes, microglia, ependymal cells, radial glial cells, and astrocytes (Nicholls et al., 2001; Purves, 2008).

Oligodendrocytes, Microglia, Ependymal Cells, and Radial Glial Cells

Oligodendrocytes are primarily found within white matter regions in the brain where they form myelin sheaths around neuron axons. This subsequently aids in increasing speed of electrical transmission. Microglia are phagocytic, specialized macrophages that are involved in scavenging and clearing debris from sites of injury or normal cell turnover. They can release cytokines as part of an inflammatory response as well as prune synapses by monitoring synaptic transmission. Ependymal cells form an epithelial layer in CNS ventricular spaces. Their apical surfaces have cilia that circulate cerebrospinal fluid (CSF) in the ventricles. Modified ependymal cells, joined by gap junctions, surrounding a core of capillaries and connective tissue collectively make up the choroid plexus, which produces CSF. Finally, radial glial cells act to guide neuronal migration during development; their processes act as physical tracks that migrating neurons traverse along toward their target region and synapse (Fields et al., 2014; Nicholls et al., 2001; Purves, 2008).

Astrocytes

Astrocytes interface with neurons and capillaries and can ensheath thousands of synapses. The two chief morphological classifications of astrocytes are fibrous and protoplasmic astrocytes. Fibrous astrocytes contain filaments and are found primarily within white matter. Their end feet envelop nodes of Ranvier. Protoplasmic astrocytes are abundant in gray matter and have end feet that surround synapses. Astrocytes serve a number of different functions in the CNS. They are involved with neurovascular coupling and can control local blood flow through release of arachidonic acid derivatives that can act on smooth muscle surrounding oxygen-supplying arterioles to either constrict or dilate vessel diameter (Attwell et al., 2010). Astrocytes also modify the concentration of extracellular K^+, neurotransmitters, and neuromodulatory substances. They can also modify the volume and geometry of the immediate extracellular space (Fields et al., 2014).

The cerebrum, also known as the forebrain, is the largest area of the mammalian brain and the most recently developed in evolutionary history. Consisting of all brain structures above the cerebellum, the cerebrum is further divided into the cerebral cortex, the brain's convoluted outer surface, and the subcortical structures beneath. The cerebrum is responsible for the higher order processes that give rise to thought, emotion, and sensory experiences.

The structures of the cerebral cortex are central to processing sensory, motor, and perceptual information. These structures are intricately connected, allowing information from disparate processing streams to combine, producing a harmonized response within a dynamic environment. The coordination between cortical and subcortical structures occurs via networks of feedback loops designed to process continuously updated sensory information. To understand the coordination between subcortical structures and different regions of the cortex, we will describe the connections between the subcortical nuclei and the cortical–subcortical feedback loops.

The Thalamus

The thalamus is a pivotal structure involved in coordinating communication between the cortex and subcortex. With the notable exception of olfaction, the thalamus is the first destination for all sensory information, earning its title as the "relay station" of the brain. The thalamus is divided into nuclei dedicated to processing sensory information and relaying information back to the relevant cortical areas. As an example, visual information initially travels from

the retina to the lateral geniculate nucleus (LGN) of the thalamus, where it is subsequently transmitted to the primary visual cortex of the occipital lobe. As described further in the chapter, the thalamus also processes incoming information from other subcortical structures.

Basal Ganglia

The basal ganglia consist of a cluster of subcortical nuclei, including the striatum, the globus pallidus, ventral pallidum, substantia nigra, and subthalamic nucleus (STN). The striatum is divided into four nuclei: the caudate and putamen (dorsal striatum) and the nucleus accumbens (NAcc) and olfactory tubercule (ventral striatum). The dorsal and ventral striatal regions are innervated by both cortical and subcortical afferents. The caudate has been described as having a critical role in planning and execution of goal-directed behavior (Grahn, Parkinson, & Owen, 2008). A recent functional connectivity study described an age-related reduction in differentiation of connections between the caudate and cortical networks. Specifically, caudate areas in younger adults were connected to the frontal parietal control network (FPN), whereas these same areas were connected to the default network (DN) in older adults. This difference in connectivity is related to memory decline in adults over the age of 75. This same study also reported that reduction dopamine transporter density in the striatum predicted memory decline in older adults (Rieckmann, Johnson, Sperling, Buckner, & Hedden, 2018).

The putamen is interconnected with the primary motor, primary somatosensory area, and premotor cortex. As such, damage observed in the putamen results in movement disorders. A recent study determined that children with complex motor stereotypies (repetitive and rhythmic movements) displayed diminished size of the putamen compared with controls (Mahone et al., 2016). Additionally, connections between the cerebellum and the putamen are active in parallel with the putamen to primary motor cortex, likely coordinating the sequence and learning of motor movements (Penhune & Steele, 2012). The internal capsule, a dense white matter tract that carries sensory and motor information from the spinal cord to the frontal cortex, separates the caudate and putamen. Lesions in the internal capsule commonly result in motor impairments, though the location of the lesion may produce variations in symptomatology. Lesions in the internal capsule resulting from stroke are associated with poorer recovery (Kobayashi et al., 2015).

The nuclei of the ventral striatum—the NAcc and the olfactory tubercle—are involved in components of behavioral reinforcement. The olfactory tubercle is located in both the ventral striatum and the olfactory cortex and, despite its name, does not appear to have a role in olfaction. The NAcc is often referred to as the "pleasure center" of the brain; however, recent research has characterized the function of the NAcc a bit differently. NAcc function is related to motivated actions toward relevant stimuli and suppression of actions that would deter unsuitable actions (Floresco, 2015). The structures of the ventral striatum are strongly coactive with the limbic system, a network of cortical and subcortical circuits that process emotions and episodic memories, implicating the role of emotion and memory in the development and maintenance of motivational behaviors.

Globus Pallidus

The globus pallidus is composed of the internus (GPi) and the externus (GPe) regions. The GPi receives inputs from both the excitatory direct path via the striatum and inhibitory, indirect path via the STN. Inputs from the striatum inhibit the activity of the GPi, preventing the release of gamma-aminobutyric acid (GABA) from GPi to the thalamus. The GPi is a target for deep brain stimulation of dystonias or movement disorders that produce uncontrolled contractions of muscles that result in irregular twisting and abnormal postures. The GPe once thought to have a singular function of suppressing motor activity via inputs from the STN recently has been described as having diversified projections through distinct subconnections (Gittis et al., 2014). The GPe is a fairly active area of research, as effective treatment of Parkinson's disease can be achieved through deep brain stimulation of the GPe (Carvalho, SuKul, Bookland, Koch, & Connolly, 2014).

Subthalamic Nucleus

Described in some detail above, the STN not only receives input via the indirect pathway but also receives direct input from cortical areas. A small structure subnuclei within the STN are associated with connectivity between motor, association networks, and the limbic system. Like the GPe, the STN is a potential target for deep brain stimulation. A recent functional connectivity study revealed that in Parkinson's patients, the STN had developed increased connectivity in two particular cortical areas (motor and precuneus), whereas controls had a more dispersed pattern of connectivity (Fernández-Seara et al., 2015).

The final major structure of the basal ganglia, the substantia nigra, is a small nucleus located in the most ventral section of the subcortex. It has two distinct regions, the substantia nigra pars compacta (SNpc) and the substantia nigra pars reticulata (SNpr). The SNpc produces and releases the majority of dopamine in the brain. A decrease in SNpc dopamine is characteristic of Parkinson's disease; however, the SNpc also plays a role in circuits between the striatum and prefrontal cortex and is implicated in the cognitive dysfunctions associated with schizophrenia (Yoon, Minzenberg, Raouf, D'Esposito, & Carter, 2013). The SNpr receives input from both the striatum (direct pathway) and the STN (indirect pathway). Inhibitory input from the striatum can prevent the SNpr from sending inhibitory GABA signals to the thalamus, increasing the potential for motor activity. Likewise, the SNpr can also receive excitatory glutamatergic signals from the STN, ultimately resulting in decreased potential for motor activity.

As described above, cortical–subcortical communication originates within the sensory regions of the cortex. The subcortical structures organize and coordinate a response through either the direct excitatory stream or indirect inhibitory stream (see Figure 1). Specific feedback loops have been defined that characterize the patterns or circuits of communication between cortical and subcortical structures. The loops are detailed below, with brief examples of different disease processes that result from alterations in the communication patterns of the feedback loops.

Skeletomotor Loop

The skeletomotor loop facilitates communication between the motor cortices and subcortical structures to produce movement. A consequence of dysfunction in the skeletomotor loop is impaired muscle movement, resulting in range of symptoms referred to as dyskinesias. Dyskinesias can be characterized as ranging from slow or hypokinetic movements resulting from excitatory pathway dysfunction to fast or hyperkinetic movements resulting from damage within the inhibitory pathway. Examples include bradykinesia, dystonia, athetosis, chorea, ballisms, and tics. Bradykinesias are hypokinesias that appear as slowed, clumsy, or inaccurate

The dashed grey lines represent the interconnected circuits between the basal ganglia and the cerebellum. The abbreviations go as follows: The Dorsolateral Prefrontal Cortex (DLPFC), Anterior Cingulate Cortex (ACC), Lateral Orbitofrontal Cortex (LOFC), Motor Cortex (MC), Globus Pallidus externus (GPe), Subthalamic Nucleus (STN), Substantia Nigra pars compacta (SNc), Globus Pallidus internus (GPi), Substantia Nigra pars reticulata (SNr), Pontine Nuclei (PN), Cerebellar Cortex (Cort), Dentate Nucleus (DN). *Source*: Original framework for this diagram can be found at Caligiore et al. movements as well as poverty or lack of movement, resulting from impairments with initiated movements. Symptoms of dytonias include involuntary contractions of muscles, creating repetitive or twisting movements of various body parts, including the entire torso. Athetosis, a condition observed in athetoid cerebral palsy, consists of involuntary, writhing movements of the hands and feet. In some patients athetosis may affect arms, legs, neck, and even the tongue. Choreas or chorionic movements are characteristic of Huntington's disease and include erratic movements that lack purpose and may include awkward movement of the facial muscles. Ballism, typically hemiballismus, is a severe form of movement disorder that involves involuntary, violent, or extreme motions that occur on one side of the body. Hemiballismus is the result of damage to the STN located on the side contralateral to the movements. Finally, tics are hyperkinesias that appear as rapid, repetitive involuntary movements often associated with conditions such as autism and Tourette's syndrome.

Oculomotor Loop

The oculomotor loop is a circuit including the frontal eye fields, prefrontal cortex, posterior parietal cortex, the caudate nucleus, GPi, SNpr, superior colliculus, and visual regions of the thalamus. One function of the oculomotor loop includes suppression of unnecessary eye movements and enables the eyes to fixate on a target. Signals from this loop originate in the posterior parietal lobe and dorsolateral prefrontal cortex (DLPFC), structures associated with spatial mapping and attentional processing. The thalamus ultimately initiates or inhibits eye movement through projections to the frontal and supplementary receptive fields of the eyes. Dysfunctions in some psychiatric disorders include inaccuracies in visual fixation. A current report indicates that schizophrenia and obsessive–compulsive disorder share both overlapping and unique patterns of dysfunction. Shared deficits appear to involve the DLPFC, anterior cingulate, and parietal circuits, whereas additional deficits in schizophrenia pointed to motor control and frontal eye field dysfunction (Damilou, Apostolakis, Thrapsanioti, Theleritis, & Smyrnis, 2016).

Executive–Associative Loops

Numerous circuits between the prefrontal cortex and subcortical structures have been defined and are continually being redefined through the use of neuroimaging tools that provide new insights into functional connections. One loop, the DLPFC, is associated with cognitive processes, including outcome prediction, working memory, reasoning, inhibition, and conscious decision making. The DLPFC loop has received a great deal of attention as it is implicated in both positive and negative behaviors associated with schizophrenia. Specifically, damage to this circuit is associated with substantial deficits in social cognition, including difficulties in reasoning and failure to follow rules (Garety, Kuipers, Fowler, Freeman, & Bebbington, 2001). The more ventrally positioned orbitofrontal cortex has both medial (mOFC) and lateral (lOFC) circuits that display distinct connectivity. These circuits are implicated in goal-directed behaviors including reward learning, mood regulation, emotional reappraisal, and decision making. The mOFC is implicated in assigning value to stimuli, whereas the lOFC is implicated in appraising or calculating the value between stimuli (Fettes, Schulze, & Downar, 2017).

Limbic Loop

The limbic loop is a circuit of nuclei including the anterior cingulate cortex (ACC), medial prefrontal cortices, NAcc, GPi, and thalamus. A variety of psychopathologies are associated with dysfunction in this circuit, including Tourette's syndrome and obsessive–compulsive disorder (Devinsky, Morrell, & Vogt, 1995). Dysregulation of the thalamus is hypothesized to result in overstimulation of the ACC, resulting in repetitive, involuntary behaviors. On the other hand, thalamic dysregulation may also result in inadequate stimulation of the ACC. Hypostimulation of the ACC may contribute to the profound apathy observed in akinetic mutism, a disorder characterized by an indifference to hunger, thirst, or pain, a lack of spontaneous movement, and an inability to respond to questions and commands (Holroyd & Yeung, 2012).

Conclusion

Because of the intricate connectivity between cortical and subcortical structures, the damage caused by neurological diseases or lesions is unlikely to be isolated entirely within the cortex or subcortex. Additionally, the loops as presented, while distinct circuits, have further interconnections not described here. Certain pathologies, as described in this chapter, might result from lesions or lack a diffuse pattern of connectivity (Fernández-Seara et al., 2015; Rieckmann et al., 2018). As has been demonstrated in this chapter, damage to the cortex can result in dysfunction in subcortical communications; likewise, damage to subcortical structures will eventually lead to reciprocal impairment and possible atrophy in cortical structures. Despite our relatively thorough understanding of cortical–subcortical feedback loops, there is much that is not well understood, including the role of other neuromodulators in producing behavior or disease processes. Ongoing research using multimodal imaging and examination of the role of other body systems (e.g., the gut–brain axis, immune system) in disease states will provide greater understanding of the complexity of cortical–subcortical communication systems.

Neurobiology of Stress–Health Relationships

R.L. Spencer, L.E. Chun, M.J. Hartsock, and E.R. Woodruff

Department of Psychology and Department of Neuroscience, University of Colorado, Boulder, CO, USA

Stress and Health Overview

The adverse effects that stress can have on physical and mental health are well established. Stress has a causal role in the development of some psychological disorders, such as major depressive disorder or posttraumatic stress disorder, and it can negatively impact all phases of physiological and psychological illness progression including precipitation of episode onset, symptom exacerbation, increased treatment resistance, delayed recovery, and increased relapse (Dimsdale, 2008; Reagan & Grillo, 2008). Recent life stress is reported to be a factor contributing to 60–80% of healthcare provider visits in the United States. Because most major stressors identified by members of our society are psychological rather than physiological in nature, understanding and mitigating the negative relationship between stress and health is a central issue for health psychology.

The Stress Concept

The foundation for the scientific study of stress was firmly established by the physiologist Walter Cannon and the endocrinologist Hans Selye. Cannon, as a physiologist at Harvard Medical School (1900–1945), coined the term homeostasis to represent the elaborate physiological processes that operate in a coordinated fashion to ensure the stability of cellular and physiological functions in the body. Cannon was instrumental in determining the critical role that the sympathetic nervous system (SNS) plays in restoring homeostasis in the face of a wide range of environmental or internal disturbances. He described the pluripotent effects of SNS activation

as mediating key physiological changes in the body, such as energy mobilization and increased cardiovascular function, that support the "fight-or-flight" response to physical threat.

Hans Selye, while working (1936–1982) at McGill University and Universite de Montreal, extensively characterized in controlled laboratory experiments the physiological effects of stress. Whereas Cannon advanced the importance of the SNS, Selye determined that another key physiological mediator of the body's stress response was increased secretion of glucocorticoid hormones as a result of hypothalamic–pituitary–adrenal (HPA) axis activation. Selye referred to stressors as the factors that cause stress and the stress response as the body's adaptive response to stressors. He proposed the theory that a wide range of experiences (stressors) have the ability to exert a similar influence on the body (stress), which can lead to detrimental effects when sustained. However, the body can detect this stress state and effectively respond by mounting a coordinated stress response. Selye described this stress state as a nonspecific demand placed upon the body. Despite the various theoretical conundrums surrounding the nature of this stress state, researchers have made a number of important discoveries concerning the neurobiology of stress.

Types of Stressors

The categorization of stressors into two general types, physiological and psychological, has proven useful for studying the specific underlying neurocircuitry that participates in the processing and response coordination to these stressors. Physiological stressors are those altered physiological states that elicit well-characterized autonomic homeostatic adjustments, such as hypothermia, hypoxia, dehydration, tissue damage, hypotension, and hemorrhage. These stressors are also referred to as interoceptive or systemic stressors. An important finding of stress research has been that the two principal physiological stress response systems (SNS and HPA) are not only activated after a disruption of homeostasis has been detected but also by a variety of environmental or psychosocial situations that do not themselves disrupt physiological function. Some of these so-called psychological (or processive) stressors are environmental stimuli that appear to be innately recognized as an immediate threat to physiological well-being, such as physical attack, sudden loud noise, impending collision with a fast moving object, or teetering on the edge of a high precipice. However, physiological stress responses are also effectively triggered by many other experiential situations that do not reflect impending bodily harm, such as public speaking, novel social circumstances, traffic jams, relationship difficulties, financial insecurity, and job performance concerns. Moreover, psychological stressors may be self-generated (e.g., traumatic experience recall and anticipation of future negative outcomes). Research has identified several underlying psychological factors that are shared by various psychosocial situations that are considered stressful, and these factors include lack of controllability, lack of predictability, novelty, and social-evaluative threat.

The ability to respond to psychological stressors with a physiological stress response confers considerable adaptive advantage to the organism. If the organism is able to initiate a physiological stress response not only to a direct physical insult (e.g., attack from a predator) but also to cues associated with the stressor (e.g., odors, sounds, or sight of a nearby predator), then the physiological stress response may be vital for the organism's ability to avoid the stressor or may optimally prepare the organism for a subsequent encounter with the stressor. Moreover, this capability can draw upon prior experience (i.e., learning and memory), such that previously neutral environmental cues, when paired with stressors, will subsequently be sufficient to elicit physiological stress responses. The ability not only to respond to immediate physical stressors but also to anticipate and prepare for future stressors is a key aspect of evolutionary stress neurobiology. However, in modern society, many complex psychosocial stressors are not associated with impending physical threat to well-being, and consequently the activation of physiological stress responses in these situations is not adaptive and contributes to the adverse effects of chronic stress on health.

Types of Stress Responses

Physiological and psychological stressors elicit not only a physiological response but also psychological responses. The psychological responses often include generation of emotional states, such as fear, anxiety, or frustration, as well as shifts in attention (e.g., hypervigilance), decision-making (e.g., bias), and memory processes. This psychological aspect of the stress response is essential for motivation and coordination of adaptive behavioral responses. The importance of behavioral responses to stress was featured early on in stress response physiology by Cannon as he framed the significance of the SNS physiological response in terms of behavior—the “fight-or-flight response.” Other basic behavioral responses elicited by stressors include freezing and withdrawal, but the psychological aspect of the response to stress may also motivate elaborate behavioral strategies to avoid or reduce stress. No physiological or psychological response alone, or in combination, is a dedicated response exclusively reserved for combatting stress. Each can occur in other contexts, and therefore the presence of these responses is not a definitive measure of stress, although they may be useful biomarkers associated with stress.

Neurobiology of the Body’s Response to Stress

The ability of the body to detect stressors and then mount a coordinated stress response that effectively copes with the stressful situation is fundamentally a neurobiological process. It requires neural communication between sensory afferents and motor efferents. However, because there is not a physical dimension of stressfulness inherent in stimuli, the determination of stressfulness or threat requires integrative neural processing. The perception of and the coordinated response to stress depend on hierarchically organized neural systems in the brain. In the case of an appropriate response to physiological stressors, the underlying neural circuitry tends to be relatively simple. For example, a sudden drop in blood pressure results in reduced activity of baroreceptors located in the aortic arch and carotid artery sinus. These specialized sensory neurons project via the vagus and glossopharyngeal cranial nerves to the vasomotor control centers in the brain stem. The vasomotor control centers then direct an increase in activity of descending spinal cord premotor efferent neurons that innervate components of the SNS. Increased SNS activity then mediates a rapid increase in cardiac output and arteriole vasoconstriction. Superimposed on these evolutionarily primitive neurocircuits are more complex neural circuits and networks (e.g., components of the limbic system) that subserve detection of the wide range of psychological stressors and orchestration of the physiological and psychological responses directed toward reducing stress.

The two primary physiological stress response systems are the SNS and the HPA axis. Each system has both a neuronal and a hormonal component. The two systems mediate complementary adaptive changes in virtually every cell and system of the body, and both systems operate on a complementary time scale. The SNS typically produces rapid (within seconds) but short-lasting (minutes) actions, whereas the HPA axis typically produces delayed (45–60 min) but long-lasting (hours to days) actions. Individuals do not have voluntary control over the initiation or termination of activity within these two stress response systems, but they may learn strategies, such as relaxation techniques to modulate their activity.

SNS

The SNS (Figure 1) is one of two subdivisions of the autonomic nervous system (ANS) (Powley, 2013). The parasympathetic nervous system (PSNS) forms the other subdivision. The ANS is primarily a motor system that innervates and controls the activity of internal organs and glands throughout the body including the heart, lungs, liver, kidney, gastrointestinal

system, bladder, reproductive organs, salivary glands, and lacrimal glands. The ANS also regulates blood pressure and blood flow to various parts of the body by adjusting the diameter of arterioles, and it regulates the amount of light that enters the eye by controlling the diameter of the iris. The ANS comprises a series of two neuron units (preganglionic neuron and postganglionic neuron) that connect the spinal cord and brain stem with the targeted organs and glands. In general, the SNS and PSNS have opposing actions on the activity and function of the target organs, for example, increased SNS activity leads to an increase in heart rate, and increased PSNS activity leads to a decrease in heart rate. Combined the SNS and PSNS provide the critical balance that largely underlies physiological homeostasis.

The SNS preganglionic neurons receive their primary inputs from descending brain stem neural pathways, which synapse onto the cell bodies of preganglionic sympathetic neurons located in the intermediolateral cell column of the thoracolumbar spinal cord. Axons of the preganglionic sympathetic neurons extend outside the spinal cord to synapse onto postganglionic cell bodies, many of which are located in sympathetic chain ganglia adjacent to the spinal column. The axons of postganglionic neurons terminate on target organs throughout the body. Preganglionic neurons release acetylcholine onto nicotinic cholinergic receptors present on postganglionic neurons, while postganglionic neurons release norepinephrine onto adrenergic receptors present on target organs. Norepinephrine release onto target organs triggers physiological changes associated with the fight-or-flight response, including pupil dilation, shunting of blood flow from the viscera to the skeletal muscles of the limbs, increased respiration, and heart rate acceleration.

In addition to this direct neural control of SNS target organs, an endocrine component of the SNS provides hormonal control over target organs. The chromaffin cells of the adrenal medulla comprise this endocrine component. The axons of sympathetic preganglionic neurons in the thoracic spinal cord extend as part of the splanchnic nerve to terminate on chromaffin cells. Chromaffin cells, in response, secrete the catecholamine molecules epinephrine (also known as adrenaline) and norepinephrine into the systemic circulation. Catecholamine hormones cannot cross the blood–brain barrier and therefore act only in the periphery, with epinephrine binding all classes of adrenergic receptors (α_1, α_2, β_1, β_2, and β_3 adrenergic receptors) and norepinephrine binding preferentially α_1, α_2, and β_1 adrenergic receptors. Given the different receptor binding affinities of epinephrine and norepinephrine and the differential distribution of adrenergic receptor subtypes on target organs throughout the periphery, epinephrine and norepinephrine generate different effects. Epinephrine, for instance, is particularly effective in increasing heart rate, cardiac output, and blood glucose, while norepinephrine is most effective in increasing blood pressure and energy mobilization by breaking down fats (lipolysis). Although homeostasis depends on the selective activation of various SNS pre- and postganglionic neuron units for specific reflexive homeostatic adjustments, a more global SNS activation, including the hormonal component, is observed in response to psychological stressors.

HPA Axis

The HPA axis (Figure 2) is a neuroendocrine system that controls the secretion of glucocorticoid hormones (Spencer & Deak, 2017). The principal glucocorticoid hormones (CORT) produced in vertebrates are cortisol (e.g., in humans, fish, dogs) and the closely related hormone corticosterone (e.g., in rats, mice, birds, and many reptiles). The HPA axis consists of three populations of cells and the hormonal signals that they use to communicate with each other and the rest of the body.

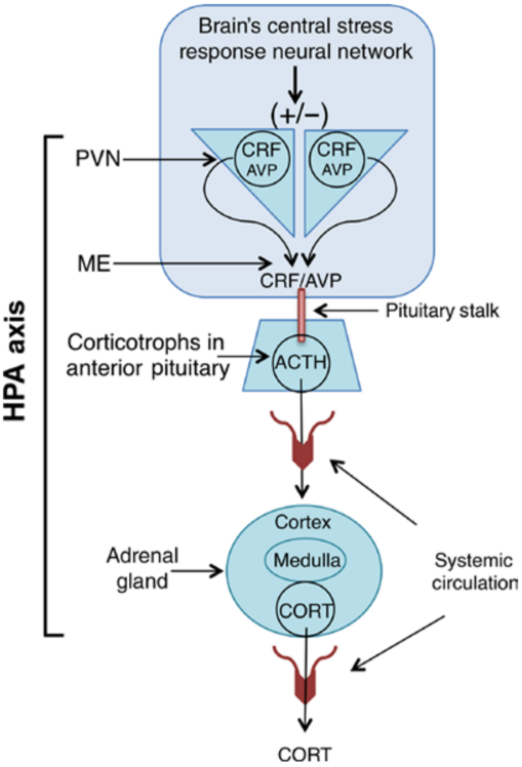

Figure 2 The hypothalamic-pituitary-adrenal axis. Neuron cell bodies located in the paraventricular nucleus (PVN) of the hypothalamus release corticotropin releasing factor (CRF) and arginine vasopressin (AVP) from axon terminals located in the median eminence (ME) at the base of the hypothalamus. CRF and AVP are carried down the portal vein within the pituitary stalk to corticotroph cells located in the anterior pituitary. In response to CRF and AVP, corticotrophs secrete adrenocorticotropic hormone (ACTH) into the systemic circulation. ACTH stimulates the production of the endogenous glucocorticoid hormones cortisol and corticosterone (CORT) in the adrenal cortex. CORT is released into the systemic circulation and acts as the effector hormone of the HPA axis throughout the body. The brain's central stress response neural networkprovides excitatory and inhibitory (+/−) neural input to the HPA axis.

The neuronal component of the HPA axis is composed of neurons whose cell bodies are located in the medial parvocellular portion of the paraventricular nucleus (PVN) of the hypothalamus. These neurons project to a region at the base of the hypothalamus (median eminence) that forms the junction between the brain and the pituitary stalk. These neurons are called hypophysiotropic neurons because they project to the interface region between the brain and pituitary (also known as hypophysis). These neurons secrete the neurohormone corticotropin-releasing factor (CRF) (also known as corticotropin-releasing hormone). CRF is carried by the portal vein within the pituitary stalk the short distance (~1 mm) down to the anterior pituitary. The second population of cells consists of endocrine cells, called corticotrophs, located in the anterior pituitary. When these cells are stimulated by CRF, they release adrenocorticotropic hormone (ACTH) into the general circulation. Some CRF neurons of the PVN also secrete vasopressin, which is co-released with CRF and acts on corticotrophs to enhance ACTH release. The third population of cells consists of endocrine cells located in the outer cortex (fasciculata layer) of the adrenal gland. ACTH causes these adrenal cortical cells to produce CORT. CORT is the effector hormone of the HPA axis; it mediates the effects of the HPA axis throughout the body. CORT is a steroid molecule, which is lipid soluble, and therefore CORT readily crosses the blood–brain barrier. Consequently, CORT can influence all tissues throughout the body, including the brain. The HPA axis endocrine cells in the anterior pituitary and the adrenal cortex have very little intrinsic activity. As a result, CORT secretion ultimately depends on the activity of the hypothalamic CRF neurons and the net excitatory neural input that these neurons receive from other brain regions. In the absence of stress, CORT exhibits a large daily fluctuation (circadian rhythm) in secretion, with maximal circulating levels present around the habitual time of awakening. Superimposed on this circadian rhythm of CORT secretion is a dynamic increase in response to stress, with peak stress levels of CORT attained about 30 min after stressor onset.

CORT exerts its effects throughout the body by activating two structurally similar receptor proteins, the mineralocorticoid receptor (MR) (which is also the primary receptor for the hormone aldosterone) and the glucocorticoid receptor (GR). These receptors are located inside cells rather than on the outer cell surface. These receptors function as transcription factors in the cell nucleus, and they act either to enhance or repress gene expression by directly binding specific sequences of DNA (glucocorticoid response elements) or indirectly by interacting with other transcription factor proteins (Granner, Wang, & Yamamoto, 2015). There are also some rapid non-genomic effects of CORT, although the molecular mechanisms of these rapid effects have not yet been fully determined. Because the majority of CORT effects on physiological function depend on alteration of gene expression, most CORT effects are slow to develop, with the earliest actions evident about 45 min after an elevation in CORT. However, once initiated, these actions are relatively long lasting (for at least several hours) and therefore can persist, even after CORT levels have returned to low basal levels.

GR is widely expressed in most cell types throughout the body. MR is more restricted in its expression but has high levels in the kidney, cardiac tissue, and hippocampus of the brain. CORT has a 10-fold higher affinity for MR than GR, and therefore low circulating levels of CORT act primarily through MR, whereas higher levels, such as those present during stress, also activate GR. For this reason, GR is believed to be the primary mediator of the stress-related actions of CORT, whereas MR is important for mediating more "permissive" or system maintenance effects of CORT. These permissive actions are important, such that glucocorticoid insufficiency (e.g., Addison's disease), as well as glucocorticoid excess, has pathological consequences. It is important to note that most synthetic glucocorticoids, which are widely prescribed for various medical conditions, primarily activate only GR.

Stress-induced CORT produces a number of effects that can be adaptive during times of stress. In the periphery this includes increased blood glucose levels, shift in fat depots, modulation of immune system function, and increased cardiovascular tone. In the brain CORT modulates the biochemical aspect of intercellular (neurotransmitter systems) and intracellular signaling function, thereby regulating neuronal activity, plasticity, and morphology. Consequently CORT regulates various aspects of brain function that may be adaptive during times of stress, including learning, memory, reward processes, emotions, sleep, and appetite.

Central Stress Response Neural Network

The neural circuitry that underlies the rapid response to physiological stressors, such as a drop in blood pressure, as described above, has been well characterized. Determining the neural circuitry that underlies the physiological and psychological response to complex psychosocial stressors such as public speaking is not nearly as straightforward. However, considerable progress has been made in recent years at identifying relevant brain regions and their connections (Ulrich-Lai & Herman, 2009) (Figure 3). The direct neural control of the output neurons of the SNS (thoracolumbar spinal cord preganglionic neurons) and the HPA axis (CRF neurons in the PVN) is limited. The SNS receives direct input (premotor neurons) from descending spinal cord projection neurons whose cell bodies are located primarily in the medulla (e.g., nucleus of the solitary tract, ventral medullary reticular formation, and A5 noradrenergic group) and hypothalamus (non-CRF neurons in the PVN and lateral hypothalamic area). There is, however, also an indirect cortical component provided by some neurons located in the ventromedial prefrontal cortex.

The CRF neurons in the PVN receive direct neural input primarily from the brain stem and a few subcortical forebrain regions. Excitatory brain stem input is provided from adrenergic and noradrenergic afferents originating in the medulla (e.g., the nucleus of the solitary tract and the ventral medulla) and from some serotonergic afferents originating in the raphe nuclei. Both excitatory and inhibitory inputs are provided by other hypothalamic brain regions, the

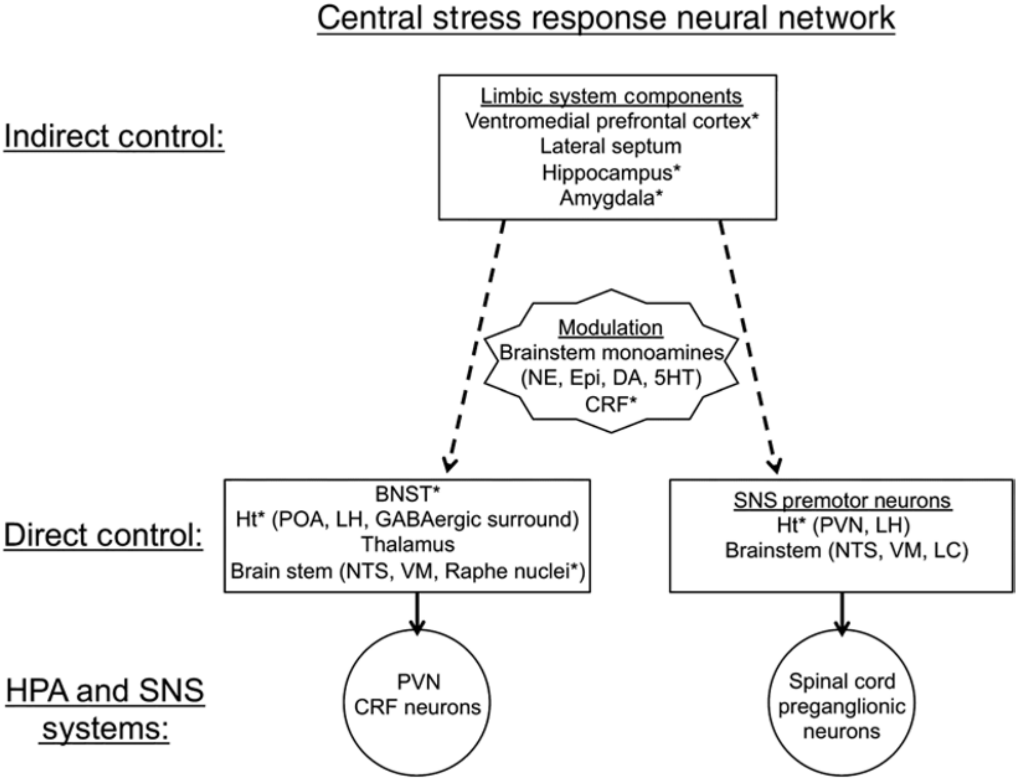

Figure 3 Key neural elements of the central stress response neural network. HPA axis elements (PVN CRFneurons) and SNS elements (spinal cord preganglionic neurons) receive limited direct neural control (primarily from the BNST, hypothalamic subnuclei and brain stem nuclei) and more extensive indirect neural control from limbic system components. Many aspects of the network are modulated by brainstem monoaminergic neurons (NE, norepinephrine; Epi, epinephrine; DA, dopamine; 5HT, serotonin), and by CRF (corticotropin releasing factor) neurons (* indicates brain regions that contain CRF neurons). bed nucleus of the stria terminalis, and the thalamus. CRF neurons in the PVN are also strongly innervated by surrounding GABAergic neurons, and much of the activation and inhibition of CRF neurons may be a result of neural modulation of tonic GABAergic inhibitory tone.

The PVN serves as a unique forebrain integrator of the physiological stress response as it contains both the motor neurons of the HPA axis (CRF hypophysiotropic neurons) and SNS premotor neurons. Other brain regions believed to engage in higher-level stressor processing and stress response coordination are components of the classically described limbic center. These brain regions include the medial prefrontal cortex, lateral septum, hippocampal formation, and amygdala. The bed nucleus of the stria terminalis and subregions of the hypothalamus (e.g., preoptic, dorsomedial, and lateral) are an important interface between these limbic structures and the SNS and HPA axis.

In the context of stress neurobiology, the medial prefrontal cortex is important for situation-specific decision making and control of emotionally motivated behaviors, including the acquisition of conditioned fear extinction learning. The medial prefrontal cortex is also necessary for the detection of stressor controllability and coordination of its protective effects. The hippocampus is especially important for formation and retrieval of contextual memories associated with stressful experiences, whereas the amygdala is critical for forming learned associations between specific environmental cues (e.g., sounds and light patterns) and stressful experiences. The amygdala is also important for generation of negative emotions and coordination of stereotypic defensive behaviors, such as freezing. The lateral septum is important for modulating affective tone, mood, and associated behaviors. The medial prefrontal cortex and the ventral hippocampus also contribute to the timely shutoff of the HPA axis response to stressors.

Strong modulatory regulation of the central stress response neural network is provided by the ascending brain stem monoamine neurotransmitter systems and by the central CRF neuropeptide system (Feldman, Meyer, & Quenzer, 1997). Many noradrenergic neurons (which secrete norepinephrine) are clustered in the brain stem locus coeruleus and project widely throughout the brain. Increased activity in the noradrenergic system contributes to general arousal, and many of these neurons are stress reactive. Adrenergic neurons (which secrete epinephrine) have a more restricted projection to the forebrain but innervate the PVN. Dopaminergic neurons (which secrete dopamine) originating in the ventral tegmental area of the midbrain provide extensive projections to the striatum and medial prefrontal cortex. This mesolimbic dopaminergic system is fundamental for reward processes, but the system is also stress reactive and contributes to emotion modulation. Serotonergic neurons (which secrete serotonin) originating in the raphe nuclei also project widely throughout the forebrain. Subsets of these serotonergic neurons in the dorsal raphe nuclei are also very stress reactive.

In addition to the CRF hypophysiotropic neurons located in the PVN, there are CRF neurons located in strategic portions of the stress response network, such as the hypothalamus, bed nucleus of the stria terminalis, and the amygdala, as well as CRF interneurons located throughout the neocortex and hippocampus. CRF central neurotransmission contributes to SNS and HPA axis activation and regulation of anxiety-related behaviors.

The central stress response network is responsible not just for activation of the SNS and HPA axis but also for generating the psychological stress response. Although there is not a specific stress emotion, there are a number of negative emotional states associated with many stressors, such as fear, anxiety, frustration, and anger. As noted above, the psychological response to stress also includes shifts in attention and decision-making. These shifts are especially dependent on altered operation of the prefrontal cortex. For example, uncontrollable stress increases norepinephrine and dopamine release in the medial prefrontal cortex, leading to an acute reduction in medial prefrontal cortex function. This reduced function contributes to a shift in behavioral control away from top-down reflective behaviors to more bottom-up reactive behaviors (Arnsten, 2015). Conversely, many of the protective effects of controllable stress depend on medial prefrontal cortex-mediated suppression of stress-induced dorsal raphe nuclei serotonergic activity (Maier, Jose, Baratta, Evan, & Watkins, 2006). Stress also produces robust effects on learning and memory, but the stress–memory relationship is not unidirectional, as stress can interfere with some memory processes but facilitate others. For example, stress can enhance formation of emotional memories while attenuating formation and retrieval of declarative or spatial memories. Stress also shifts reward incentives from a long-term to short-term perspective. In general, all of the orchestrated neural network events associated with stress are directed toward shifting physiological and psychological resources in a manner adaptive for coping with stress.

Regulation of the Stress Response

Stress Response Adaptation

In human experience, all stress responses are superimposed on a background of previous stressor exposure and adaptation. The effects of that adaptation on the expression of subsequent stress responses may be a critical factor in the overall impact of stress on the individual. The deleterious effects of chronic stress on organismal well-being (e.g., disruptions in metabolism, cardiovascular function, inflammation, and depression-like behaviors) largely stem from the cumulative effects of the stress response over time.

A key principle of stress neurobiology that has emerged from studies of stress response adaptation is that repeated exposure of an experimental subject to a particular stressor typically leads to the expression of a diminished hormonal and neural response (habituation) when the subject is then challenged again with the same stressor (homotypic stressor), but often expression of an augmented response (sensitization, also referred to as facilitation) when the subject is subsequently challenged with a different novel stressor (heterotypic stressor) (McCarty, 2016). The rate and degree of stress response habituation generally depends on the type, severity, and duration of the stressor, but the end result is a progressively diminished physiological response to the homotypic stressor. Importantly, this habituation is quite stressor selective, such that even relatively small changes in stressor properties, context, or duration can interfere with the expression of habituation.

A sensitized response to challenge with a novel stressor is evident not only after repeated exposure to a homotypic stressor but also after exposure to chronic variable stress, a procedure in which a subject is exposed to a variety of stressors on an unpredictable schedule. Single-session exposure to some relatively intense acute stressors is also sufficient to produce an exaggerated response to subsequent challenge with a novel stressor. Sensitization of the response to a novel stressor is manifest not only by an exaggerated HPA axis or SNS response but also by increased activation of the dorsal raphe nuclei serotonergic system, potentiated activity in the locus coeruleus, and increased norepinephrine release in the PVN and cortex.

Both impaired stress response habituation and increased stress response sensitization pose increased health risk. Several features of stress response habituation and sensitization described above indicate that the underlying adaptive processes critically occur within central neurocircuits that control physiological stress responses rather than within the anatomical elements of the SNS and HPA axis themselves. First, the stressor selectivity of stress response habituation rules out a generalized decreased responsiveness of the SNS and HPA axis to all stressor input.

Second, the preganglionic neurons of the SNS or the PVN CRH neuron of the HPA axis lack the direct multimodal neural input necessary to discriminate between many stressors. Third, neuronal activity in stress-responsive brain areas shows parallel adaptive changes with the SNS and HPA axis response.

The specific mechanisms that underlie this central stress response neurocircuit adaptation remain to be determined, but recent progress indicates that it is a multidimensional process. Neurocircuit components that may be especially important for the expression of this adaptation are the thalamic paraventricular nucleus, medial prefrontal cortex, and basolateral amygdala. Sensitization may depend on upregulation of generalized stressor responsiveness of serotonergic, noradrenergic, and dopaminergic systems. Although stress response adaptation fundamentally depends on neuroplastic changes within the central stress response neural network, additional adaptation within the HPA axis may fine-tune the expression of HPA axis stress response adaptation.

Sex Differences

Women have a greater prevalence of stress-related mood disorders (e.g., depression and some anxiety-related disorders such as posttraumatic stress disorder) compared with men. This prevalence difference may be due in part to sex differences in the physiological and psychological response to stress. Female rodents display greater stress-induced neuroactivation than males in some brain regions (e.g., bed nucleus of the stria terminalis, medial preoptic hypothalamic area, and the hippocampus) and lesser neuroactivation in others (e.g., amygdala, raphe nuclei, and thalamic nuclei). In the medial prefrontal cortex, female rats exhibit a smaller initial but longer-lasting pattern of neuroactivation than males. In an fMRI study of men and women exposed to negative stimuli, sex differences in blood oxygenation level-dependent signal were evident in a variety of limbic brain regions, and these sex differences varied with female menstrual cycle phase (Goldstein, Jerram, Abbs, & Whitfield-Gabrieli, 2010). There are also some sex differences in neuronal intracellular signal processing in response to acute stress (e.g., in the prefrontal cortex and locus coeruleus) that may contribute to sex differences not only in immediate neural activity but also in neural adaptation to stress.

Female rodents typically exhibit greater stress-induced HPA axis activation compared with males. These HPA axis sex differences depend on both organizational and activational effects of gonadal steroids. Sex differences in HPA axis activity are much less consistently observed in human research. Some studies have found greater stress-induced ACTH and CORT in men compared with women, but other studies have found that while men have greater basal salivary CORT levels, women have equal if not greater stress-induced salivary CORT, suggesting that women overall have a greater increase in stress-induced CORT.

Developmental and Lifespan Factors

Stress occurs throughout the lifespan, and its effects vary depending on the organism's age (Lupien, McEwen, Gunnar, & Heim, 2009). There are important prenatal, childhood, and adolescent critical periods of stress response system development. The extent to which the individual is subject to a stressful environment during these critical periods may program development to be adaptive for a lifetime of excessive stress. For example, in rodent studies, maternal stress results in offspring that as adults exhibit HPA axis hyperreactivity, social withdrawal, and deficits in prefrontal cortex-dependent and hippocampus-dependent learning and memory tasks.

Neonatal stress exposure of rats and mice can also result in increased stress reactivity as an adult. However, the detrimental effects of neonatal stress can be mitigated by good maternal care (e.g., appropriate amount of grooming and licking). Human studies also find long-lasting effects of early life stress on HPA axis function.

During adolescence, rodents and humans show a prolonged HPA axis response to acute stress compared with adults. In the rat the prolonged CORT response is due to increased PVN CRF activity and increased adrenal sensitivity to ACTH. In response to chronic stress, adolescent rats also have higher CORT levels and impaired habituation to a repeated stressor, resulting in a greater likelihood of developing depression-like behavior.

Aged animals also exhibit prolonged CORT release in response to some acute stressors, and this may be due to decreased hippocampal functioning, resulting in decreased inhibitory control of the HPA axis. In regard to chronic stress, it has been found that aged animals do not adapt to a repeated stressor as well as young rats. Similar findings have also been reported in human studies of the elderly.

Mechanisms by Which Stress Impacts Health

Research indicates that the greatest consequence of stress on physical and mental health is not a result of the immediate physiological and psychological impact of an acute stress response, but rather a result of the cumulative and emergent consequence of chronic or repeated stress. In animal studies, some of these effects of chronic stress have been shown to persist for months after chronic stress has ended.

Physiological Health

The long-term alteration of SNS and HPA axis basal and reactive function is a major mediator of the adverse effects of chronic stress on physiological health. Every physiological system has cellular and molecular elements that are directly modulated by catecholamines and glucocorticoids. A shift in the appropriate balance of these modulatory effects directly contributes to systems level pathology. Biomedical research has made tremendous progress in determining many of these specific mechanisms. In addition to the specific regulatory effects that the SNS and HPA axis exert on each physiological system, abnormal catecholamine and glucocorticoid profiles contribute to three processes that can negatively affect all physiological systems. These three processes are increased inflammation, metabolic imbalance, and circadian dysregulation.

Catecholamines lead to increased production of plasma and tissue-specific proinflammatory cytokines (e.g., interleukin-1β and interleukin-6). Although pharmacological levels of glucocorticoids have potent anti-inflammatory and immunosuppressive effects that are beneficial in treating individuals with autoimmune disorders and tissue transplant recipients, physiological levels of CORT exert a more complex regulatory influence on immune system function (Spencer, Dhabhar, & Kalman, 2001). For example, the permissive effects of CORT prior to stress exposure are necessary for mounting an appropriate proinflammatory response to pathogens, but post-stress glucocorticoids have an important anti-inflammatory influence while promoting certain aspects of acquired immunity. The dysregulation of these immune processes results not only in elevated risk for infection and increased autoimmune expression, but a shift toward chronic tissue and systemic inflammation that negatively impact all physiological systems. This includes the exacerbation of certain inflammatory-related disorders such as rheumatoid arthritis, celiac disease, inflammatory bowel diseases, and asthma.

The chronic activation of the stress response systems is associated with a host of metabolic perturbations including insulin resistance, elevated blood sugar, and adipose tissue redistribution (Bose, Oliván, & Laferrère, 2009). SNS activation acutely promotes negative energy balance, characterized by lipolysis in adipocytes via β-adrenergic receptors, increased triglyceride hydrolysis, free fatty acid mobilization, and brown adipose tissue thermogenesis. Conversely, increased CORT tends to promote positive energy balance in part by antagonizing catecholamine action (e.g., downregulation of β-adrenergic receptor expression), adipogenesis, lipogenesis, and inhibition of brown adipose tissue uncoupling protein-1. Chronic CORT exposure also increases the salience of palatable foods, thereby increasing their consumption that is beneficial for survival in an environment with limited food resources, but contributes to unhealthy diets and metabolic disruption in modern society.

The various depots of adipose tissue are distinguished by their anatomical location and the circulatory system into which they drain. A decreased ratio of subcutaneous white adipose tissue relative to visceral white adipose tissue is a predictor of negative health outcomes associated with obesity. Increased visceral adiposity is associated with chronic stress in many different species including humans. Increased glucocorticoids can promote visceral obesity even when circulating CORT levels appear normal as a result of a stress-induced upregulation within visceral fat of an enzyme (11β-hydroxysteroid dehydrogenase type 1) that converts inactive glucocorticoids into locally active glucocorticoids (Bose et al., 2009). 11β HSD-1 knockout mice are protected against high fat diet-induced metabolic disruptions and obesity. Stress-induced disruption of metabolic balance directly contributes to the metabolic syndrome, which is defined as a cluster of conditions that increases risk of cardiovascular disease, stroke, and type 2 diabetes. Metabolic syndrome symptoms include elevated blood sugar, abnormal levels of cholesterol and triglycerides, excess abdominal fat, and high blood pressure.

The optimal function of every physiological system depends on appropriate daily timing of various aspects of its operation (Dickmeis, Weger, & Weger, 2013). These daily fluctuations in operation (circadian rhythms) are maintained and coordinated by a so-called master biological clock located in the suprachiasmatic nucleus of the hypothalamus. CORT is one of the primary intercellular signals used by the suprachiasmatic nucleus to regulate each tissue's unique circadian rhythms. CORT circadian secretion can act as an entrainment factor that contributes to the rhythmic expression of clock genes within many peripheral tissues, and rhythmic clock gene expression then gives rise to tissue-specific circadian operation. Chronic stress can disrupt the body's circadian rhythms not only as a result of disturbed sleep patterns but also by leading to a loss of normal circadian CORT secretion and the resultant misalignment of circadian clocks in tissues throughout the body.

Mental Health

The SNS and HPA axis stress response systems also contribute to the negative effects of chronic stress on mental health. Although the SNS does not have direct effects on brain function, it can indirectly affect the brain through alteration of the activity of visceral sensory afferent nerves, many of which travel with the vagus nerve and project to the brain stem. Chronic elevation of glucocorticoids produces a number of molecular and cellular changes in the brain that are associated with cognitive and emotional disruptions observed in cases of impaired mental health. For example, elevated glucocorticoids lead to dendritic atrophy in the hippocampus and prefrontal cortex while increasing dendritic arborization in the basolateral amygdala. These neuronal morphological changes may enhance amygdala-dependent emotional learning while reducing the appropriate contextualization and situation-specific modulation of that emotional learning. Chronic elevation of glucocorticoids also changes the functional activity of most neurotransmitter systems by altering levels of neurotransmitter synthetic enzymes (e.g., serotonin tryptophan hydroxylase II and tyrosine hydroxylase), neurotransmitter receptors (e.g., serotonin 2A and NMDA receptors), and degradative enzymes (e.g., monoamine oxidase). However, some of the changes in brain function that emerge with chronic stress are independent of HPA axis and SNS activity. These changes may be directly related to altered activity of components of the central stress response network, as well as additional factors such as altered epigenetic factors and neuroinflammation.

Introduction

The prevalence of depression in the United States has steadily increased over the years with 6.7% of adults and 11.4% of adolescents diagnosed with major depressive disorder (MDD) in 2014 (NIMH, 2015). MDD is a complex clinical condition resulting from diverse neurobiological anomalies (Fried, Nesse, Zivin, Guille, & Sen, 2014; Milaneschi et al., 2016). A recent neuropathogenic model of MDD highlights the stress response and reduced neurogenesis in the dentate gyrus (DG) as essential underpinning components to the onset and progression of depressive symptoms. This model is referred to as the neurogenic hypothesis of depression (NHD; Jacobs, Van Praag, & Gage, 2000; Snyder, Soumier, Brewer, Pickel, & Cameron, 2011).

Functional Significance of the Dentate Gyrus

The DG is composed of molecular, granule, and polymorphic layers. Of primary interest to the NHD models is the granule layer, which is composed of a large number of tightly grouped cells. Granule cells have unique properties contributing to neurogenesis and exhibit generative

capacity as a function of progenitor cells that emerge from the subgranular zone. Interestingly, granule cell counts are static in healthy adult animals (Rapp & Gallagher, 1996), suggesting that ongoing migration of these cells from the subgranular zone is required to maintain a homeostatic level (Lyons et al., 2010). Newly derived granule cells mature and establish synaptic connectivity with adjacent cells (Amaral, Scharfman, & Lavenex, 2007). These cells are excitatory in nature and are densely populated in efferent/afferent regions of the entorhinal cortex and hippocampus. Not surprisingly, altered hippocampal neurogenesis is correlated with impaired performance on memory tasks in animal models of depression (Jessberger et al., 2009; Parihar, Hattiangady, Kuruba, Shuai, & Shetty, 2011).

Stress Response and Neurogenesis

Elevated cortisol (CORT) suppresses neurogenesis in the DG, likely due to the stimulation of NMDA receptors (Anacker et al., 2013). Granule cells and progenitor cells are sensitive to glucocorticoid levels (Alahmed & Herbert, 2008). Elevated levels of CORT inhibit the differentiation of progenitor cells into mature granule cells (Brummelte & Galea, 2010; Wong & Herbert, 2006). Chronic stress reduces neurogenesis and the total number of mature granule cells. Behaviorally, individuals with chronic stress exhibit high levels of CORT, reduced neurogenesis, and impaired memory performance (Montaron et al., 2006). Interestingly, neurogenic processes decline with normal aging (Cowen, Takase, Fornal, & Jacobs, 2008), which may contribute to memory impairments and sensitization to stressful stimuli in older individuals.

BNDF Versus Glucocorticoids

BDNF is a one of four growth factors in the neurotrophin family, including nerve growth factor, neurotrophin-3, and neurotrophin-4. Growth factors facilitate cellular maturation and differentiation. BDNF expression increases long-term potentiation, a key component to sustained cell signaling and adequate memory function (Gartner, 2006). BDNF also assists cellular activation presynaptically by modifying incoming signals from upstream neurons (Kuczewski et al., 2008). Of particular importance to the current chapter, BDNF regulates NMDA receptor activation postsynaptically (Caldeira et al., 2007) and is essential for preventing excess signaling from driving excitotoxic degradation of mature granule cells.

Reductions in BDNF disrupt NMDA activation (Xu et al., 2000). The level of signal modulation may be an important facet of neurogenic processes and helps explain why granule cells are particularly vulnerable to excitotoxicity. Indeed, injections of BDNF directly into the hippocampus enhances neurogenesis and dendritic branching (Kramár et al., 2012; Scharfman et al., 2005). Snyder et al. (2011) showed that neurogenesis helps to buffer the effects of stress by controlling CORT production through mature granule cells in the DG. The implications are the hippocampus and HPA axis are dependent on neurogenesis to adapt effectively in the context of chronic stress. Observable reductions in BDNF may be the first sign of HPA dysregulation typical of stress-induced depressive behaviors.

Acute and Chronic BDNF Activation

The mechanisms driving different changes in BDNF expression under acute and chronic stress are not well understood. In a study by Murakami, Imbe, Morikawa, Kubo, and Senba (2005), BDNF expression was reduced considerably more with acute compared with chronic stress. CORT levels continued to rise during sustained stress, whereas BDNF levels remained steady. These data, coupled with findings from Snyder et al. (2011), indicate that stress-induced reductions in neurogenesis follow initial downregulation of BDNF.

BDNF and Antidepressant Efficacy

Fluoxetine enhances the differentiation of progenitor cells and prevents cell death in the DG (Lee et al., 2001). Another antidepressant, tianeptine, reduces apoptosis in the DG (Lucassen, Fuchs, & Czéh, 2004). Chronic administration of venlafaxine, mirtazapine, and fluoxetine reduces depressive-like behaviors and increases BDNF levels (Zhang, Gu, Chen, & Dong, 2010). Of importance, only venlafaxine and mirtazapine reduced serum levels of CORT. The observation that all drugs reduced depressive-like behaviors and increased BDNF levels, but did not decrease CORT, suggests BDNF plays a primary role in the success of antidepressant treatments.

Fluoxetine displays unique properties relevant to the NHD model. Specifically, fluoxetine enhances neurogenesis, improves depressive-like behaviors, and helps to maintain drug efficacy without extensive influence on CORT secretion (Lee et al., 2001; Zhang et al., 2010). Evidence also suggests that chronic CORT administration induces hyperactivity, anxiety, and depressive-like behaviors similar to that seen with chronic stress, which can be reversed following fluoxetine administration (David et al., 2009). These findings were reduced to fluoxetine's ability to reverse CORT-induced disruptions in cellular proliferation, rather than progenitor cell differentiation or maturation. The implication is that fluoxetine modulates depressive-like behaviors through the indirect downregulation of CORT secretion via modified cellular processes derived from BDNF.

Indeed, the well-substantiated link between stress and CORT, per the NHD model, has led to the contention that the effects of BDNF on depressive-like behavior acts to indirectly aid the mechanisms of antidepressant medication, rather directly superseding the effects of CORT. Evidence suggests that lower levels of BDNF in the DG are not sufficient to produce depressive-like behavior (Adachi, Barrot, Autry, Theobald, & Monteggia, 2008; Larsen, Mikkelsen, Hay-Schmidt, & Sandi, 2010). However, genetic depletion of BDNF expression hinders the efficacy of antidepressant medication (Ibarguen-Vargas et al., 2009). Postmortem analysis has shown that BDNF is higher in the DG of patients who were using antidepressant medication at the time of death (Chen, Dowlatshahi, Macqueen, Wang, & Young, 2001).

Summary

According to the NHD, reduced neurogenesis in the DG disrupts the HPA axis with downstream effects on CORT secretion and BDNF expression. With chronic stress, continuously elevated CORT decreases BDNF and suppresses the differentiation of progenitor cells into mature granule cells. Furthermore, excess CORT inhibits the migration of progenitor cells, disrupting homeostatic regulation of mature granule cell homeostasis. Chronic stress creates a feedforward cycle that restricts recovery. Here, we contend that BDNF is an initial alteration in a sequence of physiological responses to stress in the DG (rather than CORT). This is likely consequent to the failure of proper stress adaptation, producing chronic hyperactivation of the entorhinal cortex, excessive stimulation of granule cells, and abnormal HPA negative feedback.

Pathophysiology of MS

Multiple sclerosis (MS) is a chronic inflammatory disorder affecting the central nervous system. MS affects almost 2.3 million people worldwide and approximately 250,000–400,000 people in the United States. MS primarily affects the white matter with pathology characterized by the inflammatory plaque. Inflammatory plaques exist throughout the brain, spinal cord, and optic nerves with their locations corresponding to a myriad of clinical symptoms including weakness, numbness, bowel and bladder symptoms, vision loss, or other neuropsychiatric symptoms.

Inflammation in MS occurs in several phases and manifests with considerable variability. Our initial understanding of the pathophysiology of this disease focused on the inflammatory plaque. Inflammatory plaques are often characterized by their temporal pattern and their degree of inflammation. Early inflammatory plaques feature monocytes and lymphocytes with T-cell predominant perivascular cuffing and demyelination. Early on, the blood–brain barrier remains intact with limited inflammation. Between six and twenty weeks of disease progression, lesions begin to show inflammatory infiltrates. Chronic plaques, on the other hand, feature hypo-cellularity and glial scarring with varying degrees of active inflammation present at the plaque margin (Wu & Alvarez, 2011).

The robust presence of T cells in inflammatory lesions prompted investigation into their involvement in neuronal destruction. Several studies in animal models of MS have demonstrated that autoreactive CD4 cells and to a lesser extent CD8 cells lead to a phenotype similar to MS. There are ongoing investigations into the role of a particular lineage of CD4 T cells, TH17 cells, which secrete IL17, a proinflammatory cytokine. In experimental autoimmune

encephalomyelitis (EAE), a commonly utilized animal model of MS, TH17 cells, participate in the robust inflammatory response seen in early CNS lesions (Ontaneda, Hyland, & Cohen, 2012). Further, human studies have shown that both the peripheral blood and cerebral spinal fluid (CSF) of patients with MS contain a greater proportion of TH17 cells than do controls. TH17 cells are found in perivascular infiltrates that further support their role in allowing penetration of the blood–brain barrier. B cells are also involved in CNS damage. While acute plaques feature robust active inflammation, chronic plaques often feature complement deposition and plasma cells (Weissert, 2013). This involvement is not entirely surprising; the presence of oligoclonal bands in the CSF of patients is highly suggestive of, although not specific for, a diagnosis of MS. In addition, B-cell follicles have been reported in the meninges of patients with secondary progressive MS and have also been reported underlying pathology in the corresponding cortical gray matter. The exact target of these clonal B cells and their antibodies remains unclear but is an important area of ongoing research.

While MS was initially defined by abnormalities noted in plaques, there is now substantial evidence that pathology exists in normal-appearing white matter (NAWM) and dirty-appearing white matter (DAWM) (Moore et al., 2008). These extra-lesional areas feature perivascular and parenchymal inflammation and have disruption of the blood–brain barrier that promotes proinflammatory cascades, fibrinogen deposition, and resultant demyelination. Similarly, DAWM also features demyelination and axonal loss. While the implications of NAWM and DAWM remain unclear, it does provide further evidence that MS exists as a more global inflammatory process as opposed to a clearly focal process.

In addition to white matter disease, postmortem studies have provided robust evidence that MS also involves gray matter structures (Gilmore et al., 2009). The cortex is frequently disrupted in MS with cortical pathology demonstrating demyelination, inflammation, and cell death. Similar to white matter lesions, this damage occurs both within discrete lesions as well as in normal-appearing gray matter. The functioning of areas such as the prefrontal cortex, cingulate cortex, and hippocampus is preferentially affected, which explains the dysfunction in domains of executive function, learning, information processing, and memory displayed by MS patients. Finally, disruption of deep gray matter structures, including the thalamus and basal ganglia, is also seen. Atrophy in both the cortex and deeper gray matter regions leads to more global cognitive dysfunction that ultimately contributes to significant morbidity and potentially mortality in MS patients.

Cognitive Impairment in MS

Cognitive impairment is a common complaint among MS patients and leads to considerable disability. The true prevalence of cognitive impairment varies by study; however, it is generally accepted that between 40 and 65% of MS patients experience it (Bobholz & Rao, 2003). Cognitive changes in MS are not clearly tied to disease duration or physical disability. In fact, cognitive changes can occur very early in the disease course and can even precede the diagnosis. Cognitive issues can worsen acutely during a relapse but persist even between relapses and often progress over time. Cognitive impairment seems to be more profound in the progressive subtypes of MS than in the relapsing subtypes.

The cognitive impairment in MS is not global, but rather preferentially affects individual cognitive domains. For example, processing speed is commonly slow in patients with MS. Processing speed involves one's ability to take in new information, manipulate it, and apply it to his environment. Attentional domains are also very commonly affected, especially sustained and shifting attention. When tested, patients with MS score poorly on tasks requiring them to divide their attention and attend to multiple tasks simultaneously. Other very commonly affected domains include visual memory, executive functioning, visual perception, and long-term memory. Visual perception is often confounded by poor visual acuity as many patients with MS have suffered optic neuritis and have residual deficits in visual acuity. However visual perception deficits also occur independently of visual acuity loss. With regard to long-term memory, the problem with memory is usually one of encoding memories and reflective of the poor attention of said patients. Conversely domains like language processing and naming are usually spared.

Cognitive impairment has real consequences for patients with MS and results in decreased productivity at work, high rates of unemployment, disrupted social relationships, and less ability to live independently. Cognitive deficits correlate with objective difficulties completing instrumental activities of daily living, such as managing one's finances and medications, and with worsened scores on subjective quality of life (QOL) measures as reported from a patient's perspective (Cutajar et al., 2000). QOL can be quantified using such tests as the Multiple Sclerosis Quality of Life Inventory or SF36 (part of health status questionnaire). Cognitive deficits can also interfere with the patient–physician therapeutic alliance or patient adherence to prescribed pharmacological or non-pharmacological treatment regimens.

Cognitive impairment can be measured in various ways. Traditional clinical measures of screening cognition such as the Mini-Mental State Examination (MMSE) or Montreal Cognitive Assessment (MoCA) are insensitive to the specific deficits affected in MS. If these are the only screens used to assess MS patients, their deficits and complaints can go under-recognized and underappreciated for years.

The gold standard for diagnosing cognitive impairment in MS patients is formal neuropsychiatric testing, which involves exposing patients to a battery of tests assessing multiple domains of cognition. However, such testing is time consuming, costly, and not available in all regions. A recent focus in the field has been on developing more clinic-friendly cognitive screening assessments. Several validated screening assessments are now available, and there has been considerable debate regarding which are the "best" screens. Each varies in regard to sensitivities and specificities depending on the specific domain of cognition one is interested in analyzing. Two of the most commonly utilized assessments include the Minimal Assessment of Cognitive Function in MS (MACFIMS) and Brief International Cognitive Assessment for MS (BICAMS). The MACFIMS is a ninety-minute battery, consisting of seven tests that was created by the consortium of MS centers that has been validated both in MS patients and in healthy controls (Benedict et al., 2006). The BICAMS is a fifteen-minute test created by an international expert consensus committee and includes the symbol digit modalities test (SDMT), California Verbal Learning Test second edition (CVLT-II), and revised Brief Visuospatial Memory Test (BVMT-R) (Langdon et al., 2012). The BICAMS is designed to be administered by any healthcare practitioner and would not require formal neuropsychiatric training. It is currently undergoing validation studies in multiple countries.

One recent focus in the field has been on developing a computerized or Internet-based screening test to ameliorate some of the cost and availability issues of our current screening methods. Several such screens have been developed and validated, such as the thirty-minute Cognitive Stability Index (Younes et al., 2007), but none have yet been widely incorporated into clinical practice.

Pathophysiologically, it is not known what the exact cause of the cognitive dysfunction in MS is. Likely it is a combination of both gray matter and white matter damage (as detailed earlier in the pathophysiology of MS section) and the resultant atrophy associated with these inflammatory changes in the brain.

The cognitive changes in MS do correlate with quantifiable radiographic changes such as MRI patterns of cerebral atrophy. Both gray and white matter atrophy have been implicated. A recent review article published in Lancet (Rocca et al., 2015) compiled a table of more than thirty recently published studies reporting associations between cognitive function and radiographic measures of either white matter lesions, gray matter lesions, or total brain atrophy. For example, associations have been demonstrated between cognitive impairment and total lesion areas, T1 lesion volumes, T2 lesion volumes, FLAIR lesion volumes, the size of the corpus callosum, and the third ventricular width (Rocca et al., 2015). Moreover, cortical lesions burden has been associated with cognitive disability in MS. No one measure has been shown to fully explain or predict cognitive performance, and research remains ongoing in the field.

Several agents including disease-modifying therapies aimed at tempering the inflammatory process in the CNS have been shown to decrease acute clinical relapses and decrease radiographic lesion burden among patients with MS. It is possible that these therapies slow the rate of progressive cognitive impairment; however no studies yet exist that clearly demonstrate this. No pharmacological therapies have yet been proven to reverse cognitive impairment among MS patients. Nonetheless several agents are used for symptomatic treatment of cognitive impairment in MS. These include stimulants (such as methylphenidate, amphetamine, and modafinil), cholinesterase inhibitors (such as donepezil, galantamine, and rivastigmine), and *N*-methyl-D-aspartate (NMDA) receptor antagonists (such as memantine). A recent Cochrane review of the literature concluded that there is no convincing evidence that any of these agents were effective (He, Zhou, Guo, Hao, & Wu, 2011). Further investigations into pharmacotherapy to treat MS-related cognitive impairment are warranted.

Cognitive rehabilitation is a non-pharmacological form of treatment being increasingly explored to combat MS-related cognitive impairment. Cognitive rehabilitation is an individualized treatment regimen, which combines restorative techniques with compensatory activities. Restorative techniques are designed to help restore normal brain functioning to a previously damaged area and focuses on repeated exposures and practice to harness the brain's natural repair mechanisms and plasticity. Conversely compensatory techniques focus on finding ways around the cognitive difficulties a patient has by utilizing what remaining domains a patient has. For example, behavioral interventions like employing reminders such as personal organizers, calendars, or alarms can be useful for patients with attentional or working memory difficulties. Studies have showed that cognitive rehabilitation strategies can both improve a patient's quality of life and lead to improved performance on memory tasks.

Depression and Fatigue

Both mood disorders and fatigue are very prevalent in MS patients with estimates that up to sixty and ninety percent of patients suffer from these conditions, respectively. Depression and other emotional disorders are associated with reduced functioning, reduced adherence to medical therapies, and overall decreased quality of life. The lifetime prevalence of major depression in patients with MS is elevated and estimated at 46–54% versus 16.2% in the general public (Minden et al., 2014). In addition, MS patients are more likely to have clinical diagnoses of anxiety, and suicide is twice as common in the MS population relative to controls. Recent studies suggest a relationship between depression and demyelination, particularly when demyelination involves the limbic system. Functional MRI studies have shown differences in activation between the prefrontal cortex and the amygdala in patients with concurrent MS and depression. Similar studies have also shown patients with concurrent MS and affective disorders had overall higher global disease burdens suggesting a link between structural damage and comorbid psychiatric disease.

Fatigue is also highly prevalent in MS patients. Patients complain of both cognitive and global fatigue. Researchers have demonstrated an association between cognitive fatigue and slower information processing (Andreasen, Spliid, Andersen, & Jakobsen, 2010). The impact of global fatigue, however, has been more difficult to quantify. Radiographic studies have correlated global fatigue with preferential frontoparietal cortical atrophy and disruption of frontal and parietal pathways (Sepulcre et al., 2009). Recent studies have utilized fMRI scanning to explore MS subjects undergoing cognitive evaluation of working memory and attention via Paced Auditory Serial Addition Test (PASAT) or the Paced Visual Serial Addition Test (PVSAT). Subjects with MS have demonstrated more sustained and widespread cortical activation despite worse task performance. It was hypothesized that this may contribute to “neural fatigue.” The interplay between fatigue and cognitive dysfunction requires further investigation.

Screening for fatigue and affective disorders like depression is very important, because when untreated, such conditions lead to disability. Independent evaluation of these disorders is challenging as fatigue, depression, and cognitive impairment are intricately linked. A few screening tools are currently available. Fatigue can be assessed using validated scales such as the Modified Fatigue Impact Scale (MFIS), Fatigue Severity Scale (FSS), or the Chalder Fatigue Scale. Depression can be assessed using the Beck Depression Inventory. In addition, the General Health Questionnaire can be useful in evaluating more globally for difficulty in regulating emotions. Finally, the Center for Neurologic Study Emotional Lability Scale can be useful in detecting pseudobulbar affect, which can be another important consideration in evaluating depression in MS patients. Clinicians must carefully consider the confounding impact of other related factors, such as insomnia, restless legs syndrome, and circadian rhythm abnormalities, all of which are experienced by MS patients and can influence both fatigue and depression.

Psychoneuroimmunology: Immune Markers of Psychopathology

Overview

In recent years, the role of inflammation as a disease mechanism for both physical and psychological disorders has been increasingly recognized. Immune activation appears to play a critical role in numerous physical disorders and has been observed in conditions such as cardiovascular disease, diabetes, cancer, asthma, and obesity. Accumulating evidence suggests that inflammation also may be a key factor in the development and treatment of psychological disorders (Dantzer, O'Connor, Freund, Johnson, & Kelley, 2008; Raison, Capuron, & Miller, 2006). Although research regarding inflammation and psychological disorders is still emerging, abnormal levels of immune markers have been associated with psychiatric conditions including major depressive disorder (MDD), bipolar disorder (BPD), schizophrenia, and posttraumatic stress disorder (PTSD). The immune system may be a potential treatment target for these disorders. This paper will provide a brief overview of inflammation and describe how inflammation may be a factor in the development of psychopathology. We will then characterize the prior research regarding the role of immune markers in four psychological disorders where inflammation has been more extensively examined: MDD, BPD, schizophrenia, and PTSD.

Inflammation

Inflammation is the immune system's response to both internal and external stimuli that are potentially harmful to the organism. Acute inflammation is protective, preventing spread of harmful agents to nearby tissue and initiating the healing process for damaged tissue. However, chronic inflammation becomes toxic, resulting in neuronal death, and has been linked to

neurodegenerative disorders and psychopathology (Dantzer et al., 2008). Cytokines are one family of proteins that are heavily involved in the inflammatory response and are routinely measured to assess levels of inflammation. Cytokines include interferons, interleukins (IL), and growth factors that have a diverse set of functions and can be proinflammatory or anti-inflammatory or both. Inflammation research is therefore complicated, as inflammation can be helpful or harmful, depending on the context (Yirmiya & Goshen, 2011).

As the brain is responsible for processes integral to the immune response, cytokines are expressed in the brain. The vast majority of the inflammation research has utilized peripheral indices of inflammation, such as measuring levels of cytokines in the body, as opposed to directly studying immune markers in the brain. Peripheral inflammation indices are thought to be a proxy for central nervous system (CNS) inflammation due to the significant interconnections between the peripheral and central immune systems. Proinflammatory cytokines, such as IL-6, IL-1, and tumor necrosis factor-alpha (TNF-α), can be transported across the blood–brain barrier (BBB) and thus are directly able to alter CNS functioning. Peripheral proinflammatory signals can also be propagated across the BBB by cross-talk between the peripheral and central immune systems. While there is a considerable amount of interaction between the central and peripheral immune systems, the exact degree to which peripheral inflammation indicates neuroinflammation remains unclear.

The immune system has been found to be critically involved in brain development and functioning. Cytokines play a role in shaping brain development through cell signaling, neuronal growth and development, and modulation of neurotransmission (Yirmiya & Goshen, 2011). Proinflammatory cytokines aid in the migration of neurons and regulate the process of pruning during development (Dantzer et al., 2008). Indeed, animal studies and nonhuman primate models have found that immune activation in the prenatal and early postnatal period is related to brain volume and neurogenesis. Levels of inflammatory markers have been inversely linked with brain volumes. For example, higher levels of immune markers such as IL-6 have been associated with reduced hippocampal gray matter volume. Immune cells, such as T cells and microglia, are critical for brain and cognitive functioning and help maintain brain plasticity, particularly hippocampal neurogenesis. The brain and the immune system are strongly interconnected; yet, the precise nature of these relationships is complex and not fully understood. Future research in both animal and human models that examines these complex interactions will continue to provide additional insights regarding the effects of immune activation on the brain and behavior.

Immune Markers and Psychopathology

The robust links between the immune system and the brain create numerous opportunities for inflammation to be involved in the development and maintenance of psychopathology. Peripheral immune modulators can induce psychiatric symptoms in both animal and human models (Dantzer et al., 2008). Treatments with proinflammatory cytokines can result in “sickness behavior,” a constellation of depressive-like symptoms including decreased appetite, weight loss, fatigue, sleep disturbances, and social withdrawal. In animal models, the injection of lipopolysaccharide (LPS), a marker for the immune system to identify a foreign body as toxic, induces inflammation and results in depressive-like symptoms. Immune activation via LPS is associated with depression, anxiety, and memory impairment as well as higher levels of serum IL-1b and TNF-α. Therefore, there appears to a direct link between inflammation and the emergence of psychopathology.

Physical health conditions associated with immune system abnormalities such as obesity, diabetes, rheumatoid arthritis, and multiple sclerosis are risk factors for mood disorders.

Similarly, depression is frequently observed among patients who have been diagnosed with a medical condition that is associated with cytokine activation, such as viral infections, rheumatoid arthritis, cancer, and neurodegenerative diseases. Other research has found that approximately half of individuals with hepatitis C and cancer develop depressive symptoms associated with increased levels of IL-6 and TNF-α (Dantzer et al., 2008). In addition to depression, a 30-year population study reported that having an autoimmune disease or being hospitalized from a serious infection increased the risk of developing schizophrenia by 29 and 60%, respectively (Benros et al., 2011). Although there are alternative explanations for why individuals with a physical health condition may develop a psychological disorder (i.e., situational stress, difficulties coping with illness, or lifestyle changes as a result of illness), the relationship between physical and psychological conditions suggests that inflammation is likely important in the etiology of psychopathology.

The exact mechanisms by which inflammation results in psychopathology are unclear; however, stress may be a critical factor (Raison et al., 2006). The stress response system includes the release of immune markers such as TNF-α and IL-6, which increase the release of corticotropin-releasing hormone (CRH), adrenocorticotropic hormone (ACTH), and cortisol by acting directly on hypothalamic and pituitary cells. The seminal work of Kiecolt-Glaser and colleagues has demonstrated that stress, induced experimentally or in response to an external event, is related to compromised immune function and physical health conditions. Stress predicts higher rates of illness following pathogen exposure, protracted wound healing, poorer response to immunization, and alterations in several indices of immune functioning (Glaser & Kiecolt-Glaser, 2005). Dysregulation of the hypothalamic–pituitary–adrenal (HPA) axis, the major stress response system, is also associated with depression. Stress may activate the immune response in the CNS via enhanced neuronal activity. The large and compelling literature regarding stress and the immune system has established clear links between stress, the brain, and the immune system, although again, the precise nature of these relationships still merits attention.

Another explanation for how inflammation may increase the risk for psychopathology is the ability of cytokines to regulate hippocampal neurogenesis. Hippocampal neurogenesis has been implicated as a key mechanism in the pathophysiology and treatment of depression, through the modulation of brain-derived neurotrophic factor (BDNF). Selective serotonin reuptake inhibitors (SSRIs) upregulate the expression of BDNF in the hippocampus, which promotes the proliferation and survival of neural progenitor cells, neural stem cells that differentiate according to location and function.

Inflammation may also create a vulnerability for psychological illness via serotonin (5-HT). Serotonin is a neurotransmitter that is heavily involved in mood functioning and has been implicated in the development and treatment of numerous psychological disorders. Inflammatory cytokines have been found to alter the metabolism and release of central 5-HT. Proinflammatory cytokines IL-1B and TNF-α have also been shown to activate 5-HT transporters. Therefore, immune-driven alterations in 5-HT are likely an important factor in understanding how inflammation may contribute to psychiatric illnesses.

Inflammation and Psychiatric Conditions

Major Depressive Disorder

The inflammation hypothesis posits that MDD is associated with sustained activation of the immune system, specifically increased production of proinflammatory cytokines and acute phase proteins (Maes, 1999). Numerous studies have suggested that depression is accompanied by immune dysregulation. Depressed patients have exhibited increased serum levels of numerous immune markers including IL-1, IL-1B, IL-2, IL-6, interferon gamma (IFN-γ), and TNF-α. One meta-analysis of 58 studies found that IL-6, CRP, and TNF-α were significantly associated with MDD, whereas IL-1B was not tied to MDD (Haapakoski, Mathieu, Ebmeier, Alenius, & Kivimäki, 2015). It is important to note that elevated levels of inflammation were not consistently reported in all studies or for all immune markers and there was extensive heterogeneity in study-specific estimates. Children and adolescents diagnosed with MDD have also exhibited elevated levels of immune markers such as IL-6, IFN-γ, and IL-1B. Increased levels of IL-1B, IL-2, and IL-10 have been reported among unmedicated children with MDD. Elevated protein expression levels of IL-1B and TNF-α in the prefrontal cortex were observed in adolescents who completed suicide than controls.

Immune activation may differ depending on the presence of suicidality. Most individuals who have attempted suicide or had suicidal ideation have shown an imbalance of the immune system. IL-6 and TNF-α may be significantly higher, whereas IL-2 may be lower among suicidal patients versus depressed patients without suicidality. Although further research is needed in this area to draw conclusions regarding suicidality and inflammation, suicidality should be assessed in the context of MDD inflammation research. Relatively little research has investigated the influence of treatment on inflammation; however, cytokines may be reduced to normal levels following successful antidepressant treatment.

Bipolar Disorder

Inflammatory markers, combined with oxidative damage and neurotrophins, are theorized to be one of the three key pillars in a multifactorial approach to predicting BPD among those at risk (Brietzke et al., 2012). Immune alterations have been associated with many aspects of BPD including symptom severity, mood episodes, stages, and medication effects. TNF-α, IL-6, and IL-8 have been shown to be elevated during manic and depressive phase, whereas IL-2, IL-4, and IL-6 were increased during manic episodes. Other markers, such as IL-1B and IL-1, may be normal among individuals with BPD.

A large meta-analysis of thirty studies concluded that IL-4, IL-10, and TNF-α are elevated in patients with BPD compared with healthy controls (Modabbernia, Taslimi, Brietzke, & Ashrafi, 2013). Interestingly, levels of IL-2, IFN-γ, and IL-4 were unrelated to medication status. Phasic differences were present for TNF-α and IL-6, but not IL-4 and IL-10. Levels of TNF-α and IL-6 appear to normalize during the depressive phase, whereas other markers such as IL-2R remain abnormal. Larger studies examining phasic differences are needed to elucidate trait and state markers of BPD. The research with child and adolescent samples is too limited to draw conclusions at this time; however, CRP may be related to mania symptom severity.

Regarding treatment effects, a meta-analysis reported that medication did not significantly impact markers such as IL-2, IL-4, and IFN-γ (Modabbernia et al., 2013). Medication effects of other cytokines could not be determined due to the small number of studies. While there is substantial support, the immune system being involved in BPD, at this time, it is unclear which markers are most related to specific phases and the impact of treatment on the immune system.

Schizophrenia

The development of schizophrenia may be due, in part, to immune dysregulation (Miller, Buckley, Seabolt, Mellor, & Kirkpatrick, 2011). Early work revealed that prenatal infections with bacterial or viral agents were associated with an increased risk of adult-onset schizophrenia. A substantial portion of cases diagnosed with schizophrenia spectrum disorders had mothers exposed to influenza in the first trimester of pregnancy than controls. Further, increased maternal levels of proinflammatory cytokines have been related to schizophrenia in offspring. A number of reviews describe the mechanisms by which infection alters neurodevelopment that increases the risk of developing schizophrenia (e.g., Miller et al., 2011).

However, the risk of developing schizophrenia from infection is not restricted to the prenatal period. Exposure to neurotropic virus in early childhood is associated with increased risk of subclinical psychosis during adolescence. In a 30-year population study, childhood autoimmune conditions were related to subclinical psychotic experiences in adolescents and schizophrenia in adults (Benros et al., 2011). Here, the risk of schizophrenia had a positive linear relationship with the number of severe infections among those with a history of autoimmune disease, and autoimmune conditions were more prevalent in individuals with schizophrenia than controls. One meta-analytic study revealed that the risk of schizophrenia was nearly double among adult survivors of childhood CNS viral infections (Khandaker, Zimbron, Dalman, Lewis, & Jones, 2012). Interestingly, the prevalence of autoimmune conditions is increased in people with schizophrenia as well as their unaffected first-degree relatives.

Increased levels of inflammatory markers have been recorded in those with schizophrenia and associated symptoms. First-episode psychosis and acute psychotic relapse are linked with increased concentrations of IL-6, TNF-α, IL-1β, and IFN-γ and decreased levels of IL-10. Several meta-analyses have concluded that schizophrenia is related to altered immune functioning, with a propensity toward increased production of proinflammatory cytokines (e.g., Miller et al., 2011). It is important to note that the literature may be more conflicting, as some studies have found both decreased proinflammatory markers (e.g., IL-2, IFN-γ) and increased serum and cerebral spinal fluid (CSF) anti-inflammatory cytokines (e.g., IL-10). Nonetheless, there appears to be a dominance of proinflammatory findings. Miller and colleagues reported that levels of inflammation between controls, first-episode patients, and acutely relapsed patients were similar, suggesting that abnormal cytokine levels in schizophrenia are not a result of antipsychotic treatment. Comparatively little work has been conducted with child populations, although children with schizophrenia may have comparable levels of TNF-α to controls, both before and after clozapine treatment. More studies are needed in child populations as childhood-onset schizophrenia may present with a different inflammatory profile than adult-onset schizophrenia.

In a longitudinal study of inflammatory markers and subsequent psychotic disorders, the Avon Longitudinal Study of Parents and Children (ALSPAC) birth cohort revealed that higher concentrations of IL-6 at age 9 corresponded to a twofold increased risk of developing a psychotic disorder at age 18 (Khandaker, Pearson, Zammit, Lewis, & Jones, 2014). A robust dose–response relationship was also reported between IL-6 levels in childhood and later risk of psychotic experiences in young adulthood, even after controlling for sex, body mass, and psychological and behavioral problems. Initial CRP levels were not related to later psychosis. Additional longitudinal studies will help to confirm whether which markers are tied to the development of schizophrenia and related psychosis.

The hypothesized immune-mediation etiology for schizophrenia is supported by genome-wide association studies that report significant relationships between schizophrenia and markers close to the major histocompatibility complex region, which contains many immune-related genes, including inflammatory mediators. Genome-wide studies have identified numerous genetic loci associated with schizophrenia, many of which represent genes expressed in the brain and immune cells involved in adaptive immunity. In a recent review, inflammation-related genes such as SERPINA3 and IFITM were consistently increased in schizophrenic brains (Trépanier, Hopperton, Mizrahi, Mechawar, & Bazinet, 2016). These findings suggest increased expression for immune-mediating genes in schizophrenia.

Further support for the role of the immune system in schizophrenia is found in treatment studies. Immunotherapy has led to symptomatic improvement in some cases of first-episode psychosis. TNF-α, IL-1β, IFN-γ, and IL-10 may normalize after remission of symptoms from antipsychotic treatment. Treatment of acute psychosis has been related to significant reductions in IL-1β, IL-4, and IL-6 and increases in IL-12. Thus, it appears that changes in cytokines are likely following successful treatment.

Posttraumatic Stress Disorder

Individuals with PTSD are at an increased risk for a myriad of health issues, including autoimmune disorders, diabetes, and cardiovascular disease. However, the etiology of this relationship is unknown, and studies regarding inflammation and PTSD appear more conflicting than other disorders. The first meta-analysis regarding PTSD and inflammation was recently conducted by Passos et al. (2015), which included 20 studies that contrasted inflammatory markers among individuals with PTSD compared with healthy controls. Concentrations of IL-6, IL-1B, and IFN-γ were higher in the PTSD group than controls, with large effect sizes for IL-1B and IL-6 and a medium effect size for IFN-γ. PTSD duration was positively related to IL-1B, and symptom severity was tied to IL-6. Higher levels TNF-α were observed in the unmedicated PTSD group. In the studies that excluded individuals with comorbid MDD, levels of TNF-α, IL-1B, and IL-6 remained elevated. Consequently, use of medication and comorbid conditions may account for conflicting results. It is important to note that research studies with trauma-exposed individuals, who may or may not have PTSD, have also reported higher levels of CRP, IL-1B, IL-6, and TNF-α, suggesting full PTSD diagnostic criteria need not be met for immune dysfunction to manifest.

Coelho, Viola, Walss-Bass, Brietzke, and Grassi-Oliveira (2014) reviewed the nascent literature regarding child maltreatment and inflammation. A history of child maltreatment was related to increased levels of CRP, fibrinogen, TNF-α, and IL-6. CRP was the most robust marker. However, many of the studies included individuals with MDD, only one study was specific to PTSD, and most of the studies utilized small samples (ns < 20). Thus, it is premature to draw conclusions regarding immune activation and child maltreatment at this time. There is also very limited information regarding the impact of treatment on immune markers among patients with PTSD.

Conclusions and Future Directions

There is substantial support for the role of the immune system in the development and maintenance of psychopathology, and altered levels of inflammatory markers have been observed in MDD, BPD, schizophrenia, and PTSD. Physical health issues have been consistently associated with multiple psychological disorders, and there is evidence that this relationship is mediated by immune functioning. Yet, our ability to determine the role of inflammation on psychological conditions is limited by the caliber of the current published studies. Numerous early studies had relatively poor quality, including small sample sizes and failing to control for important confounds such as body mass index and other psychiatric conditions. Further, as most studies currently use peripheral markers to establish these connections, more longitudinal studies are needed connecting inflammatory markers in the CNS before confidence can be placed on this etiological explanation.

Study differences complicate the field's ability to draw conclusions regarding inflammation and specific psychiatric disorders. Rates of comorbidity are high among patients with MDD, BPD, schizophrenia, and PTSD, which makes it more challenging to determine if there is a unique inflammatory profile associated with a specific disorder. Some studies exclude all comorbid conditions, whereas others only exclude psychosis and/or bipolar. Not all studies provide information regarding other psychiatric conditions. For example, only 47% of studies included data regarding other Axis I or Axis II diagnoses, and 26% of studies did not assess or report other Axis I or Axis II disorders (Haapakoski et al., 2015). Further, many studies do not include information on the different subtypes of MDD and PTSD, which is important in light of the variability across phenotypes of these conditions. A shift in research focus from a diagnostic construct to specific symptoms and dimensions of symptoms may shed light on how immune markers interact with psychiatric difficulties.

The majority of the evidence linking immune function to psychopathology is correlational. Research targeting the precise mechanisms by which immune dysfunction leads to psychopathology is necessary before causal conclusions can be drawn. It may be that the immune response contributes to the development of psychopathology, but it is also possible that the presence of psychopathology leads to dysfunction in the immune system or that another factor induces both immune dysregulation and psychological symptoms. There is some support for a causal relationship as studies have demonstrated that administration of proinflammatory cytokines and LPS leads to disordered behavioral symptoms and immune markers may normalize as symptoms resolve after treatment (Dantzer et al., 2008; O'Connor & Spagnola, 2009). However, these studies are relatively few and not sufficient for demonstrating causal influence. Findings in human correlational research are also inconsistent, and results vary across samples and specific immune markers. This research area is relatively young, with the first meta-analysis in some disorders being published within the last 2 years (i.e., Passos et al., 2015).

The long-term effects and development of alterations in the immune system are still unclear. Longitudinal and prospective studies of immune markers and specific psychiatric conditions are needed to more definitively conclude that inflammation is a key factor in the development of psychopathology. Given the importance of stressful life events and traumatic exposure, research is also needed to examine immune markers and indices of stress (i.e., cortisol) and psychiatric conditions. Despite these limitations, there is a preponderance of data pointing to the importance of inflammation in numerous psychiatric conditions. Immune markers represent critical putative biomarkers and intervention targets that may ultimately allow us to better ameliorate psychiatric symptoms.

The Study of Genetics

DNA molecules consist of two strands that are coiled around each other like a twisted ladder, forming a double helix. The two DNA strands are called polynucleotides since they consist of smaller units called nucleotides. Each nucleotide is composed of a nitrogen-containing nucleobase: either adenine (A) and thymine (T), creating A–T pairs, or cytosine (C) and guanine (G), creating G–C pairs, as well as sugar (deoxyribose) and a phosphate group.

Polymorphisms are variations of a particular DNA sequence. The most common type of polymorphisms involves variation at a single base pair. These are called single nucleotide polymorphisms (SNPs). For example, an SNP may replace the cytosine (C) with thymine (T) at a certain DNA locus. When such SNPs occur within a gene, they may change the amino acid sequence of the gene's protein product or change the timing, location, or level of gene expression. Another type of polymorphism is a variation (e.g., repeats) in tandems of two or more adjacent nucleotides (see Figure 1).

Despite intense research on the role of genetics in human health and behavior in the past decades, we are still far from fully understanding the complex interactions between genes and behavior. Here, we provide an overview of several genes whose polymorphisms have been extensively studied due to their role in the regulation of molecular mechanisms and modulation of neurotransmitter systems in the brain, leading to changes in human cognition and behavior.

Dopamine System

Numerous studies across a wide range of species demonstrated that the dopaminergic system plays a key role in reward, behavioral flexibility, working memory (WM), positive reinforcement, and learning processes. Malfunction in this system is associated with behavioral

abnormalities and diseases such as impulsive behaviors, addiction, Parkinson's disease, and schizophrenia.

Dopamine (DA) is a monoamine neurotransmitter that is produced by DA neurons in two regions of the midbrain, the ventral tegmental area (VTA) and substantia nigra pars compacta (SNc), and projected to a broad number of brain regions. There are three major dopaminergic projections in the central nervous system: the nigrostriatal pathway, regulating motor functions; the mesocorticolimbic pathway, which plays a key role in reward, motivation, learning, emotions, and memory; and the tuberoinfundibular pathway, involved in prolactin secretion regulation and sensory processing.

DA transmission in the brain is mediated by five (D1–D5) subtypes of DA receptors, dopamine transporters (DAT), and enzyme catabolizers, which show different patterns of distribution across brain regions and therefore affect different cognitive functions. For instance, the concentration of D1 receptors is higher in prefrontal areas, while D2 receptor concentration is most prevalent in the striatum. DAT density is highest in subcortical regions, and catechol-*O*-methyltransferase (COMT) plays a major role in DA clearance in the prefrontal cortex (PFC).

Genetic polymorphisms of the DA system include SNPs and variable number tandem repeat (VNTR) polymorphisms of the metabolizing enzymes, receptors and transporters, which modulate tonic DA (the average amount of DA available over a relatively long period of time) or phasic DA levels (the amount of DA being released in a given burst of neuronal firing). The most important genes modulating DA transmission comprise the enzyme catabolizers COMT and monoamine oxidase A (MAOA), dopamine- and cAMP-regulated phosphoprotein (DARPP-32), the dopamine receptor D2 (DRD2) and D4 (DRD4) genes, and DAT.

Serotonin System

A further important monoamine neurotransmitter is serotonin (5HT or 5-hydroxytryptamine), which is produced in the raphe nuclei of the midbrain and transported to the limbic system, cerebellum, and cortex. The serotonin system plays an important role in sensory processing, sleep, memory, mood, and arousal. Pathology in this system has been associated with diseases such as depression, antisocial behavior, bipolar disorder, and schizophrenia.

The best-investigated gene modulating serotonin transmission is the serotonin transporter-linked polymorphic region (5-HTTLPR) gene. Genetic variations in this gene have been linked to personality traits such as impulsivity and neuroticism and to a range of psychiatric illnesses as well as the treatment success of such disorders.

5HT, catecholamines, and histamine are metabolized by the COMT and monoamine oxidase (MAO) enzymes. There are two MAO isoforms (MAOA and MAOB) that are encoded by distinct genes on the X chromosome. MAOA and MAOB differ in their substrate specificity, anatomical distribution, regulation by pharmacological agents, and influence on behavior. Serotonin is mostly degraded by MAOA, while DA is degraded by both MAOA and MAOB.

Opioid System

The opioid system has been extensively studied due to its association to pain, analgesia, reward sensitivity, and substance abuse. There are several endogenous opioids—dynorphins, enkephalins, endorphins, and endomorphins—which bind with high affinity to particular μ-, δ-, and κ-opioid receptors. Important genes modulating the opioid system are the μ-opioid receptor gene (OPRM1) and prodynorphin (PDYN), a gene coding for dynorphin opioid peptides, which have a high affinity to κ-opioid receptors. Genetic variations in these genes have been associated with individual differences in the reward processing as well as different forms of addiction, such as nicotine and alcohol dependence.

Neuroendocrine System

The hypothalamus and pituitary gland are the center of integration for the nervous and the endocrine system. The neuroendocrine system plays a role in social behavior, mating, pair bonding, trust, aggression, and empathy. A well-studied gene modulating the neuroendocrine system is the oxytocin receptor (OXTR) gene, which has been implicated in a wide range of social behaviors.

In addition to the genes mentioned above, the proteins apolipoprotein E (ApoE) and the brain-derived neurotrophic factor (BDNF) have been extensively investigated due to their involvement in memory, aging, depression, anxiety, and mood disorders. ApoE is a major cholesterol carrier that supports lipid transport and injury repair in the brain, whose allele number 4 ApoE ε4 is the most important genetic risk factor for Alzheimer's disease (AD) and dementia. BDNF is a protein involved in the proliferation, neurogenesis, differentiation, survival of neuronal cells, and neuroplasticity, which is involved in the pathogenesis of a wide range of psychiatric disorders. Table 1 provides an overview of the here discussed genes and polymorphisms and their involvement in functional domains of cognition and behavior.

Polymorphisms and Behavior

Reward Processing

Rewards may be defined as events that generate approach and consummatory behavior, evoking positive emotions and leading to learning of this behavior. Rewards that are crucial for survival

Table 1 A list of genes associated with neurotransmitter systems and their related polymorphisms and the proposed mechanism of those polymorphisms on cognitive function.

Gene	*Polymorphism*	*Mechanism*	*Functional domain*
Dopamine system			
COMT (*catechol-O-methyltransferase*) Enzyme with high availability in prefrontal cortex that degrades catecholamines	SNP Val158Met (rs4680) Substitution of methionine (Met) in place of valine (Val) at codon 158	Met/Met carriers have a 2–4 fold decrease of COMT activity, compared with the Val/Val genotype, leading to higher extracellular dopamine levels in the prefrontal cortex	Reward, working memory, learning, attention
DRD2 (*dopamine receptor D2*)/ANKK1 (*ankyrin repeat and kinase domain*) Closely linked to the dopamine receptor D2 (DRD2) on chromosome band 11q23.1	DRD2/ANKK1-Taq1A (rs1800497) Located in a putative substrate-binding domain of the ANNK1 gene, resulting in a Glu713Lys substitution	This polymorphism modulates the density of DA D2 receptors. A1 allele carriers show a reduction in striatal D2 receptor density compared to the noncarriers	Reward, learning, neuroticism, addiction, schizophrenia
DRD4 (*dopamine receptor D4*) Located on chromosome 11p, predominantly expressed in prefrontal cortex	48-bp tandem repeat (VNTR) Codes for the third cytoplasmic loop of the receptor	The 7-repeat variant has been linked to decreased postsynaptic inhibition and lower dopaminergic tone	Impulsivity, novelty seeking, addiction, obsessive–compulsive disorder, ADHD
DAT (*dopamine transporter*) SLC6A3 High availability in striatum, regulates dopamine signaling at the synapse through reuptake of dopamine into presynaptic terminals, thus terminating signaling	40-bp VNTR (rs28313670) Located in the 3′-untranslated (UTR) region of the gene with repeat numbers between 3 and 13	This polymorphism produces two common alleles with 9 and 10 repeats (9R and 10R), which affect the basal level of expression of the transporter. The 9R allele is associated with increased DAT activity in human adults	Reward, addiction, learning, working memory, cognitive flexibility, ADHD
DARPP-32 (*dopamine- and cAMP-regulated phosphoprotein*) PPP1R1B (protein phosphatase 1 regulatory inhibitor subunit 1B), located on chromosome 17q12	DARPP-32 Richly expressed protein in the striatum, regulated by D1 and D2 dopamine receptors in opposing directions	The protein modulates striatal dopamine cellular excitability and synaptic plasticity related to the dopamine receptors. AA homozygotes have higher D1 dopamine receptor efficacy	Learning, cognitive flexibility, anger

Gene	*Polymorphism*	*Mechanism*	*Functional domain*
Serotonin system			
5-HTT/SLC6A4 (*serotonin transporter gene*)	5-HTTLPR Short and long repeats in the 5-HTT-linked polymorphic region. The short variation has 14 repeats of a sequence, the long variation has 16 repeats	The short allele is associated with lower levels of serotonin uptake and lower transcriptional efficiency of the serotonin transporter protein compared with the long allele	Impulsivity, aggression, antisocial behavior, anxiety, depression, bipolar disorder
MAOA (*monoamine oxidase A*) An enzyme that metabolizes catecholamines, 5HT and histamine	30-bpVNTR Located 1.2 kb upstream from exon 1 in the 5' UTR of MAOA gene	Common are 3 and 4 repeats, less frequent are 2, 3.5, and 5 repeats. The alleles with 3.5 or 4 repeats (high activity alleles) have 2–10 times more transcriptional activity than those with 2 or 3 copies (low-activity alleles)	Aggression, antisocial behavior, depression, reward, addiction
Opioid system			
OPRM1	SNP (rs1799971) Often referred to as A118G, situated in exon 1	The variant leads to the conversion of the amino acid asparagine to aspartate at codon 40	Addiction, alcoholism, Smoking
PDYN (*prodynorphin*) Codes the dynorphin opioid peptides, which have a high affinity to κ receptors	This polymorphism is located in the PDYN gene promoter region with one to four repeats of a 68-bp element containing one binding site per repeat for the transcription factor AP-1 (c-Fos/c-Jun)	Alleles with 3 or 4 repeats are associated with higher levels of dynorphins expression than alleles with 1 or 2 repeats	Reward, addiction, alcoholism, memory
Neuroendocrine system			
OXTR (*oxytocin receptor*)	SNP (rs53576), which consists of a G to A change within the third intron	Research usually compares individuals homozygous for the G allele (GG) with individuals with A allele carriers (AA/AG)	Prosocial behavior, empathy, trust, mating, depression, personality traits

Proteins			
ApoE (*apolipoprotein E*) Produces a protein that, when combined with fat, becomes a lipoprotein	ApoE-ε2, ApoE-ε3, ApoE-ε4 Three allelic variants of ApoE as defined by the two SNPs rs429358 and rs7412	ApoE ε4 is associated with an increased risk of developing Alzheimer's disease, ApoE ε2 with a reduced risk, relative to the more common ε3 allele	Memory, Alzheimer's disease, mild cognitive impairment
BDNF (*brain-derived neurotrophic factor*) Supports neuronal growth and differentiation, induces long-lasting changes in synaptic plasticity	BDNF Val66Met Substitution of methionine (Met) for valine (Val) at codon 66 of the pro-BDNF protein	The Met allele results in reduced activity-dependent release of BDNF and inefficient BDNF trafficking	Memory, aging, depression

such as eating, drinking, and reproduction are called primary rewards. Rewards that are attributed to, for instance, money, gambling, and aesthetic stimuli are called secondary rewards.

The ability to predict future rewards and losses and to assess the value of upcoming outcomes is a fundamental aspect of learning and adaptive behavior. Numerous neurophysiological and neuroimaging studies demonstrated that anticipating and receiving rewards activates the brain's reward circuitry, including the dopaminergic midbrain, striatum, and PFC. Given the fundamental role of DA in reward processing, studies investigating reward anticipation and feedback, approach motivation, goal-directed behavior, and pathological aspects of the reward system focused on several genetic variations in the dopaminergic system to reveal how those variations modulate reward-related behavior. These investigations confirmed significant effects of polymorphisms in the COMT, DAT, DRD2/Taq1A, and DRD4 genes on reward behavior and its underlying brain activity.

One of the best-investigated genetic variations in the dopaminergic system is the COMT Val158Met polymorphism, which contributes to a degradation of DA in PFC and modulates activity in the cortico-striatal loop connecting the frontal cortex and the brain's core reward center, the striatum. Imaging genomics studies found that there is a linear relationship between the number of met158 alleles and ventral striatal activity and that the activation of the ventral striatum and anterior cingulated cortex is modulated by the COMT polymorphism. Further, an interaction between the COMT Val158Met polymorphism and stressful life events was observed, such that Met/Met carriers (who have higher levels of DA in PFC) with low exposure to lifetime stress showed a lower sensitivity to reward than Met/Met carriers with high exposure to lifetime stress. A study investigating how the interaction between the COMT and DAT genes influences reward processing revealed that both variants modulated activation in PFC and striatum and that the combinations COMT Met/Met DAT 10R and COMT Val/Val 9R were associated with blunted responses to rewards in the ventral striatum. People with the 22q11.2 deletion syndrome (a microdeletion on chromosome 22q11.2, where the gene coding for COMT is located) displayed reduced activity in medial frontal regions during reward anticipation.

Studies of the DAT1 gene revealed that carriers of the 9-repeat allele, associated with high levels of DA in the striatum, showed greater activity in the ventromedial striatum during reward anticipation than homozygotes for the 10-repeat allele. Individual differences in extraversion and the presence of the DRD2 Taq1A allele predicted a significant amount of intersubject variability in the magnitudes of reward-related brain activity. Moreover, the DRD2 gene was linked to the interindividual variations in neural responses to expectations of reward and negative emotional processing, as well as stress-induced DA release.

These studies demonstrated that genetic variations in the COMT gene as well as the DAT1 and DRD2 genes alter the processing of rewards in the brain. However, effects of polymorphisms in other neurotransmitter systems have also been observed. For example, T homozygotes carriers of the oxytocin (OXTR) gene demonstrated relatively decreased activation in the mesolimbic circuitry when anticipating rewards. Moreover, individuals with the HH genotype of the 68-bp VNTR PDYN gene showed higher activation in the medial orbitofrontal cortex (mOFC) when anticipating monetary rewards and stronger functional coupling of mOFC with the ventral striatum and ventral medial PFC than individuals with the LL genotype, indicating an increased sensitivity for upcoming rewards.

Besides leading to individual differences in how rewards are processed in the healthy brain, genetic variations in neurotransmitters implicated in the reward system, genetic variations may contribute to a hyper- or hyposensitivity to rewards that can become pathological. Hypersensitivity to potential rewards may lead to an excessive increase in approach behavior in the presence of rewards, while a decreased sensitivity may lead to seeking ever more stimulating experiences in order to compensate for low levels of reward experience. Such malfunctions of the reward system can contribute to pathological forms of reward behavior, such as sensation seeking, risk-taking, pathological gambling (PG), anhedonia, and addiction.

Drugs induce a pleasurable state and are therefore experienced as rewarding and thus reinforcing. In addition, repeated self-administration of drugs causes cellular and molecular changes in neurons as well as homeostatic adaptations, which further contribute to increased tolerance of the drug and, eventually, addiction. Drugs act via different systems: opioid drugs via binding with μ-opioid receptors, cocaine and amphetamine through the DAT, and ethanol through GABAa receptors and the inhibition of NMDA glutamate receptors. Understanding genetic risk factors for individual vulnerability to addiction is of high importance for the development of prevention strategies.

There is evidence that individual variations in the opioid OPRM1 and PDYN genes are related to the development of opioid and ethanol substance dependence. Methamphetamine and heroin-dependent individuals exhibited a significantly higher frequency of the 3- or 4-repeat allele 68-bp VNTR polymorphism in the PDYN gene than healthy individuals. Similarly, several other PDYN polymorphisms (e.g., rs1022563, rs2235749) were associated with cocaine, heroin, and alcohol. Comparable findings were observed for an SNP of the μ-opioid receptor gene OPRM1 (rs1799971), which has been linked to heroin abuse, alcoholism, and smoking. A recent meta-analysis confirmed that the OPRM1 SNP contributes to mechanisms of addiction liability and is shared across different addictive substances. Moreover, studies investigating DA receptor candidate genes suggested that the DRD2 A1 allele (DRD2 Taq1A polymorphism) was associated with a higher consumption of alcohol and heroin.

A well-studied example of addiction not including substance abuse (i.e., behavioral addiction) is PG. In the recently released fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5), pathological gambling (renamed “disordered gambling”) was moved from the “Impulse Control Disorders Not Elsewhere Classified” category into the new “Substance-Related and Addictive Disorders” category. PG is a chronic, progressive disorder that is associated with the urge to gamble continuously despite harmful negative consequences or a desire to stop. Often, gambling is used as a model for investigating mechanism of developing a behavioral addiction. The heritability of PG is estimated to be 50–60%. PG shares genetic vulnerability factors with alcohol dependence and depressive disorder, with the genetic correlation between PG and alcohol dependence ranging from 0.29 to 0.44, with men showing a higher correlation than women.

Genetic studies have associated PG with the DRD2 TaqA1 polymorphism, the 10/10 alleles of the DAT1 gene, and polymorphisms of DRD2/ANKK1, revealing that pathological gamblers with genetic predispositions toward lower availability of DA and D2 receptor density are at a higher risk of cognitive flexibility difficulties. Other candidate genes that have been the focus of genetic association studies of PG are the serotonin transporter gene and the MAOA genes. Allelic frequency of the 3-copy allele MAOA polymorphism was observed to be significantly higher in male gamblers than in men without PG, and the less functional S allele of the 5-HTTPLR polymorphism was more frequent in male gamblers. However, the only genome-wide association study of PG to date in 1,312 twins found no single candidate gene reaching genome-wide significance, rendering current results of genetic variations underlying PG preliminary and in need of replication.

Substance abuse and behavioral addictions are highly comorbid with other maladaptive behaviors, such as impulsivity, risk-taking, and sensation and novelty seeking. Impulsivity is characterized as the inability to withhold an action for the time needed to estimate consequences. An example of an impulsive choice is when an individual preferentially chooses an immediately available small reward rather than enduring a certain time delay for a larger reward (“delay discounting”), a behavior that is frequently observed in individuals with substance use disorders. Independent twin and longitudinal twin studies have demonstrated a heritability of impulsivity in the range of 40–50% and implicated the DA-related genes COMT, DRD2, DRD4, and DAT in impulsivity, delay discounting, and risk-taking. However, the most extensively studied polymorphism in the context of impulsivity is the serotonin transporter 5-HTTLPR, revealing that carriers of the less active S allele score higher on attentional impulsiveness and are less sensitive to punishment-related information.

Learning

Based on the reinforcing role of rewards in learning processes, the dopaminergic system is also a key component of learning and motivation, as evidenced by a wealth of findings across a range of different species from rats to humans. In the striatum, DA is critical for reinforcing actions that are most likely to lead to a reward. Demonstrating this, striatal activation has been observed to predict the amount of learning effects regarding WM updating. In response to positive “prediction errors” (events that are better than expected), DA cells burst fire, whereas the same cells remain silent in response to negative prediction errors (events that are worse than expected). Reinforcement learning models assume that these bursts and dips act as teaching signals by modifying synaptic plasticity in the structures involved. Studies in rodents have shown that phasic (but not tonic) stimulation of dopaminergic cells induces behavioral conditioning, and conversely, selective genetic disruption of phasic dopaminergic burst firing produces behavioral learning deficits, demonstrating a direct influence between DA activity on learning in animals.

In humans, several genes controlling dopaminergic function in the frontostriatal circuitry have been investigated in the context of learning, including COMT, DARPP-32, DAT1, DRD2, and DRD4. The COMT Val158Met polymorphism has repeatedly been found to influence cognitive processing in a variety of tasks requiring prefrontal function, and a recent meta-analysis confirmed the involvement of the COMT Val158Met polymorphism in reward learning. Genetic polymorphisms modulating DARPP-32 mRNA expression and cognition in humans are associated with changes in activation in the striatum and with frontostriatal connectivity. Biophysical models showed that DARPP-32 serves to integrate DA signals across time, demonstrating a key role of this gene in probabilistic reinforcement learning. The DAT1 polymorphism is predictive of neural and behavioral responses to cognitive flexibility and has further been shown to modulate striatal activity as a function of WM load in an updating task. The DRD2 gene polymorphism affects D2 receptor density in the striatum, the brain region in which D2 receptors are by far most prevalent. DRD2 has been demonstrated to be strongly predictive of learning from negative reward prediction errors, that is, avoiding responses that lead to negative outcomes. Lastly, the DRD4 gene is associated with dopaminergic function in PFC, in which the D4 receptor is primarily expressed, and has been found predictive of error-related prefrontal activity and subsequent behavioral adjustments.

Besides the DA system, also the serotonin system has been implicated in individual differences in learning and decision making, revealing a differential association of the serotonin transporter 5-HTTLPR polymorphism with reflexive and reflective optimal learning. Moreover, the Val66Met polymorphism of the neurotrophin BDNF, which is involved in regulating synaptic plasticity in many brain areas including the hippocampus, has been suggested to affect sensorimotor cortex activity as well as motor learning in humans. Individuals with the BDNF Met allele have been reported to show increased cognitive performance and to commit more errors during short-term learning during a driving-based motor learning task. Furthermore, a recent study provided first evidence that dynorphins contribute to individual differences in reversal learning: carriers of the HH genotype (alleles with 3 or 4 repeats) of the nucleotide tandem repeat (68-bp VNTR) functional polymorphism of the prodynorphin (PDYN) made more perseverative errors than carriers of the LL genotype in a reversal learning task requiring flexible adaptation to stimulus–response associations and showed less engagement of the orbitofrontal cortex (OFC) and cortico-striatal circuitry as well as lower effective connectivity of the OFC with the anterior midcingulate cortex and the anterior insula/ventrolateral PFC during reversal learning and the processing of negative feedback.

Taken together, individual differences in human learning capacity have been robustly associated with genetic variations in the DA system. While many studies have linked single DA-related candidate genes to individual differences in learning, it has to be considered that the well-studied COMT val/met polymorphism can itself be moderated by other dopaminergic polymorphisms such as DAT1 and DRD2 as well as within the COMT gene itself, requiring future investigations taking more complex gene × gene interactions into account. Besides the COMT Val158Met polymorphism, individual differences in learning seem further modulated by the BDNF Val66Met polymorphism and the PDYN VNTR polymorphism.

Memory

The apolipoprotein E (ApoE) gene is the most important known genetic risk factor for AD, a chronic neurodegenerative disease causing dementia. ApoE has three major alleles: ApoE ε2, ε3, and ε4. ApoE ε4 is associated with an increased risk of AD, ApoE ε2 with a reduced risk, relative to the more common ε3 allele. Healthy carriers of *APOE* ε4 show an accelerated decline in memory tests starting at the age of 55–60 years. While the underlying mechanism of this effect of ApoE ε4 is not fully understood, evidence suggests an interaction with amyloid: AD is characterized by buildups of aggregates of the peptide beta-amyloid. ApoE enhances proteolytic breakdown of this peptide, and ApoE ε4 appears less effective than the other alleles at promoting these reactions, resulting in increased vulnerability to AD in individuals carrying the ApoE ε4 allele. Regarding protective factors, evidence suggests that a high education level, active leisure activities and exercise, and maintenance of vascular health are beneficial in reducing the risk of AD and cognitive decline, particularly in APOE ε4 carriers.

Besides ApoE, individual differences in memory performance are influenced by the neurotrophin BDNF, whose levels of expression are particularly high in the hippocampus, the brain's memory center, in which the consolidation of information from short-term to long-term memory takes place. The BDNF Val66Met polymorphism produces a nonconservative substitution of amino acids at codon 66 of the gene, involving a valine (Val) being replaced by a methionine (Met). The presence of a copy of the Met allele is associated with less activity-dependent BDNF secretion, as well as abnormal BDNF localization. A number of behavioral and neuroimaging studies observed that Met homozygotes perform worse on verbal episodic memory tests as well as on visual sensory memory tests than Val homozygotes and that carriers of the Met allele activate the hippocampus less during memory encoding and retrieval, suggesting weaker memory trace formation in carriers of the Met allele.

The extracellular enzyme COMT is known to degrade DA in the synapses. In humans, COMT is mostly expressed in the PFC and thus has a direct influence on prefrontal DA level. The COMT Val158Met polymorphism, which is known to affect prefrontal DA levels and D1 receptor binding, influences cognitive processing in various tasks that depend on prefrontal function. Regarding memory performance, COMT Val158Met modulates the activity and connectivity of brain regions within the WM network. This effect is stronger with increasing age, contributing to an age-related decline in memory performance. The relation between DA and WM depends on a person's baseline DA level and is thus characterized by an inverted U-shape function: administration of DA increases WM performance in individuals with low WM capacity but decreases performance in those with high WM capacity. These differences likely reflect differences in baseline DA levels, with low DA levels in individuals with low WM capacity and high DA levels in those with high WM capacity, such that additional DA administration either optimizes the DA level or exceeds it, depending on a person's baseline DA. Thus, there is an optimum concentration of DA in the PFC to perform WM tasks. These findings demonstrate that individual differences in WM performance are genetically determined by DA level and modified by the COMT Val158Met polymorphism.

A number of animal studies and some human studies have shown that memory is further modulated by dynorphins. Dynorphins are members of the opioid peptide family that are located in the hippocampus, amygdala, hypothalamus, striatum, and spinal cord and preferentially bind to κ-opioid receptors. Their functions are related to memory, learning, emotional control, pain, and stress response. Individuals with the minor dynorphin alleles rs1997794 and rs910080 have been observed to show better episodic memory performance than homozygote carriers of the major allele. Furthermore, carriers of the prodynorphin T allele at rs1997794 showed reduced fear extinction and a significantly diminished functional connectivity between amygdala and ventromedial PFC, demonstrating a role of dynorphin κ-opioid receptor signaling in fear memory and extinction in humans.

In sum, differences in individual memory capacities seem to be significantly influenced by the ε4 allele of the ApoE gene, the BDNF Val66Met polymorphism, basic DA levels and the COMT Val158Met polymorphism, and minor alleles of the opioid peptide dynorphin.

Personality

Personality traits are individual differences in general patterns of thoughts, feelings, and behavior that form the core of an individual's nature. Although it is known that both genetic and environmental factors as well as interactions between them contribute to the development of one's personality in a complex manner, the stable core of a person's nature—the behavioral continuity that makes someone unique, recognizable, and predictable—is owned to over 80% to genetic factors (McGue, Bacon, & Lykken, 1993). In the following, we will provide an overview of the current knowledge regarding genetic influences on personality.

Extraversion and introversion are part of one-dimensional continuum of the "big 5" personality traits. Extraversion is linked to positive emotionality and describes people who are outgoing and fun loving and who love to socialize, whereas introverts have lower social engagement and energy levels than extroverts and prefer to spend time alone. Whether someone is more extraverted or introverted seems is partly determined by variations in the BDNF Val66Met polymorphism and the COMT Val158Met polymorphism coding dopaminergic activity in the brain, as recent genome-wide association studies revealed.

Neuroticism, the tendency to experience negative emotions, such as anger, anxiety, or depression, appears to be linked to a variety of genetic influences. This personality trait has been associated with low BDNF serum concentrations and variations in the BDNF Val66Met polymorphism as well as with interactions between BDNF Val66Met and the dopamine D2 receptor gene (DRD2)/ANKK1 and the serotonin transporter promoter polymorphism 5-HTTLPR. A meta-analysis summarizing 26 genetic association studies confirmed a significant association between 5-HTTLPR and neuroticism, demonstrating that individual differences in neuroticism are linked to serotonin transmission in the brain. Moreover, high neuroticism and low extraversion have been linked to several functional variants of the COMT gene, indicating an association of these two traits with dopaminergic activity.

Harm avoidance, a further personality trait that is characterized by excessive worrying and fear of uncertainty, has been found to be influenced by a combination of the BDNF Val66Met and the dopamine-coding DRD2/ANKK1 TaqIa polymorphisms. Moreover, higher levels of harm avoidance in women have been associated with the neuropeptide oxytocin as well as with MAOA, an enzyme encoding the MAOA gene catalyzing serotonin, DA, and norepinephrine.

Neuroticism, harm avoidance, and low levels of extraversion belong to the anxiety-related personality traits, which—in extreme form—may predispose individuals to develop psychopathological conditions. Meta-analytic evidence on the serotonin-coding 5-HTTLPR polymorphism and psychiatric disorders suggests that the relationship between 5-HTTLPR and anxiety-related personality traits is mediated by hyperreactivity of the amygdala during the processing of emotions. Particularly the S allele of the 5-HTTLPR polymorphism appears to be the "risk allele" for a variety of mood disorders, such as anxiety, depression, and bipolar disorder, putatively due to decreased transcriptional activity of the 5-HTTLPR S allele. In contrast, increased transcriptional activity of the 5-HTTLPR L allele has been associated with nicotine dependence and attention-deficit hyperactivity disorder (ADHD). Not only the development of psychiatric disorders but also their treatment seems to be partially dependent upon the 5-HTTLPR polymorphism: treatment responses in disorders such as posttraumatic stress disorder (PTSD), major depressive disorder, and alcohol dependence reportedly vary by 5-HTTLPR allele, suggesting a significant influence of the 5-HTTLPR polymorphism on treatment success.

A further personality trait describing how a person deals with feelings is alexithymia. Alexithymia characterizes individual differences in the ability to consciously experience and regulate one's emotions. The more alexithymic an individual, the more difficulty they will experience identifying, describing, and verbalizing their feelings to others. Similarly to anxiety-related personality traits, alexithymia is linked to aberrant functioning and structure of the amygdala and other brain areas involved in emotion processing and thus constitutes a further risk factor for a range of psychiatric conditions. Preliminary evidence suggests that alexithymia may be linked to the serotonin polymorphism 5-HTTLPR (with carriers of the L/L allele having significantly higher alexithymia levels than S/S and L/S carriers) and to the dopamine-coding COMT Val108/158Met polymorphism (with carriers of the Val/Val genotype having significantly higher alexithymia levels than Met/Met or Met/Val carriers). Furthermore, an interaction between BDNF and the dopamine DRD2/ANKK1 gene has been reported to contribute to individual differences in alexithymia. However, these findings were based on rather small sample sizes and thus warrant replication in future research.

As opposed to alexithymia, which refers to one's own emotions, trait empathy describes individual differences in people's sensitivity to the feelings of others, that is, their capacity to share and understand other persons' feelings. Many studies have linked empathic abilities to oxytocin, a neuropeptide implicated in a wide range of social behaviors. Individuals homozygous for the G allele of OXTR SNP rs53576 exhibit greater empathy for others and show more activity in their own pain-related brain areas when seeing others suffering. Moreover, cognitive empathy (the capacity to understand another's perspective or mental state) and affective empathy (the ability to respond with an appropriate emotion to another's mental state) have been linked to different SNPs of OXTR, suggesting on the one hand an involvement of several OXTR SNPs in empathy and on the other hand a genetically differential disposition for cognitive and affective empathic abilities. In addition, this disposition seems to be influenced by gender: more empathic concern for others, an aspect of affective empathy, appears to be significantly linked to OXTR SNP rs53576 in women, but in men, this association may be weaker or even absent. Moving beyond genetic association studies, treatment studies intranasally administering oxytocin indicated some promise of this neuropeptide in treating psychiatric symptoms involving deficits in social functioning, such as autism, social anxiety disorders, borderline personality disorder (BPD), and schizophrenia, possibly by increasing the saliency of social stimuli, thus helping social attunement. Besides oxytocin, other genes appearing to influence human empathic abilities are the BDNF Val66Met polymorphism, which correlates with self-reported empathy; the serotonin transporter polymorphism 5-HTTLPR, which has been linked to levels of emotional reactivity (affective empathy); and the dopamine D4 receptor gene (DRD4 exon 3 polymorphism), which has been related to cognitive empathy.

Impulsivity, antisocial behavior, aggression, and violence form a group of negative personality traits, which have been linked to the MAOA gene located on the X chromosome, giving rise to this gene being popularly referred to as the "warrior gene." This term is based on repeated observations that the low-activity MAOA genotype in men, causing MAO deficiency, is associated with offending behavior, conduct problems, and hostility and that male carriers of this genotype who experienced early abuse are more prone to exhibiting antisocial behaviors throughout their lifetime. A recent meta-analysis on the 30-base pair variable number of tandem repeats of MAOA-uVNTR confirmed the link between the MAOA gene and antisocial behavior in humans. Regarding the question whether the effect of the MAOA gene on antisocial and aggressive behavior is driven by modulations in the DA or serotonin system, recent research suggests an inconclusive role of DA release in relation to MAOA. In contrast, a disrupted serotonergic system linked to the low functioning MAOA genotype has been concluded to predispose individuals to aggressive behavior by increasing impulsive reactivity to negative affect.

The important role of the serotonin system in impulsivity, antisocial behavior, and aggression is corroborated by other studies investigating the relationship between serotonin and psychiatric disorders marked by such behaviors. Several studies showed that the serotonin 5-HTTLPR polymorphism predisposes individuals not only to mood disorders such as anxiety and depression as addressed above but also to psychiatric problems involving impulsivity and aggressive behaviors, such as BPD. Children and teenagers in the ages of 9–15 years, who are carriers of the two S alleles of the serotonin 5-HTTLPR polymorphism, have the highest levels of BPD traits, even when controlling for depressive symptoms, providing evidence for a developmental etiological risk for BPD among youth. Such findings were replicated in adults with BPD, showing the carriers of the two S alleles of 5-HTTLPR suffered from the most severe affective symptoms of BPD.

In summary, research has linked a number of candidate genes to personality traits and the risk for developing psychiatric illness. However, no known gene is either necessary or sufficient to produce mental disease. Instead, there are many susceptibility genes with small effects, each increasing an individual's risk of illness to a small percentage. This is illustrated, for instance, by a recent genome-wide association study of 36,989 cases by the Schizophrenia Working Group of the Psychiatric Genomics Consortium, which found that 108 genetic loci were involved in the heritability of schizophrenia. Moreover, genes interact with each other and with environmental factors, and phenotypes are thus more than the sum of independent genetic and environmental factors. Certain life events may interact with brain vulnerabilities created by particular genes to produce behavioral patterns. For instance, a recent study aiming to identify genetic contributions to delinquency in teenagers found that such behaviors were not linked to one specific gene and also not to gene × gene interactions, but instead to four-way interactions between three genes (BDNF Val66Met, 5-HTTLPR, MAOA) and the environmental risk factors family conflict and sexual abuse, suggesting that genotypes per se do not confer risk for delinquent behaviors of the teenagers but rather alter their susceptibility to environmental factors. Importantly, this was not only true for negative but for positive environmental factors as well: interactions between the same genes and a positive child–parent relationship were associated with the lowest delinquency scores, highlighting the power of a positive environment on human behavior and demonstrating that it is ultimately the interaction with the environment a person is surrounded with that eventually determines their behavior, despite the presence of potential risk genes.

Conclusion

Despite their limitations, candidate gene and genome-wide association studies have demonstrated their potential in helping scientists understand the effects of changes in our genetic endowment on brain functions and systems on various aspects of human cognition and behavior as well as their potential as risk factors for a range of diseases. With the costs of full genomic sequencing becoming more and more affordable, the collection of big sets of genomics data and their integration with behavioral, environmental, clinical, and functional and structural neuroimaging data will become possible in the near future. Together with modern technologies of "big data" processing, analysis, sharing, and visualization, such future studies will enable us to move to another level of understanding the highly complex patterns of interactions between multiple genes and between our genetic disposition and the environment in which we grow up and surround ourselves with. Understanding the complex patterns of genetics and behavior will provide indispensable knowledge regarding the workings of the human mind and the mechanisms underlying our mental health.

Epigenetics in Developmental Disorders

Introduction

An array of disorders find their origin in early development and profoundly affect brain function and cognitive health throughout the lifetime. Several years of research have contributed to our understanding of how these disorders arise, and epigenetic modifications have emerged as a primary mechanism in many cases. Epigenetics refers to chemical marking of the DNA that changes transcriptional and translational outcomes (i.e., gene and protein expression) without changing the underlying sequence of DNA. This marking can be accomplished in more than one manner, and each process involves an assortment of molecular characters.

One of the best understood epigenetic mechanisms is DNA methylation. Generally associated with silencing of genes, methylation is carried out by DNA methyltransferases (DNMTs). DNMTs attach methyl groups to cytosines, typically at cytosine–guanine pairings. These methyl groups are most well known for blocking transcription factor access to DNA and for their ability to recruit repressor proteins (Moore, Le, & Fan, 2013). One of these proteins, methyl-CpG-binding protein 2 (MeCP2), possesses a transcriptional repression domain that interacts with the Sin3/HDAC complex (Nan et al., 1998). The *SIN3* gene encodes a transcriptional regulatory protein whereas histone deacetylases (HDACs) are enzymes that remove acetyl groups from proteins, including histones. MeCP2 can also recruit coactivators such as CREB1 (Chahrour et al., 2008) though less is known about this occurrence.

Histones are the proteins around which DNA is packaged, and modifications to these histones are another type of epigenetic mechanism. The two best-studied histone modifications involve the addition or removal of acetyl and/or methyl groups, that is, histone acetylation and histone methylation. These alterations determine whether the DNA/histone complex (chromatin) is accessible (euchromatin) or inaccessible (heterochromatin) to transcription. The addition of acetyl groups to histones is associated with euchromatin (Grunstein, 1997;

The Wiley Encyclopedia of Health Psychology: Volume 1: Biological Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editor: Robert H. Paul.

Hebbes, Thorne, & Crane-Robinson, 1988) whereas the effects of histone methylation depend on the location and number of methyl groups. Histone acetylation is catalyzed by histone acetyltransferases (Grunstein, 1997) and is reversed by HDACs (De Ruijter, Van Gennip, Caron, Kemp, & van Kuilenburg, 2003). Histone methylation is catalyzed by histone methyltransferases and is reversed by histone demethylases (Bannister & Kouzarides, 2005).

Epigenetic mechanisms are responsible for a large portion of developmental events including critical processes such as cell fate and germ cell imprinting. Developmental epigenetic changes are tightly controlled as typical patterns are necessary for optimal development and continued function. Thus, many developmental disorders are attributed, at least in part, to atypical epigenetic activity.

Fragile X Syndrome

The clinical features of fragile X syndrome range from slight cognitive deficits to severe mental retardation. The disorder preferentially affects males due to its X-linked inheritance (i.e., the mutation responsible for the phenotype exists on the X chromosome, of which males inherit only one). In the case of fragile X, DNA methylation is responsible for silencing the fragile X mental retardation 1 gene, or *FMR1* (Sutcliffe et al., 1992). Normally, this gene encompasses a small number of repeats of a specific DNA segment (the trinucleotide CGG). However, the genome of individuals with the full mutation responsible for fragile X syndrome can contain between 200 and 1,000 repeats of this segment. This results in hypermethylation of *FMR1* resulting in a lack of the FMR protein and subsequent alterations of synaptic structure and function. These alterations underlie the cognitive difficulties associated with the disorder, likely due to the regulatory role the FMR protein plays in translation, especially at the synapse (Zalfa et al., 2003).

Angelman and Prader–Willi Syndrome

The clinical features of Angelman Syndrome include intellectual impairment, jerky movements, seizures, and joyful demeanor (Williams, Driscoll, & Dagli, 2010). This disease is attributed to genomic imprinting, a phenomenon responsible for the expression of certain genes in a parent-of-origin manner accomplished via epigenetic means (Reik & Walter, 2001). In such cases, either the allele inherited from the mother or the allele inherited by the father is imprinted, leading to expression only of the non-imprinted parent allele. In Angelman syndrome, the paternally inherited allele of ubiquitin-protein ligase E3A (*UBE3A*) is silenced via methylation, leaving expression to the maternally inherited allele. *UBE3A* is involved in cell maintenance by producing an enzyme involved in the degradation of unwanted or unnecessary proteins. In Angelman syndrome however, the maternally inherited allele is typically lost to a chromosomal deletion, leaving no expression to take place (Kishino, Lalande, & Wagstaff, 1997). Though far less common, Angelman can be caused by imprinting defects (i.e., methylation) of the maternal allele, likewise disrupting expression (Bürger et al., 1997).

The clinical features of Prader–Willi syndrome include intellectual impairment and obesity caused by constant hunger. Like Angelman syndrome, Prader–Willi syndrome is due to genomic imprinting, but in this case maternal alleles are silenced by hypermethylation, and paternal alleles have been deleted (or in rare cases methylated), leaving no expression of several genes along a section of chromosome 15 (Cassidy, Schwartz, Miller, & Driscoll, 2012).

Rett Syndrome

The clinical features of Rett syndrome include a small head due to improper brain development, abnormal hand movements, cognitive deficits, impaired social and language abilities, breathing problems, and coordination issues. The syndrome preferentially affects females and is the result of mutations to MeCP2, located on the X chromosome (Amir et al., 1999). It is the most common cause of mental retardation in females; affected males rarely survive past birth. Both nonsense and missense mutations have been uncovered. The former involve incomplete protein formation while the latter involve nucleotide deletions or substitutions. MeCP2 missense mutations found in Rett syndrome may reduce or halt methyl-CpG binding, result in abnormal protein folding, or disturb protein interactions within the SIN3A/HDAC silencing complex (Wan et al., 1999). Various phenotypes are associated with each mutation and range from mild cognitive deficits to the classic Rett symptoms described above.

Autism Spectrum Disorders

Some clinical features of autism spectrum disorders (ASD) include impairments in language and social skills as well as highly repetitive behaviors. While genetic factors have been strongly associated with this disorder, evidence increasingly supports a significant role for epigenetic modifications as either biomarkers or causal mechanisms. Differentially methylated sites have been reported for several genes in relation to ASDs. A reduction in the methyl-binding protein MeCP2, which is generally associated with decreased transcription, has been reported in the frontal cortex of autistic brains (Nagarajan, Hogart, Gwye, Martin, & LaSalle, 2006). This may be indicative of overactive gene expression in the frontal cortex. In addition, the manner in which MeCP2 is silenced is most likely epigenetic as the decreased expression in these ASD brains is accompanied by increased promoter methylation. Disrupted patterns of methyl-binding domain genes 3 and 4 have also been reported in autistic individuals (Cukier et al., 2010).

In the cerebellum of ASD patients, MeCP2 binding to glutamate decarboxylase 1 (*GAD1* or *GAD67)* and reelin (*RELN*) is significantly increased, a change that presumably (though not definitely) decreases expression (Zhubi et al., 2014). The primary inhibitory neurotransmitter gamma-aminobutyric acid (GABA) is produced from glutamate by an enzyme encoded by *GAD67. RELN* is heavily involved in processes of synaptic plasticity and also plays a role in neuronal migration during brain development. Both of these genes have suggested roles in ASD etiology.

Epigenetic regulation of the oxytocin receptor gene (*OXTR*) may be another critical mechanism underlying ASD etiology. Oxytocin is a known promoter of social behavior, and *OXTR* hypermethylation has been reported in human ASD brains (Gregory et al., 2009). Moreover, hypermethylation was reported to take place at more *OXTR* loci in males than in females, a compelling piece of evidence for a disorder that preferentially affects males (Gregory et al., 2009).

The scaffolding protein SHANK3 has been heavily implicated in autism etiology. This protein is found in high levels at neuronal postsynaptic densities where they play a critical role in synaptic function (Wang et al., 2011). Several CpG sites are located within the *SHANK* genes, but *SHANK3* expression in particular appears to be highly epigenetically regulated (Beri et al., 2007). Examination of postmortem brain tissue of ASD patients revealed significantly higher methylation levels at multiple *SHANK3* CpG islands (Zhu et al., 2013), presumably indicating a decrease in expression and thus in synaptic function.

Finally, investigation of the maternal methylome has provided some correlative evidence for the contribution of the prenatal epigenetic landscape to the development of ASDs. Overall decreases in methylation levels as well as the methylation precursors homocysteine and *S*-adenosylhomocysteine (SAH) have been reported in mothers of autistic children (James et al., 2008).

Fetal Alcohol Spectrum Disorder

The clinical features of fetal alcohol spectrum disorders (FASD) include a range of atypical growth patterns and facial features and cognitive deficits resulting from disturbance of the central nervous system. This disorder is a result of alcohol consumption during the gestational period, an act that disrupts many essential developmental processes. Methyl group metabolism is highly affected by alcohol consumption (Schalinske & Nieman, 2005). Thus, bidirectional disruption of epigenetic patterns is hypothesized to be one manner through which alcohol exerts its teratogenic effects. It is difficult to pinpoint a specific epigenetic abnormality at fault as they vary based on factors such as the time during gestation when alcohol consumption occurs.

Altered methylation is seen at several genes associated with cellular and developmental processes in mouse embryos exposed to alcohol during early neurulation, the folding process whereby the neural tube forms from the neural plate. In alcohol-exposed embryos expressing neural tube defects, the number of genes exhibiting increased levels of methylation on chromosomes 10 and X increased more than 10-fold (Liu, Balaraman, Wang, Nephew, & Zhou, 2009). Perinatal exposure to alcohol significantly decreases DNMT activity and expression in the rodent hippocampus (Perkins, Lehmann, Lawrence, & Kelly, 2013), providing a mechanism by which methylation alterations occur in response to alcohol. Evidence has also emerged for the role of histone modifications following developmental alcohol exposure. Increased histone methyltransferase activity and alterations of both repressive and activating histone marks occur in the early alcohol-exposed rodent brain (Subbanna et al., 2013, 2014).

In male and female rodent offspring exposed to alcohol during gestation, methylation of the proopiomelanocortin (*POMC*) gene is significantly increased (Govorko, Bekdash, Zhang, & Sarkar, 2012). The *POMC* gene codes for the protein proopiomelanocortin, which is used to form peptides like adrenocorticotropic hormone (ACTH). These peptides serve various functions throughout the body by influencing signaling pathways via protein binding. These signaling pathways are critical to systems involved in stress response, immune function, and reward. Alcohol exposure and craving are associated with *POMC* dysregulation (Muschler et al., 2010; Zhou et al., 2000), and evidence points to epigenetic alterations as the mechanism underlying these associations.

Gain-of-function studies have also provided support for epigenetic mechanisms of FASD. Typical epigenetic patterns, including the presence of methylation at specific locations in the genome, are critical to developmental processes. Alcohol consumption decreases levels of the methyl donor *S*-adenosylmethionine (SAM) by inhibiting the absorption of folic acid. Methylation of DNA is dependent on SAM and is thus disrupted by alcohol consumption, leading to aberrant developmental trajectories. Choline supplementation may rescue some of these trajectories. For example, choline administration attenuates learning impairments in alcohol-exposed rodents (Ryan, Williams, & Thomas, 2008). Given that choline is one of the nutrients from which methyl groups are derived (Niculescu & Zeisel, 2002), it is hypothesized that altered DNA methylation is the mechanism of behavioral rescue, a hypothesis that has continued to be supported. Alcohol-induced epigenetic modifications in the hippocampus and frontal cortex (Otero, Thomas, Saski, Xia, & Kelly, 2012) and hypothalamus (Bekdash, Zhang, & Sarkar, 2013) are also attenuated with choline supplementation.

Epigenetics in Behavior and Mental Health

Tiffany S. Doherty and Tania L. Roth

Introduction

Exposure to adversity during development significantly increases the risk of manifesting a mental health disorder. Examination of the consequences of early adversity in rodent and human models has brought epigenetic mechanisms to the forefront of adversity-induced mental health outcomes, with research continuously revealing a significant relationship between psychopathology and the epigenome following early life adversity.

Epigenetic mechanisms are chemical modifications of chromatin (the DNA/histone complex) that result in genetic modulation without altering the DNA sequence. The most heavily studied of these are DNA methylation and histone modifications.

DNA methylation occurs upon the addition of a methyl group to a cytosine base in the DNA sequence, typically at cytosine–guanine dinucleotides. This modification generally results in gene silencing via blockage of transcription factor access or recruitment of repressive proteins (Moore, Le, & Fan, 2013). DNA hydroxymethylation occurs via oxidation of methylated cytosines, a modification that may be involved in the process of demethylation but may also play a stable role in gene expression depending on the context in which it occurs (Kato & Iwamoto, 2014).

Histones, the proteins around which DNA is packaged, are subject to several posttranslational modifications. These include acetylation, methylation, phosphorylation, SUMOylation, and ubiquitylation. Acetylation and methylation are the best understood of these modifications and have thus far been the focus of studies on epigenetic mechanisms in mental health. Acetylation results in a more open chromatin structure and increased gene expression. Histone methylation has both activating and repressive effects on gene expression depending on the number and location of methyl groups.

Epigenetic regulators are enzymes responsible for the addition or removal of epigenetic markers. DNA methyltransferases (DNMTs) are responsible for the addition of methyl groups to DNA, and various demethylases (of which much less is currently known) are responsible for their removal (Chen, Wang, & Shen, 2013). Hydroxymethylation is catalyzed by the ten-eleven translocation (TET) family of proteins (Kato & Iwamoto, 2014). Histone acetyltransferases (HATs) and histone methyltransferases (HMTs) are responsible for the addition of acetyl and methyl groups to histones, respectively. The removal of these groups from histones is accomplished by histone deacetylases (HDACs) and histone demethylases (Bolger, Cohen, & Yao, 2006).

Epigenetic Consequences of Prenatal Stress

Both adverse and enriching experiences during gestation are capable of catalyzing epigenetic changes in the developing brain. These changes precede an array of behavioral alterations ranging from altered stress responses to deficits in cognitive performance. Epigenetic alterations affecting the stress response are generally found to interrupt function of the hypothalamic–pituitary–adrenal gland (HPA) axis and are known to occur as early as the gestational period. Upon exposure to a prenatal stressor, the enzyme responsible for protecting the fetus against maternally derived glucocorticoids, 11β-hydroxysteroid dehydrogenase type 2 (*Hsd11B2*), is decreased. This decrease occurs alongside significantly increased promoter methylation and DNMT expression in the placenta (Peña, Monk, & Champagne, 2012). In other rodent models of prenatal stress, aberrant stress responses in adult offspring correspond to epigenetic alterations of genes coding for the stress-related glucocorticoid receptor (*GR*) and corticotropin-releasing factor (*Crf*) (Mueller & Bale, 2008).

Cognitive deficits resulting from stress exposure in the prenatal period are also correlated with epigenetic remodeling. Spatial memory impairments in adult male and female rats that were stressed while in utero are accompanied by significantly elevated levels of the epigenetic regulator DNMT1 and significantly decreased levels of histone acetylation in the hippocampus (Benoit, Rakic, & Frick, 2015). Neurotrophins, which promote healthy brain development and plasticity across the lifespan, are also epigenetically modified by gestational stress. For example, brain-derived neurotrophic factor (*Bdnf*) methylation is increased in adult offspring in a rodent model of prenatal stress, an epigenetic change accompanied by behavioral alterations in both male and female offspring (St-Cyr & McGowan, 2015).

The link between prenatal stress and mental health outcomes also appears to be epigenetic in nature. Following gestational restraint stress, mice displaying a schizophrenia-like phenotype exhibit epigenetic alterations of genes that have been implicated in schizophrenia (Matrisciano et al., 2013). In humans, mother-reported anxiety during pregnancy correlates with increased *11BHSD2* methylation in offspring, whereas mother-reported depressive symptoms during pregnancy correlate with increased *GR* methylation (Conradt, Lester, Appleton, Armstrong, & Marsit, 2013). Disrupted epigenetic patterns at these genes, both of which are involved in the stress response, have implications for behavioral outcomes relevant to mental health disorders. In mothers carrying a specific variant of the *MTHFR* gene, a gene that codes for an enzyme critical in the production of methionine, depressive symptoms during pregnancy are associated with epigenetic changes within the serotonin system (Devlin, Brain, Austin, & Oberlander, 2010). The serotonin transporter gene *SLC6A4,* implicated in many mental health disorders, exhibits decreased methylation in these mothers and their offspring.

Epigenetic Consequences of Postnatal Stress

Postnatal stressors, often occurring within the context of the caregiving relationship, exert many of the same effects as gestational stressors and similarly disrupt the HPA axis. In rodent models of subprime caregiving, altered methylation of the *GR* gene is found in offspring hippocampus and is accompanied by exaggerated stress responses in adulthood (Weaver et al., 2004). Pharmacological alteration of the epigenome is sufficient to prevent these outcomes. In a mouse model of postnatal stress wherein pups are repeatedly separated from their mother, offspring exhibit increased HPA axis activity due to decreased methylation of arginine vasopressin (*Avp*). The behavioral correlates of this epigenetic alteration include memory deficits and decreased ability to cope with stress (Murgatroyd et al., 2009). Maternally separated mice also exhibit decreased methylation of proopiomelanocortin (*Pomc*), the precursor hormone for ACTH (Wu, Patchev, Daniel, Almeida, & Spengler, 2014).

Genes associated with neuroplasticity are also epigenetically altered following postnatal stress exposure. In a rodent model of adverse caregiving, maltreated offspring exhibit altered *Bdnf* methylation patterns in several brain regions across development (Doherty & Roth, 2016). The associated behavioral deficits expressed by maltreated offspring in adulthood (Doherty, Keller, Blaze, & Roth, 2017) implicate epigenetic mechanisms in the cognitive and mental health outcomes that often result from early adversity.

In human studies, postnatal adversity is also associated with epigenetic change. Increased *GR* methylation is found in infants of mothers who report postpartum depression (Murgatroyd, Quinn, Sharp, Pickles, & Hill, 2015). Adverse parental care is associated with methylation levels of *BDNF* and OXTR (oxytocin receptor, associated with bonding and other social behaviors) in offspring (Unternaehrer et al., 2015). The same has been found for *SLC6A4* (the serotonin transporter gene) (Vijayendran, Beach, Plume, Brody, & Philibert, 2012). Offspring of Holocaust survivors also exhibit increased *GR* methylation and altered stress responses, as well as altered methylation of FK506 binding protein 5 (*FKBP5*) (Bowers & Yehuda, 2016). *FKBP5* plays a role in GR regulation and is associated with major depressive and posttraumatic stress disorder (PTSD).

Epigenetic Consequences Stress Outside of Development

The epigenome remains responsive outside of early life developmental windows. Acute stress applied to adult rodents produces short-term alterations in *Bdnf* methylation (Fuchikami, Morinobu, Kurata, Yamamoto, & Yamawaki, 2009). Stress of varying intensities (acute to chronic) applied to adult rodents results in varying patterns of histone methylation (Hunter, McCarthy, Milne, Pfaff, & McEwen, 2009). Decreased *Crf* methylation is found in adult mice that develop a socially avoidant phenotype following chronic social stress (Elliott, Ezra-Nevo, Regev, Neufeld-Cohen, & Chen, 2010). Further, following chronic social defeat, adult rodents express significantly more DNMT3A in the nucleus accumbens (Covington et al., 2009), an area associated with reward.

The sensitivity of the human epigenome beyond childhood continues to be empirically supported. For example, the *GR* gene exhibits increased methylation in teenagers following a social stress task, a change that is associated with slower post-task cortisol recovery (Van Der Knaap, Oldehinkel, Verhulst, Van Oort, & Riese, 2015). In addition, *OXTR* methylation is altered in adult participants following the Trier social stress test (Unternaehrer et al., 2012).

Mental Health and the Epigenome

Compelling evidence in humans supports the association between epigenetics and mental health outcomes first suggested in rodent models. In suicide victims with a history of child abuse, *GR* methylation is significantly increased in postmortem hippocampal tissue (McGowan et al., 2009). Increased methylation of *Reelin*, a gene implicated in schizophrenia, is found in postmortem cortical tissue of schizophrenia patients (Grayson et al., 2005). In postmortem parietal cortex tissue of psychotic patients, there is an upregulation of TET1, one of the enzymes involved in hydroxymethylation (Dong, Gavin, Chen, & Davis, 2012). Furthermore, the antipsychotic medication haloperidol is known to alter the epigenetic state in rodents (Bertran-Gonzalez et al., 2008; Shimabukuro, Jinno, Fuke, & Okazaki, 2006). In patients diagnosed with borderline personality disorder, *BDNF* is hypermethylated, an epigenetic change that correlates with childhood trauma (i.e., the more trauma the more methylation) (Perroud et al., 2013).

Epigenetic mechanisms also appear to play a role in depression and anxiety-related disorders. Altered epigenetic patterns have been associated with depressive states, and the epigenome is known to be affected by antidepressants (Vialou, Feng, Robison, & Nestler, 2013). Epigenetic markers have also been heavily associated with risk for and development of PTSD (Yehuda & Bierer, 2009).

Epigenomic Remodeling Outside of Adverse Experience: Therapeutic Implications

The epigenome changes in response to therapeutic experiences. In rodents, enrichment of the environment with toys, increased opportunity for social interaction, and/or increased exercise results in epigenetic remodeling. Environmental enrichment during the gestational period leads to a decrease in hippocampal and frontal cortex methylation in rodent offspring (Mychasiuk et al., 2012). Enrichment of the environment of adult rodents is associated with more open chromatin and increased expression of *Bdnf* in the hippocampus (Kuzumaki et al., 2011). Voluntary exercise in rodents results in improved stress coping abilities and chromatin remodeling (Collins et al., 2009) as well as downregulation of epigenetic regulators (Abel & Rissman, 2013).

Therapeutic and meditative activities also impact humans at the level of the epigenome. In individuals diagnosed with borderline personality disorder, aberrant *BDNF* methylation patterns can be rescued with intensive behavioral therapy in some patients (Perroud et al., 2013). In addition, children with anxiety disorders who exhibit positive responses to cognitive behavioral therapy exhibit increased *SLC6A4* methylation (Roberts et al., 2014). In females, long-term tai-chi practice remodels the epigenome such that it exhibits less typical age-related changes (Ren et al., 2012). It stands to reason that treatment and intervention strategies for mental health disorders can benefit from this epigenomic malleability.

Author Biographies

Tiffany S. Doherty is a doctoral candidate in the Department of Psychological and Brain Sciences at the University of Delaware, where she conducts research in the lab of Dr. Tania Roth. Her dissertation research is focused on the utility of drug intervention in preventing aberrant epigenetic and behavioral trajectories following developmental exposure to adversity.

Dr. Tania L. Roth is an associate professor and director of Graduate Education in Psychological and Brain Sciences at the University of Delaware, where she teaches upper-level and graduate courses in psychology and neuroscience. Her research program is focused on defining epigenetic mechanisms responsible for environmental influences on CNS gene activity, development of behavior, and psychiatric disorder.

Diffusion MRI: Introduction

Diffusion MRI: An Introduction

Diffusion-weighted imaging (DWI) is a noninvasive magnetic resonance imaging (MRI) technique that enables the study of the brain *in vivo*. It is used frequently to investigate the integrity of the brain's white matter. This chapter aims to introduce the basic principles of diffusion and how it is measured and to summarize some of the inferences that can (or cannot) be drawn from this technique. We then briefly discuss some of the contributions that may come from applying diffusion imaging to the understanding of white matter.

The Basics of Diffusion Imaging

Measuring Diffusion

Over a century ago, Albert Einstein described the random motion of particles due to thermal energy (Einstein, 1905). Due to this random movement, also known as Brownian motion, molecules collide with each other and cause a net displacement. This process is called diffusion.

DWI is an MRI technique that can be used to measure the diffusion process. In diffusion-weighted MR sequences, the magnetic field varies along a direction of interest (Stejskal & Tanner, 1965). Its gradients label the location of water molecules along this direction. As water moves along the direction of the applied gradient, there is a decrease in the MR signal from the water molecules in each voxel. The greater the displacement of the molecules, the greater the signal loss. This signal loss is then used to calculate the amount of diffusion, or apparent diffusion coefficient.

Box 1 The Parameters of a DTI Sequence

DTI sequences vary immensely between studies. One crucial parameter is the number of diffusion-encoding gradient directions. Although only three directions are required for DWI, a minimum of six is necessary to calculate the diffusion tensor. As a larger number of gradient directions result in a more accurate estimate of the diffusion tensor, DTI sequences often include more directions. Since increasing the number of gradient directions requires an increase in scan time, it is not always feasible to adopt these optimized parameters though. Another important consideration is the voxel dimension. Ideally, the smallest voxel size should be used. In practice, however, decreasing voxel size comes at an increasingly larger cost to the signal-to-noise ratio and must therefore be carefully considered. In a 3 Tesla scanner, a suggested frame of reference is that DWI images maintain the signal-to-noise ratio above 3 : 1, with an isotropic voxel size between 1.5 and 2 mm (Jones et al., 2013).

Three-dimensional diffusivity is frequently modeled using a symmetrical matrix of numbers or tensor—thus giving rise to the name diffusion tensor imaging (DTI). When molecules are equally likely to move in any direction (i.e., isotropic diffusion), the diffusion pattern can be thought of as a sphere. However, in an anisotropic environment, this spherical representation is no longer suitable because diffusion in one direction is more likely than the others. Accordingly, the diffusion tensor is "rugby-ball" shaped, an ellipsoid in which the major axis reflects the principle direction of diffusion within a voxel (Basser, 1995).

By fitting the tensor model to measurements at each voxel, several useful parameters can be estimated (Box 1). Fractional anisotropy (FA) is an index of the degree of diffusion directionality and can range from 0 to 1. While higher values reflect increased diffusion directionality, lower FA values are indicative of more isotropic diffusion. Other diffusivity metrics include axial diffusivity (AD) (also referred to as parallel diffusivity), mean diffusivity (MD), radial diffusivity (RD) (also referred to as perpendicular diffusivity), and mode of anisotropy (MO) (Table 1).

Table 1 Overview of diffusion measurements estimated from the tensor model.

Metric	*Interpretation*
Fractional anisotropy (FA)	Index of the degree of diffusion directionality. Ranges from 0 (isotropic diffusion) to 1 (increased directionality, anisotropic diffusion)
Axial diffusivity (AD)	Measure of the diffusivity in the direction of maximum diffusion in a voxel. May relate to axonal health (Kinoshita, Ohnishi, Kohshi, & Yokota, 1999)
Radial diffusivity (RD)	Average of the diffusivity values in the two axes perpendicular to the principle direction of diffusion. May be indicative of myelin content (Klawiter et al., 2011; Song et al., 2005)
Mean diffusivity (MD)	Mean amount of diffusion of the three directions calculated by the tensor
Mode of anisotropy (MO)	Index of the type or shape of anisotropy. Ranges from −1 (planar shape, e.g. in regions of crossing fibers) to 1 (linear shape, e.g. in regions with one dominating fiber orientation)

Diffusion in White Matter

The diffusion measures obtained with DTI can be used to examine the integrity of white matter in the brain *in vivo*. Within white matter, a variety of biological boundaries restrict the diffusion process and create a more directional (anisotropic) pattern of water molecule displacement. For instance, axonal membranes result in diffusion occurring more easily along a fiber bundle than across it. Further, increased myelination and axonal density can enhance the degree of anisotropy, while increased axon caliber can decrease anisotropy (Beaulieu, 2002, 2009). Consequently, the measures of anisotropy and overall molecule displacement obtained with DTI can serve as quantitative indices of the orientation and relative integrity of white matter tracts in the brain.

Crucially, it is important to note that, as with MRI parameters in general, there is no direct relationship between diffusion MRI measures and any particular anatomical feature. Measures reflect a number of tissue properties (e.g., membrane integrity, myelin thickness, axon caliber, and axon density) without being specific to any. DTI measures are also sensitive to fiber architecture. In areas containing crossing fiber bundles such as the centrum semiovale, FA values are naturally low because any given voxel will include fiber bundles going in different directions. Moreover, DTI measures can also be affected by factors such as partial volume contamination (mixing of tissue types within a voxel) and spatial filtering. For instance, since diffusion within the cerebrospinal fluid (CSF) is isotropic and approximately four times larger than that in white matter (Jones, Knosche, & Turner, 2013), any partial volume of CSF within the recorded voxel will contaminate findings. This is particularly problematic at the borders between tissue and CSF-filled spaces. It is, therefore, not possible to hold specific biological microstructures (e.g., myelin sheaths) accountable for observed changes in DTI measures.

More recent DWI techniques might be able to provide more direct markers of tissue microstructure than DTI metrics. Although the tensor model is currently the most frequently employed technique in diffusion MRI, DWI can be modeled in a number of ways (Winston, 2015). For example, neurite orientation dispersion and density imaging (NODDI) is a novel DWI technique that aims to overcome the nonspecificity of DTI parameters (Zhang, Schneider, Wheeler-Kingshott, & Alexander, 2012). For example, by providing additional estimates of tissue microstructure, NODDI can disentangle two factors that contribute to FA: fiber orientation and neurite density (Table 2).

Table 2 Overview of diffusion measurements estimated through neurite orientation dispersion and density imaging (NODDI).

Metric	*Definition*	*Interpretation*
Intracellular volume fraction (ICVF)	An index of white matter neurite density	Ranges from 0 (complete extraneurite diffusion) to 1 (complete intraneurite diffusion)
Isotropic or free water olume fraction (ISOVF)	Volume within a voxel occupied by isotropic water diffusion like freely moving cerebrospinal fluid (CSF)	Ranges from 0 (no CSF-like fluid) to 1 (complete CSF-like fluid)
Orientation dispersion index (ODI)	A measure of within-voxel tract disorganization	Ranges from 0 (complete directional coherence) to 1 (fully dispersed neurites)

Analysis Approaches

Regardless of the model selected to estimate diffusion metrics, the collected data must undergo a series of processing steps before it can be used in statistical analysis.

This pipeline typically involves three stages: preprocessing (motion correction, eddy current corrections, and brain extraction), estimation of the diffusion tensor (or alternative DWI model), and statistical analysis. A variety of software packages offer tools to perform these processing stages—many of which are freely available (see Hasan, Walimuni, Abid, & Hahn, 2011 for review).

Similarly, a variety of analysis approaches can be used to prepare the individual diffusion data for the final step of the pipeline, the statistical analysis. Diffusion data can be extracted locally in a priori defined regions using region of interest (ROI) analysis or tractography (i.e., using specific regional hypotheses), or globally using the voxel-based method (VBM) or tract-based spatial statistics (TBSS) and controlling for multiple testing a posteriori. With regard to regional analysis approaches, ROI analysis involves delineating specific, predefined, regions of the brain, either manually or using an automated parcellation method. Although manual ROI placement avoids registration errors, it is labor intensive and susceptible to user bias. Automated parcellation, on the other hand, has the advantage of being less time consuming but may be less sensitive to individual anatomical variability. Tractography, an automated method, involves the reconstruction of white matter tracts and thus allows inferences about the connectivity between brain regions.

In terms of global analysis methods, VBM consists of registering individual images to a common template and performing a voxel-by-voxel whole-brain statistical test, either by comparing white matter between groups or by examining correlations between diffusion measurements and a descriptor variable. This method is limited by the quality of the registration between individual images and the amount of spatial smoothing imposed on the data. In order to address these issues, TBSS projects the FA data of all participants onto an average FA tract skeleton before applying voxel-wise cross-participant statistics (Smith et al., 2006). However, since the TBSS skeleton assumes that peak FA values are the center of the tract, TBSS may be insensitive to changes along the width of the tract. While an in-depth description of the various analysis methods is beyond the scope of this chapter, a review of these techniques can be found elsewhere (Bodini & Ciccarelli, 2009; Mueller, Lim, Hemmy, & Camchong, 2015).

Diffusion-Weighted Imaging in Practice

DWI has made substantial contributions to the understanding of the brain *in vivo*, both in health and in disease. This technique has allowed researchers to compare estimates of tissue microstructure between groups (e.g., patients and healthy populations) and to explore correlations between brain and behavior. As previously mentioned, although DWI is not limited to the tensor model, DTI remains the most widely employed method in diffusion imaging. This section focuses, therefore, on findings from DTI studies.

Changes in white matter occur throughout our lifespan: in development, adulthood, and old age. Early development sets the stage for rapid growth and brain maturation, and a substantial amount of myelination occurs in this period (Dubois et al., 2014). DTI parameters are sensitive to the changes during white matter maturation, with studies showing increased FA in the developing white matter, especially between birth and 2 years of age (Dubois et al., 2014). Through childhood and adolescence, the continued development of white matter microstructure is reflected in an increase in FA (Peters et al., 2012). In late adulthood, this trajectory is reversed. Postmortem studies have shown that brain aging is marked by loss of myelinated fibers (Marner, Nyengaard, Tang, & Pakkenberg, 2003) and degradation of white matter integrity (Peters, 2002). Accordingly, DTI studies have shown a decrease in FA in older adults (Bennett & Madden, 2014). Recent studies have complemented the age-related changes observed in FA with other diffusivity parameters (MD, AD, and RD)—an advisable practice as, in some cases, these measures may be more sensitive to changes in white matter integrity (Bennett & Madden, 2014).

Besides demonstrating the trajectory of white matter development and decline, DTI studies have also highlighted regional differences in these changes. Although functional networks are established early on, the infant brain is not a scaled-down adult brain. Brain maturation occurs successively in a mosaic pattern: while some regions, such as the sensory and motor areas, develop early and quickly, other regions, like the frontal white matter, develop later and at a slower pace (Dubois et al., 2014). In contrast, the decline observed in white matter integrity in late adulthood is most prominent in frontal and parietal white matter and less marked in the occipital and posterior white matter (see Bennett & Madden, 2014 for review).

Understanding the healthy changes that occur in white matter microstructure with age is an essential step for examining the role of white matter changes in illness. Changes in white matter can be seen with DTI not only with conditions that have typically been considered white matter diseases (e.g., multiple sclerosis) but also across a host of conditions. For example, studies have reported indices of reduced white matter integrity in patients with Alzheimer's dementia and mild cognitive impairment, Parkinsonian syndromes, major depression and bipolar disorder, schizophrenia, and obsessive–compulsive disorders (Table 3). These findings indicate a role for white matter changes in psychiatric and neurological disorders. Considerable research is still necessary to understand how pathological changes in white matter structures contribute to each condition.

Changes in white matter structure are not limited to development, aging, and disease, though. Learning new skills and fine-tuning existing abilities can also alter brain structure, a phenomenon known as plasticity. DTI measures are sensitive to these experience-dependent alterations and have contributed to evidence that white matter plasticity is a rapid and dynamic

Table 3 Factors associated with reduced white matter integrity in DTI studies.

Disease	*Change in DTI measures*	*Review of findings*
Multiple sclerosis (MS)	Reduced FA and increased MD in lesions and in the normal-appearing white matter	Sbardella, Tona, Petsas, & Pantano (2013)
Alzheimer's disease and mild cognitive impairment	Widespread white matter abnormalities: reduced FA, increased MD	Pini et al. (2016)
Parkinsonian syndromes	Reduced FA in the substantia nigra	Cochrane & Ebmeier (2013)
Major depression and bipolar disorder	Reduced FA in the genu of the corpus callosum	Wise et al. (2016)
Schizophrenia	Widespread reduction in FA; DTI changes may vary with illness duration	Kubicki, Westin, Pasternak and Shenton (2014), Peters & Karlsgodt (2015)

process, one that can be observed after weeks (Scholz, Klein, Behrens, & Johansen-Berg, 2009), or even just hours (Sagi et al., 2012), of learning. Moreover, plasticity is not limited to a single type of learning: changes in DTI measures have been associated with training in juggling (Scholz et al., 2009), memory (Takeuchi et al., 2010), reasoning (Mackey, Whitaker, & Bunge, 2012), meditation (Tang, Lu, Fan, Yang, & Posner, 2012), and lifelong musical skills (Bengtsson et al., 2005; for reviews see Wang & Young, 2014; Thomas & Baker, 2013; Zatorre, Fields, & Johansen-Berg, 2012).

DTI studies are likely to benefit from the trend toward larger cohorts and open access imaging data. With increased power, such datasets will allow more robust investigations of the role of white matter integrity in health and disease. For instance, the UK Biobank, the world's largest health imaging study to date, aims to collect brain imaging data in 100,000 adults, alongside measures of cognitive functioning, medical history, lifestyle, and genotypes (Sudlow et al., 2015). This open access dataset, which includes diffusion-weighted images, will enable powerful research into the genotypes and lifestyle factors that may have protective or detrimental effects on white matter structure and overall brain health.

Conclusions

Diffusion MRI provides a unique method for understanding the living brain. While it is important not to overinterpret DTI measures, charting changes through development and aging has provided valuable insight into the changes that normally occur in white matter. Further, equipped with the understanding of healthy age-related white matter changes, clinical studies have identified a wide range of psychiatric and neurological disorders that are associated with white matter abnormalities. While the tensor model has served this field well for over twenty years, it is likely that novel DWI techniques may rise in importance given their ability to provide additional estimates of tissue microstructure.

Structural Neuroimaging of Hippocampal Subfields in Healthy Aging, Alzheimer's Disease, Schizophrenia, and Major Depressive Disorder

Lok-Kin Yeung and Adam M. Brickman

Columbia University Medical Center, New York, NY, USA

Introduction

The hippocampus is critically important for episodic memory and spatial representation. It contains a number of distinct subfields, which differ on the basis of neuronal populations and organization (Duvernoy, Cattin, & Risold, 2013). In recent years, a number of segmentation protocols have been developed to map these histological divisions onto high-resolution scans in living individuals using geometric rules derived from anatomical studies (see Yushkevich et al., 2015, for review). Applying this method, researchers have begun to examine how hippocampal subfields differ in the course of healthy aging and along the trajectory of diseases that affect the hippocampus. Among neurological and psychiatric diseases, the most work on hippocampal subfield volume differences has been done in Alzheimer's disease (AD), schizophrenia, and major depressive disorder (MDD), which are well known to involve structural changes in the hippocampus. This chapter will present a brief overview of this research.

A quick anatomical survey of the hippocampus may be helpful to orient the reader (Duvernoy et al., 2013). Unlike much of the brain, which has six-celled layers (i.e., neocortex), the hippocampus is made of allocortex (also called archicortex), with only three cell layers. Internally, the hippocampus is made up of two interlocking lamina. The inner lamina is known as the dentate gyrus, while the outer lamina is known as the cornu Ammonis (CA). In turn, the CA is subdivided into four distinct subfields (labeled CA1–4) due to their cellular

heterogeneity. Along the long axis of the hippocampus, distinctions are also made between the head, body, and tail regions (moving anterior to posterior), which differ in their distribution of hippocampal subfields when viewed cross-sectionally. In addition, the subiculum, which sits between CA1 and the entorhinal cortex, is usually considered part of the hippocampal formation along with the rest of the hippocampus proper.

Within the last few years, a number of MRI segmentation protocols were developed to quantify the volume of hippocampal subfields *in vivo* (Yushkevich et al., 2015). Typically, these segmentation protocols involve taking a non-isotropic T2-weighted fast spin echo (FSE) or turbo spin echo (TSE) scan aligned to the long axis of the hippocampus. These protocols produce "high-resolution" images that have in-plane resolution of 0.4 mm by 0.4 mm or less in the coronal plane, but with a slice gap of 1 mm (using a 7 T magnet) or 2 mm (using a 3 T magnet). By comparison, standard T1-weighted functional scans typically produce images at a resolution of 1 mm by 1 mm. With the higher resolution afforded by these new scanning methods, it is possible to visualize the stratum radiatum, lacunosum, and moleculare (SRLM), a thin band of white matter that separates the dentate gyrus from the CA subfields (i.e., where the CA wraps around the dentate gyrus). This makes it possible to distinguish the two hippocampal lamina with confidence on an MRI scan. Each segmentation protocol then employs histological atlases to devise geometric rules based on anatomical landmarks to subdivide the hippocampus into subfields. For instance, Figure 1 shows manual delineation of three hippocampal subfields (CA1, subiculum, and a combined CA3/dentate gyrus region) using the Olsen–Amaral–Palombo protocol, while Figure 2 shows a 3D reconstruction of the same hippocampal subfields using the same protocol.

It is important to note that this kind of segmentation cannot identify with certainty that a specific location on a particular brain scan belongs to a certain hippocampal subfield. Histological studies typically analyze a large number of hippocampi and define the boundaries

of subfields on the basis of anatomical landmarks based on the most typical arrangement observed. However, each individual brain exhibits idiosyncratic variation from the norm. Therefore, it is only possible to say that based on the reference atlases, a particular location on an MRI scan is likely to belong to a certain subfield. This issue is particularly problematic in regions with highly variable anatomical landmarks or a large degree of variation across different brains. Here, subfield identification can only be achieved to a lower degree of accuracy. For example, the irregularity of the digitations in the hippocampal head makes it difficult to differentiate clearly the arrangement of subfields. Many segmentation protocols exclude the hippocampal head entirely for this reason. Moreover, there is some disagreement about where the boundaries between subfields lie (Yushkevich et al., 2015). For instance, one particular area of disagreement is where the boundary between CA1 and subiculum is situated (and how that boundary changes along the long axis of the hippocampus). Further, segmentation protocols differ on which subfields are grouped together because they are difficult to distinguish anatomically. For instance, many segmentation protocols define a combined CA3/dentate gyrus region due to the difficulty of separating those regions visually. However, this decision makes it difficult to ascertain which of these two regions mediates observed effects—this is of particular importance as these two regions have putatively different cognitive functions. It is important to keep in mind these protocol differences when comparing different studies. There is an ongoing effort to create a harmonized segmentation protocol to address these issues (see www.hippocampalsubfields.com for more information).

In addition to manual segmentation, there are a number of automated approaches for hippocampus subfield segmentation. The three most commonly used automated methods are (a) the protocol included in the FreeSurfer segmentation software, (b) the Multiple Automatically Generated Templates Brain Segmentation Algorithm (MAGet-Brain), and (c) the Automated Segmentation of Hippocampal Subfields (ASHS) toolbox. There are two major advantages of automated hippocampal subfield segmentation. Firstly, manual segmentation of hippocampal subfields requires significant training to achieve a necessary level of skill to produce accurate segmentations reliably. Further, even a skilled tracer requires 4–6 hr to segment hippocampal subfields on each scan. Thus, automated segmentation offers savings in terms of workload and overall processing time. Secondly, automated segmentation follows algorithmic rules far more precisely than human tracers, resulting in more reliable results. Typically, human tracers achieve a reliability of approximately 0.8–0.9, as indexed by the Dice overlap coefficient, with worse reliability in smaller subfields. Automated approaches, on the other hand, theoretically give exactly the same result when run multiple times on the same data. However, these advantages of automated segmentation must be weighed against its disadvantages. At the current moment, the accuracy of a human tracer is still greater than the accuracy of an automated algorithm, and expert manual tracing remains the "gold standard" of hippocampus segmentation. Thus, interpretation of results produced by automated segmentation must keep this in consideration.

This chapter focuses on recent studies that employ high-resolution structural volumetric imaging of hippocampal subfields in the course of normal aging and three clinical disorders associated with reduced hippocampus volume: AD, schizophrenia, and MDD. There is a detailed body of work that focuses on surface deformations of the hippocampus, which will not be discussed here. While surface deformation analysis is sensitive to differences in the CA subfields and the subiculum, the anatomy of the hippocampus prevents this method from being able to detect differences in the dentate gyrus, which lies in the interior of the hippocampus.

There are also a number of studies that use the automated hippocampus subfield segmentation protocol implemented in FreeSurfer 5.3. However, concerns have been expressed about the accuracy of the results produced using this method (Wisse, Biessels, & Geerlings, 2014) for two important reasons. Firstly, FreeSurfer 5.3 performs hippocampal segmentation on T1-weighted images taken at a lower resolution (1 mm^3 isotropic). At that resolution, the contrast between white and gray matter is insufficient to be able to demarcate the boundaries between the two hippocampal lamina (i.e., the SRLM between dentate gyrus and the other hippocampal subfields) accurately. Secondly, FreeSurfer 5.3 segments the hippocampus based on its division within a single coronal slice and then projects that division to slices along the length of the hippocampus. However, the placement of subfields is heterogeneous along the hippocampal long axis. Other segmentation protocols rely on anatomical landmarks and internal boundaries to define subfield boundaries for this very reason. Because of these two issues, the subfields identified by FreeSurfer 5.3 do not accurately reflect the internal structure of the hippocampus. A newer version of the FreeSurfer software (v6.0) has addressed these concerns to some degree (Iglesias et al., 2015). The newer software performs segmentation on high-resolution scans and bases its subdivisions on a novel atlas derived from 15 postmortem brains. As far as possible, this chapter excludes findings from studies that rely on automated segmentation of the hippocampus using FreeSurfer 5.3. Studies segmented using this method are explicitly identified as such. Otherwise, all the studies cited in this article employed manual segmentation of hippocampal subfields.

Aging

A number of studies looked cross-sectionally at the effect of aging on hippocampal subfield volumes in neurologically healthy adults across the adult lifespan using manual segmentation. There are two subfields where volume reductions have been consistently associated with increasing age. Firstly, many studies reported a negative relationship between age and CA1 volume (e.g., Mueller et al., 2007; Wisse, Biessels, & Geerlings, 2014, but see also La Joie et al., 2010). Studies that contrast regional volumes between younger adult (20–30) and older adult (65+) groups also report selective volume reductions in CA1 (e.g., Kerchner et al., 2013). Secondly, volume reductions in the dentate gyrus are associated with increased age in healthy older adults when the dentate gyrus is evaluated independently (Wisse, Biessels, Heringa, et al., 2014), instead of being combined with CA3. Some studies also reported age-related differences in subiculum volume (La Joie et al., 2010), but other studies have not. This discrepancy might be explained by differences in the relative position of the CA1/subiculum boundary across different segmentation protocols.

Alzheimer's Disease

In AD, high-resolution *in vivo* hippocampus subfield volumetry studies show a progressive pattern of volume loss, consistent with direct postmortem analysis of pathology and neuronal loss. The staging work of Braak and Braak (1991) reported that neurofibrillary tangles first appear in the hippocampus/adjacent entorhinal cortex, before appearing in the hippocampus in CA1, then spreading to the subiculum, and finally to the remaining CA subfields, affecting the dentate gyrus particularly late in the progression of the disease. Histological studies of neuronal loss demonstrate a similar progression. There is acute neuronal loss in CA1, even in the earlier stages of the disease (Bobinski et al., 1995). At more advanced stages, there is neuronal loss in the other CA subfields, and even in layers of the dentate gyrus.

This pattern of AD-related volume loss is mirrored in the imaging results. Nearly all studies contrasting healthy controls with AD patients, or with patients with amnestic mild cognitive impairment (MCI), who are at particularly risk for developing AD, report volume reductions in CA1 (e.g., La Joie et al., 2013; Mueller et al., 2007), as well as in the hippocampus/adjacent entorhinal cortex (e.g., Kerchner et al., 2013). A number of studies also report volume reductions of the subiculum in AD and MCI (e.g., La Joie et al., 2013; Mueller et al., 2007). Studies that differentiate patient groups into a less advanced MCI group and a more advanced AD group tend to show a progressive pattern of volume loss matching the histological studies. For instance, La Joie et al. (2013) reported CA1 and subiculum reductions in individuals with MCI and additional volume reductions in a combined CA3/DG region in their AD group. Scanning at 7T, Kerchner et al. (2013) and Wisse, Biessels, Heringa, et al. (2014) both report no volume reductions in MCI patients, but volume reductions in all subfields in AD patients. However, other studies have also reported that all subfields are reduced in volume in MCI and the volume reductions are larger with progression to AD.

Schizophrenia

Hippocampus subfield volumetry studies comparing schizophrenia patients with healthy controls suggest that all subfields might be affected, with an emphasis on CA1 volume changes early in the disease process. Cross-sectional studies using FreeSurfer 5.3 to segment the hippocampus have reported that that severity of positive symptoms in schizophrenia patients was related to volume reductions in CA1 and CA2/3, but other studies have reported that schizophrenia patients might also be affected by volume reductions in the dentate gyrus and subiculum as well. A more recent study (Ho et al., 2017)—using the FreeSurfer 6.0 segmentation algorithm—that divided schizophrenia patients by the length of illness found that participants who had schizophrenia for a longer period of time (mean = 18 years) had volume reductions in all hippocampal subfields. However, a second patient group who developed schizophrenia more recently (mean = 7 years) only had volume reductions in CA1. Longitudinal follow-up of the latter group showed volume reduction in all subfields over time. Studies employing other automated segmentation methods provide similar results. For instance, a recent study using the ASHS protocol on high-resolution scans reported volume reductions in CA1 and the dentate gyrus in schizophrenia patients relative to controls (Ota et al., 2017).

Depression

Studies examining hippocampal subfield volume in individuals with MDD tend to report one of two different effects. Some studies report selective reduction in dentate gyrus volume in MDD patients compared with healthy controls (e.g., Travis et al., 2015). Dentate gyrus volume has also been linked to peripheral markers of oxidative stress associated with MDD. In contrast, other studies reported no subfield volume differences in individuals with depression compared with non-depressed controls. For instance, Ota et al. (2017) used the ASHS toolbox to examine subfield volume differences between 36 MDD patients (17 medicated, 19 unmedicated) and age-matched controls and found no differences in the volumes of any of the subfields in either patient group. One plausible explanation for the contradictory results reported by different studies arises from differences in segmentation protocols used by different groups. For instance, Travis et al. (2015) combined all the CA subfields, whereas Ota et al. (2017) split up those subfields. There are differing opinions about where the boundary between the dentate gyrus and CA3/4 lies, which may also explain observed differences.

Conclusion

High-resolution structural imaging, combined with the development of sophisticated segmentation protocols, has made it possible to examine how hippocampal subfields are affected *in vivo* by healthy aging and by neurological and psychiatric disease. This work has shown specific patterns of decline in different subfields due to aging and the progression of AD. However, studies looking at schizophrenia and MDD have yet to reach a consensus about how these diseases might affect individual hippocampus subfields differently. Taking the results of the studies reviewed here, schizophrenia may affect all hippocampal subfields, perhaps with a preference for CA1 in the earlier stages. MDD may be related to volume reductions in dentate gyrus and subiculum, but some studies also find no effects on any hippocampal subfield.

This chapter focused solely on the hippocampus as an anatomical structure and discussed how aging and disease might affect its constituent subfields. The importance of the hippocampus, however, rests in its involvement in cognition, primarily in terms of long-term memory and spatial representation. By looking at variation and change in the anatomy of different hippocampus subfields as a result of aging or disease, we can better understand how different hippocampal subfields might subserve distinct parts of the cognitive roles attributed to the hippocampus. For instance, a commonly accepted model of hippocampal subfield function (McClelland, McNaughton, & O'Reilly, 1995) proposes that the dentate gyrus is responsible for parsing apart essential details of similar or overlapping stimuli ("pattern separation"), CA3 is responsible for storing and recalling episodic memory information from incomplete cues ("pattern completion"), and CA1 connects the hippocampus to neocortical regions that support the different aspects of a memory. These anatomical–behavioral dissociations suggest that changes that affect one hippocampus subfield would yield distinct behavioral consequences compared with changes that affect a different subfield (i.e., explaining why we might see differences between the cognitive symptoms of different diseases). Hippocampal subfield volumetric studies of aging and disease are important because they connect models of hippocampus function to clinical practice. This works both ways: our understanding of what the subfields are doing might be applicable to a better understanding of aging/disease processes (i.e., uncovering aspects of AD that have been overlooked), and clinical observations might inform our theories of hippocampus function.

Like any developing body of work, the experimental results of hippocampus subfield volumetry are sometimes unclear or even contradictory. Additional studies involving larger sample sizes and finer in-plane scan resolution may help us tease apart what is actually happening and to better understand how potential contradictory findings reported by different groups arose. These shortcomings of the current work are caused by technical as well as practical considerations. For instance, there are limitations to the resolution of structural MRI that limit the precision of previous results. The future development of new methods that can boost the resolution of our images would improve the accuracy of our results and might clarify our understanding of how disease processes actually affect the hippocampus. Further, few hippocampal subfield volumetry studies have been conducted with large sample sizes. Aside from the difficulty of recruiting and imaging patient populations, the process of manual segmentation required for accurate results is both time consuming and requires significant skill, acquired only after extensive training and practice. Differences between the segmentation protocols used might also account for some of the inconsistent results between different studies. The development of more accurate automated hippocampal segmentation methods and of a consensus protocol for hippocampus subfield segmentation will hopefully alleviate these issues.

DTI Tractography Metrics: Fiber Bundle Length

Diffusion Tensor Imaging

The MRI technique of diffusion tensor imaging (DTI) measures the three-dimensional translational motion of water diffusion (i.e., Brownian motion) in biological tissue (Basser, Matteillo, & LeBihan, 1994a, 1994b; Mori & Zhang, 2006) or non-biological phantom (Hubbard, Zhou, Eichorn, & Parker, 2015; U.S. Patent No. 7,667,458 B2, 2010). The rate of diffusion of a water molecule in biological tissue depends on temperature and its local structural environment.

The translational movement (i.e., diffusion) of a water molecule in the brain varies by tissue type. The probabilistic spatial dispersion of a water molecule over a period of time in a structurally unconstrained setting such as within the lateral ventricles of the human brain is largely random or "isotropic" and can be visualized as a sphere. In contrast, water diffusion in cerebral white matter is constrained by axon membranes, microtubules, and axons sheathed in hydrophobic myelin (Beaulieu, 2002; Weise, 1985). Accordingly, the probabilistic displacement of a molecule in cerebral white matter is generally linear. That is, a water molecule is more likely to move along the axon linearly than across it. This is particularly the case in regions where axons are oriented in a coherent direction (e.g., corpus callosum). In general, axon membranes and fiber packing densities play prominent roles in diffusion anisotropy, whereas myelin appears to play a secondary role (Beaulieu, 2009; LeBihan et al., 2001). In cerebral gray matter, water diffusion is constrained by the less linear membranes of cell bodies and organelles and, accordingly, is more randomly dispersed (less anisotropic).

The foregoing is the context for how DTI provides information about the structural coherence (also referred to as "integrity") of white matter. Highly coherent fiber bundles, such as the corpus callosum, are highly anisotropic, whereas isotropy typically increases in regions of

white matter bundles that are less coherent. Lower directional coherence can be due to normal anatomic variation such as crossing fibers, large axon diameters, and lower fiber packing density; or to pathological processes such as axon loss, demyelination, and intracellular or extracellular edema (Beaulieu, 2009).

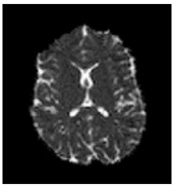
Derivation of DTI Scalar Metrics

Three-dimensional characterization of water motion requires measurement of water diffusion (i.e., diffusion encoding) in a minimum of six orthogonal directions (Buxton, 2002). This means that at least six entire brain volumes are collected, one for each direction. An additional volume is collected with no diffusion encoding to permit calculation of an apparent diffusion coefficient (ADC), based on the signal intensity differences between the diffusion-encoded and non-diffusion-encoded images. The ADC is a measure of water diffusion that takes into account tissue barriers such as cellular membranes and filaments (Mori & Zhang, 2006). After appropriate spatial registration across volumes, each image voxel will have six diffusion values, one for each direction. DTI acquisitions of brain typically involve many more diffusion encoding directions (e.g., >30). More diffusion encoding directions permits better characterization of the underlying white matter. The details of the MRI sequences required for such measurements vary across scanners and research settings and are beyond the scope of this chapter.

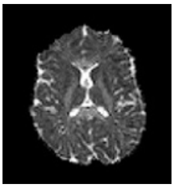
The ADC values in each image voxel can be expressed as a second-order tensor that can then be decomposed into three non-negative eigenvalues ($\lambda_1 > \lambda_2 > \lambda_3$) and their corresponding eigenvectors (ε_1, ε_2, and ε) that respectively capture the magnitude and direction of diffusion in each imaging voxel. The eigenvectors are in the frame of reference of the underlying tissue and are therefore independent of the scanner axes. The dominant fiber orientation within an image voxel (ε_1) is the orientation with the largest magnitude of diffusion (λ_1) (Basser et al., 1994a, 1994b; Buxton, 2002; Mori & Zhang, 2006).

The eigenvalues can then be mathematically combined into scalar metrics describing various aspects of diffusion in each imaging voxel. Commonly used DTI scalar metrics include mean diffusivity (MD), or the average magnitude of diffusion in each voxel; axial diffusivity (AD or DA) or rate of diffusion in the principal diffusion direction (i.e., λ_1); radial diffusivity (RD) or off-axis diffusivity (i.e., λ_2, λ_3); and fractional anisotropy (FA) or the degree to which diffusion is directionally restricted in each image voxel. These scalar metrics have values between 0.0 and 1.0. Higher values of FA indicate greater directional restriction of water diffusion (e.g., greater white matter structural coherence), whereas higher MD values indicate greater isotropic diffusion possibly related to lower fiber coherence. MD, RD, and DA are in units of mm²/s, whereas FA is dimensionless. These scalar metrics are typically displayed as grayscale images. Formulas and sample images for MD, DA, RD, and FA are provided below. Other scalar metrics such as relative anisotropy and volume ratio appear less frequently in published research and will not be discussed further here.

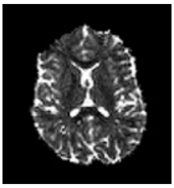
$$\mathrm{MD} = (\lambda_1 + \lambda_2 + \lambda_3)/3$$



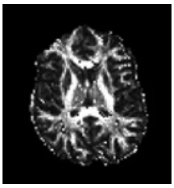
$$\mathrm{AD}\ (\text{or DA}) = \lambda_1$$



$$\mathrm{RD} = (\lambda_2 + \lambda_3)/2$$



$$\mathrm{FA} = \sqrt{\frac{1}{2}}\,\frac{\sqrt{(\lambda_1-\lambda_2)^2+(\lambda_2-\lambda_3)^2+(\lambda_3-\lambda_1)^2}}{\sqrt{\lambda_1^2+\lambda_2^2+\lambda_3^2}}$$



DTI is sensitive to multiple factors that impact the structural integrity of cerebral white matter. This includes developmental maturation (Vertes & Bullmore, 2015) and aging (Marner, Nyengaard, Tang, & Pakkenberg, 2003; McLaughlin et al., 2007; Tang, Nyengaard, Pakkenberg, & Gundersen, 1997) as well as acquired conditions causing white matter injury, edema, demyelination, and degeneration (e.g., traumatic brain injury, ischemia, multiple sclerosis, Alzheimer's disease, etc.). The scalar metrics listed above are sensitive to these and other pathologies causing alterations of white matter structural integrity although the individual metrics are not specific to any particular pathologic process. For example, Wallerian degeneration seen in Alzheimer's disease has been associated with increased diffusivity measures (DA, MD, and RD) and decreased fractional anisotropy (Alves et al., 2012). A similar pattern of change in FA, MD, and RD was found in widespread white matter regions in retired athletes with history of mild traumatic brain injuries (Tremblay et al., 2014). Increased diffusivity has been shown in inflammation (Logygensky et al., 2010). Increased RD has been shown to be sensitive to myelin changes as in multiple sclerosis (Ontaneda et al., 2014). Myriad other human and animal studies show sensitivity of DTI scalar metrics to various developmental and pathological factors that impact white matter integrity.

DTI data can also be displayed using tractography. This method incorporates the scalar and vector information to provide indirect visual information about the orientation and path of white matter fibers as they course through the cerebrum. The resulting images are visualized *mathematical representations* (i.e., integral curves; a.k.a. streamtubes) of the underlying white matter anatomy based on the acquired diffusion signal.

Typical tractography color-coding convention is that red indicates fibers or tracts running in the left–right direction, blue indicates inferior–superior direction, and green indicates anterior–posterior (Pajevic & Pierpaoli, 1999), although this convention is not always followed.

Tractography can be accomplished based on the diffusion tensor (deterministic tractography, e.g., Mori, Crain, Chacko, & van Zijl, 1999; Zhang, Demiralp, & Laidlaw, 2003) or can be performed without tensor computation using probabilistic methods (probabilistic tractography,

Behrens, Berg, Jbabdi, Rushworth, & Woolrich, 2007; Behrens, Johansen-Berg, et al., 2003). In deterministic methods, the visualized fibers are actually integral curves that have been propagated through three-dimensional image space based on seed points. The curves follow the spatial orientation of the principal eigenvector. The algorithm is set to terminate curve propagation when FA falls below a prespecified value (often <0.2) chosen to reduce likelihood of fibers entering grey matter, ventricles, or extra-cerebral space. The curves are also terminated when curvature exceeds a predetermined value (typically ≥90°) to avoid image noise-driven errors that cause propagation of curves with anatomically implausible turns.

Probabilistic methods differ from tensor-based approaches. Probabilistic methods incorporate uncertainty into the fiber tracking process using a Bayesian approach that models the diffusion signal. Probabilistic tractography takes into account uncertainty in fiber tracking due to anomalies in the diffusion signal resulting from noise and artifact. The approach produces probability distributions of parameters in a model of the diffusion signal and uses these parameter distributions to produce a tractography fiber representation that reflects the likelihood of a connection between brain regions (Behrens, Woolrich, et al., 2003; Correia & Gongvatana, 2010).

Irrespective of the tractography model, individual tracks (e.g., forceps minor, uncinate fasciculus, corticospinal tract, etc.) can be selected manually using specialized software or can be segmented using prespecified white matter atlases. Once selected, the structural integrity of a tract can be described using summary scalar values (e.g., mean FA, MD, or RD summed across all voxels comprising all fibers of the tract) or by other values such as number of fibers in a bundle, distances between fibers, or FBL.

Correia et al., 2008, demonstrated the potential utility of FBL as a marker of white matter integrity. The rationale for FBL is that that even subtle reductions in white matter integrity, such as those related to older age (Marner et al., 2003; Pakkenberg et al., 2003) or very mild cerebrovascular injury that falls below the threshold of visualization on conventional T2-weighted clinical imaging (Moseley, 2002), can cause local alterations in diffusion signal and anisotropy (e.g., reduced FA). Alterations of sufficient magnitude (e.g., FA < 0.2) should cause fiber propagation to terminate prematurely, thereby resulting in reduced fiber length (and possibly number) irrespective of the method used to generate the tractography model.

For example, a small lesion with FA < 0.2 in the center of the left cingulate bundle should cause fiber propagation to terminate at the boundaries of the lesion, whereas cingulate fibers that circumvent the lesion should propagate the length of the bundle without disruption. For this reason, mean left cingulate FBL should be lower compared with an individual without such lesion. In contrast, mean FA summed across all *propagated* left cingulate fibers could be comparable for both individuals. Accordingly, FBL provides information about white matter integrity that complements other DTI tractography metrics such as average white matter bundle FA or MD.

FBL is subject to the limitations impacting tractography generally, such as ambiguity and possible errors in fiber tracking in regions of fiber crossing. Probabilistic methods and higher dimensional DTI acquisitions involving high numbers of diffusion encoding directions (e.g., 512 directions) help to minimize such errors, thereby improving accuracy of FBL metrics (Yao et al., 2015).

A variety of FBL metrics can be computed (Correia et al., 2008) such as total length (length of each fiber in millimeters summed across all fibers in a white matter bundle, e.g., forceps major) and average FBL (total bundle length divided by the number of fibers in the bundle). Other metrics can be weighted for FA or normalized by white matter volume. Average FBL has now been incorporated into several software analysis packages.

Research Using FBL

Several studies have used FBL to characterize clinical entities. A subset of those studies is reviewed, briefly demonstrating the breadth of applicability of the metric.

Bolzenius et al. (2013) showed age-related declines in mean FBL in frontal, temporal, and whole-brain white matter in 72 healthy adults age 51–85 years (mean age = 63.26 ± 8.76 years). Moreover, they showed that elevated body mass index was associated with shorter mean FBL in the temporal lobes bilaterally independent of age. The authors interpreted the findings as evidence that elevated BMI is adversely associated with cerebral white matter changes.

Behrman-Lay et al. (2015) found shorter mean FBLs were associated with older age and with decreased executive function and cognitive processing speed in a sample of 73 healthy older adults (mean age = 63.56 ± 8.59 years). Specifically, FBL in parietal and occipital regions accounted for a significant portion of the variance in executive function; whereas FBL in frontal, temporal, and occipital regions accounted for a significant amount of variance in cognitive processing speed.

Baker et al. (2016) examined the association between FBL and cognitive reserve in a sample of 63 healthy older adults (mean age = 63.13 ± 8.23 years). Cognitive reserve was determined as estimated IQ, and a total score on a brief cognitive battery was used as a measure of current cognitive status. Shorter whole-brain FBL was related to both lower cognitive reserve and lower current cognitive status. Cognitive reserve moderated the relationship between current cognitive status and FBL in the hippocampal segment of the cingulum bundle. The association between FBL and cognitive status was attenuated in individuals with higher cognitive reserve. The authors concluded that higher cognitive reserve protects older adults against poor cognitive status and against age-related decline in FBL.

Salminen et al. (2013) used FBL to examine the influence of the epsilon 4 (e4) isoform of the apolipoprotein E (ApoE) gene, a known genetic risk factor for Alzheimer's disease, on temporal lobe white matter integrity. They studied 64 healthy older adults including 24 participants with at least one ApoE e4 allele (mean age = 58.78; SD = 6.65) and 51 participants with no e4 allele (mean age 64.71; SD = 8.60). They also examined memory status using a standard neuropsychological measure. Results showed significantly shorter FBL in the left uncinate fasciculus in e4 carriers compared with non-e4 carriers. Overall, results also showed that increasing age correlated with shorter temporal lobe and uncinate FBL and lower memory scores. The authors concluded that ApoE e4 status alters FBL status in the uncinate fasciculus.

Nakata et al. (2009) used DTI to examine the integrity of the ventral cingulum bundle (VCB), the posterior portion of the cingulum bundle coursing inferolaterally into the inferomedial temporal lobe in patients with partial or complete agenesis of the corpus callosum. Compared with controls, individuals with complete or partial callosal agenesis showed reduced FA in the right VCB and reduced VCB volume bilaterally. Additionally, FBL was reduced bilaterally in the subgroup with complete callosal agenesis. The authors concluded the agenesis of the corpus callosum is associated with abnormalities in intrahemispheric pathways.

FBL has also been examined in animal models of traumatic brain injury and in humans with traumatic brain injury and aneurysmal subarachnoid hemorrhage (e.g., Harris, Verley, Gutman, & Sutton, 2016; Sener et al., 2016). It has also been examined in multiple sclerosis (Li et al., 2013), HIV infection (e.g., Tate et al., 2010), and development (e.g., Wierenga et al., 2016). These applications demonstrate the wide applicability of this metric.

In sum, FBL is a tractography-based metric that provides unique information about cerebral white matter integrity and complements other quantitative DTI metrics. FBL has clinical research utility in conditions known to impact white matter integrity in aging and development.

Diffusional Kurtosis Imaging

Molecular diffusion is the random movement of molecules due to thermal agitation. In an unrestricted medium, such as a glass of water, the distance a diffusing water molecule moves over a given time interval is described by a normal or Gaussian probability distribution. Diffusion of this type is referred to as Gaussian diffusion. However in many biological tissues including brain, the presence of cellular membranes, organelles, and other barriers to the water molecules' free movement causes the diffusion process to deviate from the Gaussian behavior of pure water. This deviation can be quantified by a standard statistical metric called the (excess) kurtosis (DeCarlo, 1997). When the kurtosis of the diffusion probability distribution differs significantly from zero, the diffusion dynamics is said to be non-Gaussian. The kurtosis provides a precise measure of the degree of non-Gaussianity and an indirect means of characterizing the tissue microstructure that comprise the diffusion barriers.

Diffusion magnetic resonance imaging (MRI) is a broad category of noninvasive MRI methods that are sensitive to water diffusion and widely applied in both human and animal MRI studies. One of these is diffusional kurtosis imaging (DKI), which as its name suggests is

distinguished by its ability to measure the kurtosis for water diffusion (Jensen & Helpern, 2010). Since the kurtosis is intimately linked to microstructure, this technique is effective in detecting subtle changes, due to disease or injury, which occur in a tissue on a cellular level. When utilizing DKI, one obtains three-dimensional images of an anatomical region of interest that spatially map the kurtosis to a resolution of a few millimeters.

For the brain, there is an added complication that water diffusion is anisotropic. This means that the diffusion probability distribution, and hence the kurtosis, varies with the direction in which it is measured. This is largely a consequence of the brain containing many elongated cellular projections, like axons and dendrites, which steer the water to preferentially diffuse along their axes. Hence the kurtosis becomes a function of orientation as well as spatial location. This orientational dependence of the kurtosis can be summarized by several specific kurtosis metrics. The most commonly used are the mean kurtosis (MK, the kurtosis averaged over all orientations), the axial kurtosis ($K_{||}$, the kurtosis in the orientation for which the diffusion probability distribution is widest), and the radial kurtosis ($K_{\perp}$, the kurtosis averaged over all directions orthogonal to that for which the diffusion probability distribution is widest).

In addition to these kurtosis metrics, DKI also enables the measurement of several other diffusion metrics that are related to the diffusivity, which is simply the mean-square width of

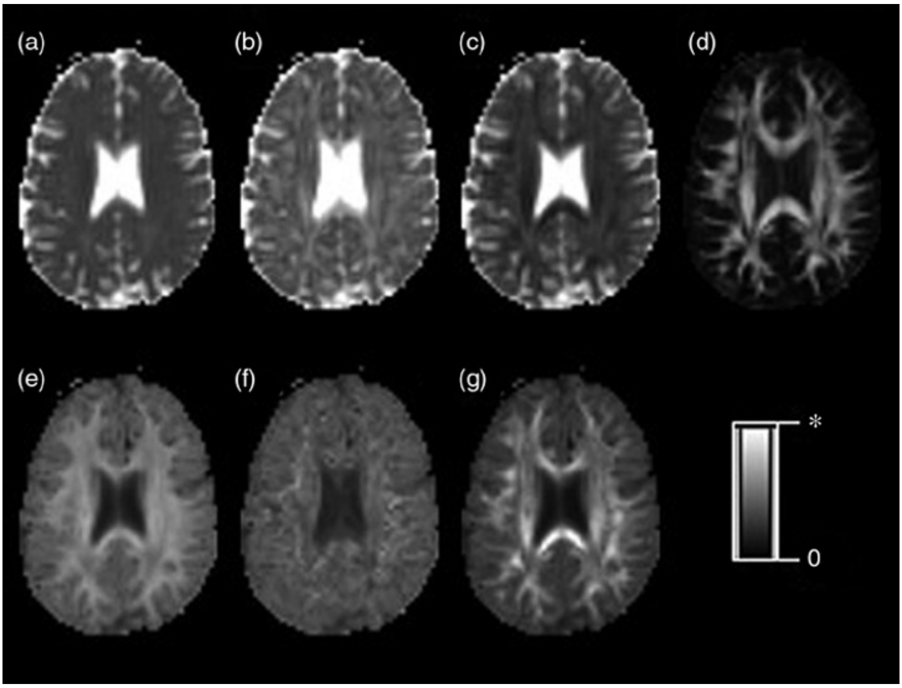

Figure 1 Diffusional kurtosis images of a healthy brain. Each image corresponds to the same anatomical slice. The parameters shown are the mean diffusivity (a), axial diffusivity (b), radial diffusivity (c), fractional anisotropy (d), mean kurtosis (e), axial kurtosis (f), and radial kurtosis (g). The differing contrasts reflect the distinct diffusion properties that each parameter quantifies. The parameters for panels (a), (b), and (c) have units of $\mu m^2/ms$, while (d), (e), (f), and (g) are dimensionless. The asterisk (*) by the scale bar indicates the upper limit. This upper limit has a value of 3 for (a), (b), (c), and (g), a value of 2 for (e) and (f), and a value of 1 for (d).

the diffusion probability distribution divided by twice the observation time. Similar to the kurtosis, the diffusivity depends on orientation, allowing one to define a mean diffusivity (MD), axial diffusivity ($D_{||}$), and radial diffusivity ($D_{\perp}$). These diffusivity metrics can also be measured with an alternative diffusion MRI approach known as diffusion tensor imaging (DTI), which is a forerunner to DKI but does not quantify the kurtosis. DTI is one of the oldest and most commonly used diffusion MRI methods (Mori & Zhang, 2006). However, it has important limitations, which has spurred the recent development of more advanced techniques such as DKI.

With this battery of diffusion metrics (i.e., MK, $K_{||}$, $K_{\perp}$, MD, $D_{||}$, and $D_{\perp}$), DKI provides a fairly comprehensive assessment of the diffusion dynamics. Some examples of images corresponding to these metrics are shown in Figure 1. Each metric quantifies a different aspect of diffusion, and the ensemble of metrics is interpreted as a group in order to build up a full picture of this complex molecular process.

Because of the close connection between diffusion and tissue microstructure, DKI enables the *in vivo* detection of microstructural changes associated with pathology, something that is otherwise usually accomplished by microscopic examination of *ex vivo* tissue specimens. As a consequence, DKI is being actively applied to the study of a variety of diseases, particularly in brain (Steven, Zhuo, & Melhem, 2014). However, this work is still at an early stage, with more research being needed to determine the ultimate clinical utility of DKI. Here we review some of this work related to stroke and dementia, two important diseases for which MRI is often used in both clinical and research studies.

Stroke

Ischemic stroke occurs when blood vessels in the brain are blocked by a clot, thereby depriving the downstream tissue of oxygen. This results in a cascade of changes in cell metabolism and structure that can eventually lead to cell death, if blood flow is not quickly restored. It was observed many years ago with diffusion MRI that the water diffusivity decreases sharply following ischemic stroke (Knight et al., 1991; Kucharczyk, Mintorovitch, Asgari, & Moseley, 1991). For this reason diffusion MRI is routinely used clinically for stroke diagnosis (Fung, Roccatagliata, Gonzalez, & Schaefer, 2011). Recently, it has been found with DKI that ischemic stroke greatly increases the kurtosis in the affected areas (Hui, Fieremans, et al., 2012; Jensen et al., 2011). Current research is aimed at determining the meaning and practical value of this finding.

Interestingly, multiple clinical and animal studies have demonstrated that the kurtosis and diffusivity metrics provide complimentary characterization of the damaged regions in ischemic stroke, with the spatiotemporal dynamics of MD and MK being markedly different (Hui, Du, Huang, Shen, & Duong, 2012). In particular, the size of the lesion identified with MK is sometimes smaller than that revealed by the MD changes (Cheung, Wang, Lo, & Sun, 2012). This has led to the hypothesis that the MK may be better in predicting the more seriously damaged tissue (Grinberg, Ciobanu, Farrher, & Shah, 2012). If physicians were able to predict the brain regions most likely to recover, treatment and rehabilitation planning may be more effective. In addition, it has been observed that the kurtosis changes persist longer after the onset of stroke than do those associated with the diffusivity, which could provide clues that might help guide therapy (Weber et al., 2015).

Perhaps the most notable contribution of DKI to stroke research is that it lends compelling support to a recent theory (Budde & Frank, 2010) for the biophysical mechanism behind the diffusion changes associated with ischemic stroke, which has been a long-standing puzzle in the field. According to this theory, the beading of axons and dendrites is the key process behind the sensitivity of diffusion to stroke. By combining DKI data with a simple model of white matter structure, it was then shown that the model parameters changed after stroke precisely as predicted by Budde and Frank's theory (Hui, Fieremans, et al., 2012). Solving this old riddle may inspire new ideas for improved stroke treatments.

Dementia

The most common cause of dementia is Alzheimer's disease (AD), which is chronic and incurable. It is currently the sixth leading cause of death in the United States. Prior to being diagnosed with AD, some subjects are classified as having mild cognitive impairment (MCI), which means that they have a measurable decline in certain cognitive abilities but not so much as to significantly impact their daily activities. Approximately 10–15% of MCI subjects per year will progress to AD, and MCI is often regarded a precursory or prodromal form of AD. There is great interest in studying the brain changes that occur during MCI, because it is at this early stage of the disease process that potential therapies are believed to have the best chance of being effective.

Recently, several studies have indicated that DKI may be a useful tool for quantifying the microstructural brain changes associated with AD and MCI (Benitez et al., 2014; Falangola et al., 2013; Fieremans et al., 2013; Gong, Wong, Chan, Leung, & Chu, 2013; Struyfs et al., 2015; Vanhoutte et al., 2013; D. Wang, Guo, Liu, Li, & Wang, 2015; Yuan et al., 2016). For example, it has been reported that DKI can distinguish MCI from age-matched controls with a high degree of sensitivity and specificity. In one study, the most accurate parameters were specific combinations of the diffusion metrics that are expected to be especially sensitive to water diffusion taking place in white matter spaces external to the axons (Fieremans et al., 2013). This suggests that subtle structural changes in the extra-axonal white matter occur early in the progression of AD pathology, an observation consistent with at least one theory for the genesis of AD that posits myelin breakdown as playing a central role in AD development (Bartzokis, 2011). Myelin forms sheaths that surround many axons, and a disruption of myelin integrity can plausibly cause the type of diffusion parameter changes detected with DKI. However, it is important to note that the etiology of AD is currently quite controversial, and there is no broad consensus regarding which biological mechanisms are most important.

Looking forward, one possible application of DKI to AD would be to help monitor drug trials. At present, the drugs used for AD improve some symptoms but do not slow down disease progression. DKI and other diffusion MRI methods may eventually prove useful in testing whether new drug therapies are more effective in preserving brain tissue, although work in this direction is still very preliminary. The advantage of using MRI over alternative imaging methods, such as positron emission tomography, is that MRI does not use ionizing radiation and is more widely available.

Besides AD, there is also a limited amount of research applying DKI to other disorders with associated dementia, including Parkinson's and Huntington's diseases (Blockx, De Groof, et al., 2012; Blockx, Verhoye, et al., 2012; Kamagata et al., 2013, 2014; J. J. Wang et al., 2011). Again DKI seems to be quite sensitive to changes in brain microstructure. This fact, together with the relative ease with which DKI can be implemented on clinical MRI scanners, makes DKI a promising tool for yielding new insights and better treatments for this devastating class of maladies.

Future Directions

DKI has yielded encouraging results in several research studies of a variety of diseases, including stroke and dementia. However, several improvements would facilitate its wider use in clinical settings. First, the sensitivity and specificity of DKI-derived diffusion metrics to various pathological processes could be better documented. Second, the DKI image acquisition protocols could be better optimized to accommodate clinical work flows. Third, convenient software tools could be developed that allow the diffusion metrics to be accurately quantified from DKI data without the need of specialized training. DKI is currently a useful research tool that is growing in popularity. As the development of this image method progresses, it may one day become a standard imaging modality available on most clinical MRI systems.

Functional Magnetic Resonance Imaging: fMRI

Magnetic resonance imaging (MRI) is a noninvasive neuroimaging technique that utilizes a standard MRI scanner. Depending on the changing magnetic pulse sequences employed, images are created that are sensitive to tissue properties and tissue types. While structural MRI (e.g., neuroanatomy, volumetrics) and diffusion tensor imaging (e.g., tractography or fractional anisotropy of white matter) use specific pulse sequences to identify neuroanatomical structure, functional magnetic resonance imaging (fMRI) pulse sequences reveal short-term physiological changes associated with active functioning of the brain. The blood oxygenation level-dependent (BOLD) signal reflects a delayed hemodynamic response to neural activity; however, the exact mechanism of the coupling between the brain's activity and the vascular response is not well understood. More specifically, increases or decreases in BOLD response when a participant performs a task are compared with BOLD response during a contrasting task to provide information on changes in oxygen level in voxels over time. These changes in deoxygenated hemoglobin are in response to the metabolic requirements of active neurons during different task processes that involve the extraction of oxygen by active neurons as well as changes in the blood flow and volume. BOLD contrast is the difference in signal images as a function of the amount of deoxygenated hemoglobin. BOLD contrast values are then used as an indirect indicator of neuronal activity.

Within a task-based fMRI experiment, it is critical that the two conditions are as similar as possible to each other and only differ based on the one key property (i.e., the independent variable). If the conditions differ in more than one way, then these additional differences are confounding variables that offer alternative plausible hypotheses, in addition to the original hypothesis for which the study was designed. For that reason, it is critical that comparisons aim to hold as many extraneous variables as possible constant across tasks.

Task-based fMRI studies primarily employ either block or event-related designs. However some designs combine features of each (e.g., mixed design). In a block design, each condition

is presented continuously over a period of time (i.e., block), and then alternating conditions occur across the run. In contrast in an event-related design, stimuli are presented one at a time with variable interstimulus intervals, rather than repeated across a block. Therefore, an event-related design isolates individual trial events in which trial types are randomly intermixed in rapid succession. Event-related fMRI paradigms are sensitive to transient changes to specific events. Block design is also sensitive to transient signal change, but this transient change is averaged over the course of a block. Moreover, block design is most sensitive to sustained changes in activity. Mixed block/event-related fMRI designs have also been employed to characterize these complementary BOLD signal components (Peterson & Dubois, 2012).

Working Memory: N-Back Paradigm

One commonly used block design paradigm is the n-back. It has been used internationally and across a wide age range to better understand working memory. Working memory is a cognitive skill that enables temporary storage and manipulation of remembered information (Baddeley, 1986). Many researchers have established that working memory is a fundamental cognitive process that supports a range of abilities from selective attention to complex decision making and more distal skills of intelligence and academic achievement.

The n-back task requires active monitoring, updating, and manipulation of information. A variety of stimuli have been employed across various sensory modalities using this paradigm. Participants must monitor a series of stimuli and respond yes or no if the stimuli were seen n-trials before. The parametric design typically includes varying loads of 1-, 2-, and 3-back blocks. Depending on the instructions for the respective block, the participant endorses when the stimuli repeat itself n-stimuli before. For example, a letter n-back presents a series of letters (e.g., X, S, S, T, S, T…). For a 1-back block, the participant would endorse yes for the third letter because S repeated itself 1 letter before. During a 2-back block with these same stimuli, the participant would endorse yes for the fifth and sixth letter because the respective letter occurred two stimuli before. During a 3-back block, the participant would endorse yes for the fifth letter because S occurred 3 stimuli back (second stimuli). Researchers interested in examining vigilance within the same paradigm may add 0-back and crosshair blocks. For the 0-back the participant would endorse yes only when a prespecified letter appears. A higher "n" value (i.e., 2- and 3-back) represents a higher cognitive load due to higher monitoring, updating, and manipulating demands and thus working memory. In contrast, an "*n*" value of 0 or 1 is conceptualized as a measure of vigilance as it requires primarily monitoring. The most common n-back BOLD contrast employed is 2-back versus 0-back to examine working memory.

Clinical Relevance

Owen, McMillan, Laird, and Bullmore (2005) conducted a meta-analysis of studies with healthy adult participants without neurological or psychiatric conditions and identified a highly consistent frontal and parietal system activation across various stimuli. Given this highly reliable frontoparietal network activated by n-back contrasts, researchers have employed the n-back paradigm to investigate working memory in a wide range of clinical populations. Researchers investigate the BOLD contrast for the clinical population and how it activates similar to the control group (i.e., conjunction analyses) as well as how activations may differ between groups with the BOLD contrast. However, when group differences in BOLD activation (e.g., 2-back versus 0-back) have been identified, it is critical to determine whether BOLD activation differences are due to (a) higher activations on the 2-back task in the clinical group compared with the control group, with identical 0-back activations; (b) lower activations on the 0-back in the clinical group compared with the control group, with identical activations on the 2-back; or (c) a combination of higher 2-back activation and lower 0-back activation in the clinical group compared with the control group. In addition, establishing the relationship between the percent of BOLD change in an identified ROI with n-back behavioral performance (e.g., accuracy) and with clinical measures of working memory (e.g., performance on clinical measures and self or informant ratings) is also important to consider when researchers are interpreting the results of their fMRI analyses.

For example, in adult survivors of childhood brain tumors and demographically matched controls, conjunction analyses (2-back versus 0-back) revealed a similar distributed frontoparietal network with comparable activations in the right superior parietal lobe, right paracingulate, right insular cortex, left middle frontal gyrus, thalamus, and right lateral cerebellum (King, Na, & Mao, 2015). This finding highlighted the common distributed frontoparietal network employed by both groups. However, the main goal of this research was to investigate if group differences exist. In fact, adult survivors of childhood cerebellar brain tumors had significantly greater BOLD activation in the left superior/middle frontal gyri and left parietal lobe (2-back versus 0-back contrast). In addition, the differences during the 2-back working memory task were due to higher activations in survivors relative to controls, as there were no BOLD differences between groups on the 0-back versus crosshair contrast. Furthermore, the left superior/middle frontal activation was specifically negatively associated with 2-back and 3-back performance as well as clinical measures of working memory, and it was not associated with lower load n-back performance or clinical attention measures. In summary, these findings highlighted that as working memory load increased, and performance declined, it was specifically associated with increased frontal regions of BOLD response and not overall cognitive abilities. This increased activation that is associated with poorer performance likely reflects recruitment of additional cognitive resources for the more challenging task and not compensation or brain reorganization (see Hillary, 2008).

Another example is using the n-back to examine working memory of adolescents with congenital heart disease (King et al., 2017), another population known to have executive function difficulties. The clinical and demographically matched control groups both activated similar frontoparietal working memory networks when using conjunction analyses. Yet, participants with congenital heart disease demonstrated significant differences within the left precuneus and right inferior frontal gyrus relative to controls. These differences appeared to be due to less task-induced deactivation in the congenital heart disease group during working memory and greater task-induced deactivation in the control group. Furthermore, the performance on clinical measures and informant ratings reflected significantly greater working memory and executive function differences. The frontal regions identified by significant group differences were negatively associated with performance suggesting that greater deactivation was associated with improved working memory performance in participants with congenital heart disease. These findings, similar to the interpretation of findings with adult survivors of childhood brain tumor, are consistent with reallocation of processing resources during challenging tasks.

Future Directions

Future directions in fMRI are beginning to include multiple methods of neuroscience and sophisticated neuroimaging analyses. For example, combining fMRI data to include one or more of the following (effective connectivity modeling, resting state functional connectivity, EEG time course methods, genetics, and/or structural MRI studies (e.g., DTI or MRI volumetric studies)) is appearing more frequently in the literature given the complementary information each distinct approach provides. In addition, more research is examining BOLD activation changes following intervention or over the course of recovery from brain injury. For example, healthy individuals who participated in an intensive working memory training of a dual n-back paradigm demonstrated brain plasticity (i.e., reduced activation selectively for 2- and 3-back conditions) and behavioral accuracy improvements that are not demonstrated in a group of individuals who received a different cognitive training experience (Thompson, Waskom, & Gabrieli, 2016). Furthermore, the two frontoparietal networks of executive control and dorsal attention were similar pre-training in showing load-dependent activation. However, post-training, these two networks were dissociated, and the executive control network no longer evidenced the relationship with WM load. Furthermore, training-specific increases of functional connectivity of the executive control network and the dorsal attention network correlated with improved behavioral performance. Together, these findings highlight the changes in traditional fMRI BOLD activation magnitudes as well as altered network connectivity in response to intensive working memory training. These diverse and complementary methods used together help to highlight the complex and dynamic nature of brain functions and the exciting developments in neuroimaging research that are designed to better understand brain–behavior relationships.

Introduction

Over the past decade, there has been growing interest in neuroimaging methods that characterize functional and structural connectivity between neighboring brain regions, as well as within and between large-scale neural networks. A particularly promising neuroimaging technique that can be used to examine functional connectivity is resting-state functional magnetic resonance imaging (rs-fMRI). rs-fMRI measures correlations in spontaneous low-frequency fluctuations in the blood oxygen level-dependent (BOLD) response while participants are at rest, thus depicting the functional network architecture of the brain (Power, Schlaggar, & Petersen, 2014 for review). rs-fMRI has been effectively applied to nonclinical as well as clinical populations, in an effort to identify dysfunction in resting-state functional connectivity (rsFC) in large-scale neural circuits across a variety of neurological and psychiatric conditions, such as Alzheimer's disease, depression, and schizophrenia (Greicius, 2008). Because of this capability, it has been suggested that rsFC may serve as a neurobiological marker of pathology to distinguish between various neuropsychiatric disorders (Finn & Constable, 2016; Menon, 2011; Williams, 2017). In this chapter, we present (a) a brief overview of rs-fMRI and analytic techniques to examine rsFC, (b) a review of literature on rsFC in several neuropsychiatric conditions, and (c) the advantages and limitations of using rs-fMRI as an outcome measure to predict treatment response and to assess the usefulness of interventions in clinical studies at the single-subject level. Finally, we highlight future directions for rs-fMRI research in neuropsychiatric populations, including dimensional approaches.

Resting-State fMRI: Methods and Analytic Techniques

rs-fMRI Background

In contrast to task-based fMRI, which measures changes in the BOLD signal evoked in response to specific stimuli (e.g., emotional faces), rs-fMRI measures spontaneous low-frequency fluctuations (<0.1 Hz) in the BOLD signal during periods of relaxed wakefulness (i.e., at rest). During a typical rs-fMRI scan, participants are instructed to keep their thoughts unfocused while remaining alert as they passively view a fixation cross or close their eyes (Power et al., 2014 for review). These different rs-fMRI conditions are generally considered comparable, though research suggests that participants may be more likely to fall asleep in eyes-closed conditions (Power et al., 2014). The average duration of a rs-fMRI scan is about 5–7 minutes.

Biswal, Zerrin Yetkin, Haughton, and Hyde (1995) were the first researchers to perform rsFC using fMRI. In this seminal rs-fMRI study, significant rsFC was observed between homologous brain regions in the sensorimotor cortex as well as other regions of the motor system (Biswal et al., 1995). These results suggested that neural systems involving specific functions, such as movement, could be isolated using functional connectivity methods during rs-fMRI. Subsequent rsFC research has identified numerous resting-state networks associated with sensory, motor, cognitive, and affective processes in healthy populations including sensory (e.g., visual), subcortical (e.g., striatal), and cortical (e.g., default mode, central executive, salience) networks (Power et al., 2014). The rsFC research reviewed later in the chapter will focus on alterations in those cortical, subcortical, and/or limbic resting-state networks consistently associated with neuropsychiatric conditions. In the next section, we briefly review common preprocessing and rsFC connectivity methods.

rs-fMRI Preprocessing and rsFC Methods

As in task-based fMRI, typical preprocessing steps for rs-fMRI data include removing the first several volumes, despiking, slice-time correction, alignment of the rs-fMRI scan with the anatomical image, and spatial smoothing (e.g., Yeo et al., 2011). To remove nonneuronal noise from the rs-fMRI signal, additional preprocessing steps are often performed including nuisance regression, motion correction and/or censoring, and bandpass filtering to isolate the low-frequency BOLD signal (~0.009–0.1 Hz) (Power et al., 2014 for review). For nuisance regression, signals associated with the ventricles, white matter, and physiological noise (e.g., cardiac and respiratory signal) are typically regressed from the rs-fMRI data (Power et al., 2014). In some cases, global signal regression (i.e., regressing the signal averaged across the whole brain) is also performed to remove noise in the data related to motion or physiological artifacts (Power et al., 2014). To account for individual differences in motion that can alter rsFC, most researchers perform regression for motion across the scan and censor the rs-fMRI data for excessive framewise motion (i.e., volume-to-volume movement >0.2 mm) (Power, Schlaggar, & Petersen, 2015 for review). However, several controversies remain in rs-fMRI preprocessing, such as whether the global signal should be included (Power et al., 2014).

Following preprocessing, functional connectivity analyses are performed on the rs-fMRI data using any of numerous different methodological approaches that have been developed to compute rsFC. For the purposes of this chapter, the rsFC methods discussed below will be those techniques used most frequently in neuropsychiatric populations: seed-based connectivity and independent component analysis (ICA). The first of the rsFC methods is seed-based connectivity, where the average BOLD time course within a seed region of interest (ROI) (e.g., posterior cingulate cortex) is correlated with the time courses of all other voxels in the brain (e.g., Biswal et al., 1995). One main advantage of seed-based connectivity is ease of interpretation, while a major disadvantage is the potential bias in a priori selection of seed ROIs.

In contrast to seed-based analyses, ICA is a data-driven approach that does not require a priori selection of seed ROIs. In ICA, multivariate statistics are used to isolate maximally independent spatial components, which correspond to individual resting-state networks, such as the default mode network (DMN) (Calhoun, Liu, & Adali, 2009). Each voxel within a spatial component represents the correlation between the BOLD time course in that voxel and the BOLD time course for that component. To identify the known resting-state networks in ICA, a semiautomated method can be used to calculate the maximum overlap between each spatial component and existing resting-state network masks (e.g., Yeo et al., 2011), an approach implemented in the GIFT toolbox (Calhoun et al., 2009). Besides identifying resting-state networks, ICA can also be useful for isolating independent components associated with nonneuronal signals, such as movement or physiological noise (Power et al., 2014). Other rsFC methods, including graph-theoretical and hierarchical clustering algorithms, are reviewed elsewhere (Power et al., 2014).

Compared with task-based fMRI, rs-fMRI has two main advantages in examining large-scale network functioning in neuropsychiatric populations. First, rs-fMRI scans can be acquired relatively quickly, which reduces the total scan duration. Second, rs-fMRI does not require that participants perform a task, which may be ideal for patient populations with cognitive impairments, such as individuals with Alzheimer's disease (Greicius, 2008). In the following sections, we provide a targeted review of rs-fMRI findings in neuropsychiatric conditions including major depression, posttraumatic stress disorder (PTSD), and traumatic brain injury.

rs-fMRI in Neuropsychiatric Conditions

Neuropsychiatric conditions are increasingly being understood as disorders of neural circuits (Menon, 2011; Williams, 2017). A growing body of neuroimaging research has identified rsFC alterations in distinct cortical (e.g., DMN; frontoparietal/central executive network [CEN]; cingulo-opercular/salience network [SN]) and subcortical or limbic (e.g., affective network [AN]) networks across different psychiatric and neurological disorders (Greicius, 2008; Lanius, Frewen, Tursich, Jetly, & McKinnon, 2015; Menon, 2011; Williams, 2017). Briefly, to describe these networks, the DMN consists of the medial prefrontal (mPFC), posterior cingulate/retrosplenial (PCC), and inferior parietal cortices and is associated with an internal focus of attention to self-related thoughts including mind wandering, autobiographical memory, and self-reflection (Buckner, Andrews-Hanna, & Schacter, 2008 for review). The CEN consists of the dorsolateral prefrontal (dlPFC) and lateral superior parietal cortices and is associated with externally directed attention (Corbetta & Shulman, 2002; Fox et al., 2005; Seeley et al., 2007) and may function to initiate top-down attentional control during cognitive tasks (Corbetta & Shulman, 2002). The SN, consisting of anterior insula/frontal operculum, dorsal anterior cingulate/medial prefrontal cortex, and amygdala, is implicated in detecting and integrating salient external stimuli and internal states (Seeley et al., 2007). Thus, alterations in these cortical networks may underlie specific cognitive, affective, and self-reflective symptoms in neurological and psychiatric disorders (Lanius et al., 2015; Menon, 2011; Williams, 2017). Therefore, in our review of rsFC in neuropsychiatric conditions, we focus on changes to the DMN, CEN, and SN, with some mention of subcortical and/or limbic networks.

Major Depressive Disorder

Major depressive disorder (MDD) is one of the most prevalent psychiatric disorders and is associated with a variety of affective and cognitive symptoms, such as dysphoria, anhedonia, and rumination. Neuroscientific research has associated MDD with abnormalities in several subcortical, limbic, and cortical brain regions (Drevets, Price, & Furey, 2008; Mayberg, 2003), with a growing recognition that dysfunction in large-scale neural networks likely plays a critical role in the pathophysiology of the disorder (Drevets et al., 2008; Mayberg, 2003). Using rs-fMRI, considerable progress has been made in identifying network dysfunction in MDD, including in the DMN, CEN, and SN.

Patients with MDD consistently exhibit enhanced rsFC within mPFC regions of the DMN (i.e., ventromedial prefrontal cortex, dorsomedial prefrontal cortex, pregenual ACC) for both seed-based and ICA methods (Mulders, van Eijndhoven, Schene, Beckmann, & Tendolkar, 2015 for review). A recent meta-analysis of 27 seed-based rsFC studies in MDD also provided confirmatory evidence for DMN hyperconnectivity in this population, specifically in the medial prefrontal cortex and the right hippocampus extending into middle temporal gyrus (Kaiser, Andrews-Hanna, Wager, & Pizzagalli, 2015). Research suggests that heightened rsFC within the DMN in MDD may be associated with increased negative self-related thought, such as the rumination typical to MDD (Philippi & Koenigs, 2014 for review).

In MDD, seed-based rsFC analyses using dlPFC seeds of the CEN have consistently shown diminished connectivity with posterior parietal regions of the CEN (Kaiser et al., 2015; Mulders et al., 2015). Kaiser et al. (2015) propose that hypoconnectivity within frontoparietal CEN regions may contribute to cognitive and emotional symptoms in MDD, such as impaired attention and emotion regulation. However, further research is warranted, as ICA studies are inconsistent in this regard (Mulders et al., 2015). In MDD, findings for the SN have been mixed, with evidence for both increased and decreased connectivity of the SN (Kaiser et al., 2015; Mulders et al., 2015). For the AN, MDD patients often exhibit hypoconnectivity, including decreased rsFC between the sgACC and nucleus accumbens of the AN (Kaiser et al., 2015).

Besides within network alterations in rsFC, MDD patients frequently exhibit enhanced connectivity between the DMN and CEN, due to either reduced negative correlations or enhanced positive correlations between these networks in MDD (Kaiser et al., 2015). The DMN and CEN are typically negatively correlated at rest (Fox et al., 2005). Thus, one possible interpretation of these findings in MDD is that regions of CEN are over-recruited to accommodate the elevated focus on self-related thoughts occurring in this condition. In support of this hypothesis, regions within the DMN and CEN are both active during periods of mind wandering (Fox, Spreng, Ellamil, Andrews-Hanna, & Christoff, 2015). Interestingly, neuromodulatory treatments for MDD, including transcranial magnetic stimulation, target stimulation of the dlPFC within the CEN and may exert their therapeutic effects in part by normalizing network interactions between the CEN and DMN (Fox, Buckner, White, Greicius, & Pascual-Leone, 2012). In sum, using a variety of rsFC and meta-analytic methods, research is beginning to identify common dysfunction within and between large-scale neural circuits throughout the brain in MDD. Comparatively fewer rsFC studies have been conducted in PTSD, which is addressed in the next section.

Posttraumatic Stress Disorder

PTSD is a psychiatric condition that may develop after exposure to a traumatic event and is associated with clusters of cognitive and affective symptoms including reexperiencing, hyperarousal, avoidance of trauma-related stimuli, and both negative cognitions and mood

(American Psychiatric Association, 2013). Using rs-fMRI, researchers are beginning to characterize large-scale network dysfunction for cortical, subcortical, and limbic networks in PTSD (Lanius et al., 2015), with primarily case–control analyses (e.g., PTSD versus trauma-exposed groups) and some dimensional analyses (e.g., PTSD symptom severity).

Individuals with PTSD consistently exhibit diminished rsFC within the DMN (e.g., Bluhm et al., 2009; Shang et al., 2014; Sripada et al., 2012), which may be related in part to dissociative symptoms of PTSD (Tursich et al., 2015). By contrast, using a dimensional approach, PTSD severity was associated with greater rsFC within the DMN (Lanius et al., 2010). While seemingly inconsistent, these findings may be at least partially explained by differences in characteristics of the control group (e.g., trauma exposed versus non-trauma exposed). Nevertheless, DMN connectivity may be a particularly robust biomarker of PTSD. A preliminary study, for example, found that rsFC within the DMN 2 days after a motor vehicle accident predicted the onset of PTSD (Qin et al., 2012). Compared with the DMN, few rs-fMRI studies to date have focused on the frontoparietal CEN in PTSD, with one study reporting decreased rsFC within the CEN in PTSD using ICA (Shang et al., 2014). The SN has been associated with both elevated and diminished rsFC in PTSD, primarily for insula and amygdala regions of the SN (Lanius et al., 2015 for review). Based on the findings of elevated SN, Sripada et al. (2012) proposed that the hyperarousal symptoms of PTSD may be specifically related to enhanced rsFC of the SN and more generally may reflect increased attention to salient external/internal stimuli in PTSD. Conversely, a study using ICA to calculate rsFC found that increased hyperarousal was associated with reduced rsFC with the posterior insula of the SN in individuals with PTSD related to childhood trauma (Tursich et al., 2015). Thus, further research is necessary to determine the precise relationship between hyperarousal symptoms and SN rsFC in PTSD.

Besides aberrant within network rsFC, there is also evidence for disrupted interactions between networks, in particular the SN and DMN (e.g., Sripada et al., 2012). In the context of altered SN rsFC in PTSD, abnormal coupling between the SN and DMN may also interfere with the ability to flexibly shift away from external or salient stimuli (Sripada et al., 2012). To test this hypothesis, future research could examine dynamic rsFC using a time window analysis to determine the relative dominance of SN and DMN in PTSD.

A summary of the rsFC findings to date in PTSD suggests that there is evidence for alterations within and between the DMN, CEN, and SN. Given that there are inconsistencies in the direction of the changes in rsFC in PTSD (i.e., increased or decreased), future meta-analyses of rs-fMRI studies for seed-based and ICA methods in PTSD will be required to determine whether specific participant variables contribute to rsFC results in PTSD. Additionally, a dimensional approach may be used to examine whether individual differences in symptom clusters in PTSD, such as hyperarousal or reexperiencing, are associated with overlapping and/or distinct rsFC network variations. Nevertheless, this research suggests that rsFC may represent a viable biomarker that could be used to predict diagnosis of PTSD and to develop targeted treatments, a topic we will consider further in our concluding sections.

Mild Traumatic Brain Injury

Mild traumatic brain injury (mTBI) is often associated with a variety of somatic, cognitive, and emotional symptoms, such as headaches and fatigue, attention and memory impairments, and changes in mood (e.g., symptoms of depression; Levin & Diaz-Arrastia, 2015). Research examining network dysfunction in mTBI has been steadily increasing in recent years using various rsFC approaches, with studies predominantly concentrating on the DMN. Several studies have reported decreased rsFC within the DMN in subacute/acute mTBI, for both mPFC and PCC DMN regions, using seed-based or ICA analyses (Johnson et al., 2012;

Mayer, Mannell, Ling, Gasparovic, & Yeo, 2011; Palacios et al., 2017; Stevens et al., 2012). Increased rsFC within the DMN has also been found in mTBI, though usually when individuals are in the chronic phase of recovery (>6 months' post-injury) (e.g., Palacios et al., 2013; Sharp et al., 2011). Given that reduced DMN connectivity has been reported more frequently for subacute/acute mTBI, it is possible that time since injury could impact rsFC in the DMN. Another potential explanation of differential rsFC of the DMN across studies in mTBI could be due to individual differences in depression symptoms, as depression severity has been consistently associated with increased rsFC within the DMN (Kaiser et al., 2015). However, additional research will be crucial to understand what subject-specific factors, including chronicity and depression, may contribute to rsFC of the DMN after mTBI.

In comparison to the DMN, results for rsFC within the CEN and SN in mTBI have been more inconsistent, with reports of both increased and decreased rsFC in mTBI for both seed-based and ICA methods (Palacios et al., 2017; Shumskaya, Andriessen, Norris, & Vos, 2012; Slobounov et al., 2011; Stevens et al., 2012). While fewer studies have focused on subcortical or limbic connectivity in mTBI, there is some evidence for altered rsFC within hippocampal, striatal, and amygdala networks in mTBI (Shumskaya et al., 2012; Slobounov et al., 2011; Stevens et al., 2012). Analogous to altered between-network rsFC in MDD, studies have consistently demonstrated enhanced rsFC between DMN regions and the lateral prefrontal cortex of the CEN in mTBI (e.g., Johnson et al., 2012; Mayer et al., 2011; Sharp et al., 2011).

Despite some contradictory findings, research to date has identified rsFC alterations across multiple cortical and subcortical/limbic networks in mTBI. Researchers have further proposed that such complex alterations in rsFC in mTBI, in particular for the DMN and SN, may predict specific cognitive and affective symptom profiles in individuals with mTBI (Sharp, Scott, & Leech, 2014). Nevertheless, further research is warranted to understand the relationship between mTBI and large-scale neural network connectivity as it relates to specific physical, cognitive, and emotional symptoms and stages of recovery after brain injury.

Together, the reviewed findings across MDD, PTSD, and mTBI underscore the potential for rsFC analysis of large-scale neural networks to be used as a novel tool for diagnosis, individually targeted treatment plans, and a clinical outcome measure following treatment; these topics will be discussed in the next section.

rsFC as an Outcome Measure for Clinical Studies

Clinical neuroscientific research is increasingly using rsFC as an outcome measure to determine the treatment efficacy of psychotherapeutic, pharmacological, and brain stimulation treatments for neuropsychiatric conditions, with particular emphasis on MDD. Review of rs-fMRI studies in MDD suggests that response to treatment regardless of the type, including brain stimulation methods, may restore aberrant rsFC, in particular within DMN and cortical/limbic networks (Gudayol-Ferré, Peró-Cebollero, González-Garrido, & Guàrdia-Olmos, 2015). Fewer studies have measured changes in rsFC after treatment in PTSD, but preliminary work indicates that effective treatment response, such as for alpha neurofeedback, may also normalize rsFC in PTSD, especially within the DMN and SN (Lanius et al., 2015). In PTSD, normalization of the DMN and SN may be associated with specific changes in self-related processes and hyperarousal, respectively. However, future research will be needed to determine the specific relationships between network modulation after treatment and symptom clusters in individuals with PTSD (Lanius et al., 2015). To our knowledge, few studies have investigated changes in rsFC after treatment for mTBI. Further research in mTBI is warranted as preliminary studies suggest that behavioral and brain stimulation interventions in mTBI improve cognitive symptoms, which would likely modulate large-scale rsFC networks involved in attention and cognitive control, such as the CEN (Barbey et al., 2015).

Challenges and Limitations

While the findings from clinical treatment studies are promising, there are several challenges and limitations to consider in rsFC clinical outcome research for neuropsychiatric conditions. First, it can be difficult to interpret the functional significance of hyper- and hypoconnectivity in rs-fMRI, either within a single network or without reference to other clinical or behavioral measures. Potential solutions to these problems would include characterizing rsFC within and between multiple networks in one study, combining rs-fMRI with task-based fMRI or other imaging modalities (e.g., diffusion tensor imaging), and collecting relevant clinical and behavioral measures. Second, concerns have been raised about individual variability in rsFC, which may lessen the reliability of rsFC measures used to predict clinical outcomes (Finn & Constable, 2016). Though, it seems that this may not be an issue, as recent studies have shown that whole-brain rsFC can accurately discriminate among healthy individuals (Finn & Constable, 2016). Neuroimaging researchers are also working to increase the reliability and validity of rsFC through multicenter projects and large data sharing initiatives, which will further facilitate the use of rsFC metrics as biomarkers at the single-subject level for neuropsychiatric conditions (Finn & Constable, 2016). Thus, despite these current limitations and challenges, progress is being made in identifying rsFC biomarkers to improve personalized treatment and prevention of neuropsychiatric conditions.

Future Directions

Below we highlight key areas of future rsFC research and their potential impact on clinical practice:

- Mapping specific profiles of cognitive, affective, and somatic symptoms onto specific neural circuit dysfunction across different neuropsychiatric conditions. This dimensional approach could help clinicians develop targeted treatments to restore network dysfunction (Lanius et al., 2015; Williams, 2017).
- Applying machine learning algorithms to rsFC data gathered from populations at risk for developing neuropsychiatric conditions, such as schizophrenia or anxiety. This may lead to insights that help predict the onset of a neuropsychiatric condition and/or demarcate the transition from subclinical to clinical symptomatology (Finn & Constable, 2016).
- Developing novel methodological approaches of rs-fMRI to further characterize alterations in rsFC in neuropsychiatric conditions, such as dynamic rsFC (i.e., moment-to-moment variations in rsFC). This may help further differentiate between disorders by enhancing knowledge of large-scale network dysfunction on a shorter time scale, such as when individuals switch between networks.

Author Biographies

Carissa L. Philippi is an assistant professor in the Department of Psychological Sciences at the University of Missouri–St. Louis (UMSL). Her research takes a dimensional approach to understanding the behavioral (e.g., negative self-related thought) and neural correlates of neuropsychiatric conditions, such as depression. For example, in a recent study, she identified associations between subclinical depression severity and resting-state functional connectivity of the anterior cingulate cortex that mirrored neural circuit dysfunction in major depression.

Tasheia Floyd is a second year doctoral student in the Behavioral Neuroscience Program at the UMSL. She graduated from UMSL with her Bachelor of Arts in Psychology in May 2015. Her research interests include examining the neurobiological, behavioral, and emotional consequences of spontaneous imagery and thought (e.g., mind wandering) in healthy and clinical adult and pediatric populations.

Gregory Dahl is a graduate research assistant in the Behavioral Neuroscience Program at UMSL. He completed his undergraduate work in psychology and philosophy in May of 2015 and began working with client data/statistics for a not-for-profit mental health clinic. Upon entry to graduate school, he began working with Professor Philippi on the cognitive and affective neurobiology of self. His research interests include the neurobiology of memory and the cognitive/behavioral/environmental factors that can affect memory.

The electroencephalogram (EEG) is a noninvasive and relatively inexpensive technique that records differences in electrical potential from scalp electrodes. The resulting waveform represents time (*x*-axis) and potential amplitude changes (*y*-axis). Event-related potentials (ERPs) record voltage fluctuations in the ongoing EEG in response to time-locked stimuli that can be associated with particular cognitive operations. ERPs are sensitive to small voltage changes with precise temporal resolution, making it one of the most widely used methods for studying behavior and cognition.

Clinically, ERPs have been used to examine a variety of disorders. ERP is widely used to test the integrity of both visual and auditory systems. Abnormalities in visual and somatosensory ERPs have been observed in multiple sclerosis, showing promise in detecting degeneration more subtle than MRI can detect (Giesser et al., 1987). ERP markers of Alzheimer's disease are observable during the early stages of disease progression (Polich, 2003). As discussed below, ERP abnormalities have been shown in diverse neurological conditions, and many attempts have been made to relate electrophysiological responses to behavioral disorders. In subsequent sections, this chapter will describe ERP data collection and analysis, associations between ERP components and cognitive processes, and applications in clinical research.

ERP Data Collection and Analysis

Acquisition of the EEG Waveform

In order to record electrical changes on the scalp surface, highly conductive silver chloride electrodes are applied. Voltage changes reflect postsynaptic potentials, and thus, ERPs indirectly measure neurotransmission of large populations of neurons, called "neurogenerators," that are oriented in the same direction on the order of milliseconds. Roughly 6–10 neurogenerators are simultaneously active at any given time point (Luck, 2005). Waveforms from a given electrode are not exclusive to the cortical area directly below the electrode, rather the weighted sum of all the cortical activity beneath the electrode. Spatial resolution is affected by the number of electrodes in the electrode array, which typically range from 16 to 250 units, such that the greater the array, the easier it is to identify underlying neurogenerators. However, spatial resolution is relatively poor compared with the technique's outstanding temporal resolution. ERP waveforms can reveal temporal dynamics of specific cognitive behaviors with detailed precision and without requiring participants to provide a motor or verbal response (Key, Dove, & Maguire, 2005).

Post-acquisition Data Processing

The result of data acquisition is a trace of voltage changes over time at each electrode site. In order to perform analyses, these data must be processed. In most experimental paradigms, amplitudes and latencies are averaged over several trials within a subject. Averaging across multiple time windows, called "epochs," reveals ERPs that would not otherwise be visible on single trials due to trial-to-trial variability and individual differences. Grand averages combining waveforms of a group are reported in most studies. Each subject contributes to statistical differences between groups/conditions. While this simplifies data processing, it also can discount significant variability among subjects and introduce distortions. Latency jitter, differences in cognitive strategies, and differences in cortical folding patterns resulting in opposite polarity for a particular component could arise. Therefore, grand averages are most useful when the sample size of each group is large enough to withstand individual differences without losing the effect of the cognitive operation under investigation. In addition to waveforms, topographic maps plot data at selected time periods from ERP sets to represent areas of relative cortical negative/positive polarity.

Components

ERP components are segments of the waveform, typically associated with particular cognitive operations, which are defined by (a) latency (time point at which they occur in response to the stimuli), (b) polarity (all components are dipoles with positive and negative peaks at some place in the head), (c) scalp location (components can be grouped into "families" but are standalone components of distinct functions that occur at the same time and general location), and (d) amplitude (the strength of the amplitude typically reflects the sensitivity to experimental conditions and indicate the brain has reacted to a stimulus) (Luck, 2005). For example, the N400 component is a negative (N) peak in a waveform occurring around 400 ms post-stimulus presentation and reflects cognitive operations of word finding.

Components are not simply peaks in the waveforms as their names suggest, nor do they always occur at the same time or polarity. Waveforms reflect the sum of negative and positive amplitudes. Consequently, polarities can appear greater or smaller, and latencies appear longer or shorter in the waveform. Therefore, the duration and amplitude of peaks in a waveform may differ from the duration and amplitude of the components themselves, which could lead to erroneous conclusions about what caused the observed waveform effects (Luck, 2005).

Associations Between ERP Components and Cognitive Processes

ERPs have been extensively used to investigate the neural underpinnings of a variety of cognitive processes. The timing of responses is thought to provide insight into the neural communication and information processing being done. Different cognitive domains tend to focus on different ERP components.

Attention

In order to encode and respond to a sensory stimulus, the brain must first attend to it. Depending on the sensory domain of the stimulus, various attentional mechanisms are elicited at varying latencies post-stimulus onset. ERPs are robust measures for revealing the temporal order of attentional processes because ERP components occur at characteristic times throughout the waveform. By correlating components to cognitive operations of attentional processes, researchers can construct more accurate descriptions of sensory perception.

While visual attention processes generally occur between 80 and 600 ms after stimulus onset, auditory attention processes typically occur even earlier, with latencies of 50–400 ms (Key et al., 2005). Most studies suggest that the visual system first orients to the spatial location of the stimulus, beginning around 80 ms after onset (Hillyard & Anllo-Vento, 1998). In the auditory system, the P1 component (P for *positive* and 1 *for first peak in the waveform*) peaks with a latency of around 50 ms, as the brain actively suppresses irrelevant auditory signals (Key et al., 2005). In both sensory domains, modulations of the P1 and N1 components amplify the sensory signal and reduce the noise of irrelevant stimuli, making the attended stimulus more salient (Lange, 2012). Nonspatial features of visual stimuli (e.g., color, motion, shape) are processed within 100–150 ms, whereas auditory features are processed around 200 ms after onset (Key et al., 2005). Around 150–300 ms, the visual features are integrated, allowing for object recognition. P2 and N2 amplitudes correspond to attention to task-relevant stimuli and inhibition of task-irrelevant stimuli (Chernyshev, Lazarev, Byzgalov, & Novikov, 2015). With a latency of about 300 ms, the P3a component indicates a reorienting of attentional resources as distracting stimuli vie for attention (Horváth, 2014). The P3b amplitude, also occurring approximately 300 ms after stimulus onset, indicates how visual features are encoded into working memory as a meaningful whole (Acqua et al., 2015).

Memory

ERP techniques can be useful to distinguish memory subtypes such as short-term, working, and long-term memory. ERP is also used to investigate emotional memory and false memories. The P300 component is the most commonly studied memory component and is believed to reflect context integration for working memory. ERPs are also sensitive to differences in recognition memory tasks (Rugg & Curan, 2007).

Language

Language integrates a myriad of cognitions including hallmark components of communication—expression (speech and writing), reception (reading and auditory comprehension), and social feedback—as well as attention, memory, and executive function. ERP can capture fine distinctions between these domains and provide key insights into the detailed interaction of these processes. Specifically, ERP has been used extensively to study semantics (word meaning), syntax (word order and grammatical rules), and phonology (speech sounds and the rules that govern sound combinations in a language).

One of the first successful applications of ERP to measure language processing occurred almost four decades ago when Kutas and Hillyard (1980) discovered the N400 component. The N400 is associated with accessing word meaning and is sensitive to semantic violations and incongruences. As words in sentences are encoded, semantic expectations are developed through top-down processing of contextual information. This results in increased ease of lexical access and decreased N400 amplitudes as words fit into plausible sentences. However, when words in a sentence violate the expectation, large N400 amplitudes are observed. The amplitude of the N400 can be modulated by manipulating the plausibility of the sentence stimuli. For example, the sentence “Joe washed dishes with soap and *sugar*” contains a sentence final word (sugar) that violates the expectation (water) and disrupts the meaning of the overall sentence. Differences in N400 latencies and amplitudes have been used for detecting reading and language impairments due to poor semantic processing (Kutas & Hillyard, 1980).

Similar to semantic violations, syntactic violations elicit changes in ERP components. In contrast to the N400 elicited for semantic violations, an asyntactic sentence like “The husband is startled by the emotional rather response of his wife” elicits positive peak around 500 ms after the word “rather” is presented.

Phonetic distinctions for speech can be slight and difficult to distinguish from other auditory processes. Using the ERP technique, researchers are able to detect processing changes through phonological manipulations in order to identify breakdowns in speech/reading comprehension and processing speed.

Applications in Clinical Research

Psychiatric Disorders

ERPs are a powerful tool for discerning breakdowns in neural processes associated with psychiatric dysfunction. Researchers have studied disturbances in the N1, N2, P2, P3, and N400 components in order to characterize deficits associated with schizophrenia. Researchers have also made progress in correctly diagnosing schizophrenia by using ERP data. In one study, machine learning algorithms were able to diagnose schizophrenia with an accuracy of 72.4% using only the N1 and P3 components (Neuhaus, Popescu, Bates, Goldberg, & Malhotra, 2012).

Several studies report reduced amplitudes and increased latencies for a range of ERP components in patients with bipolar disorder (BD) (Andersson, Barder, Hellvin, Løvdahl, & Malt, 2008). For example, patients with bipolar II disorder (BDII) were found to have reduced frontal mismatch negativity (MMN) amplitudes and longer MMN latencies when performing an auditory oddball task, suggesting that patients with BDII have deficits in change detection or pre-attentive stimulus discrimination (Andersson et al., 2008).

Patients with major depressive disorder (MDD) typically exhibit reduced ERP amplitudes for a variety of cognitive tasks, mirroring the decreased interest in activities and fatigue that are common in MDD. However, patients with MDD exhibit increased ERP amplitudes when they engage in negative behaviors. For example, when asked if a list of positive and negative words applied to them, individuals with MDD had increased P1 amplitudes for negative words (Auerbach, Stanton, Proudfit, & Pizzagalli, 2015).

ERPs have been used to characterize a range of anxiety disorders, including generalized anxiety disorder, panic disorder (PD), obsessive–compulsive disorder (OCD), and posttraumatic stress disorder. Patients with OCD exhibit increased P3 amplitudes for novel auditory stimuli, consistent with attentional biases toward potentially threatening stimuli (Ischebeck, Endrass, Simon, & Kathmann, 2011). By understanding the electrophysiological underpinnings of psychiatric disorders, researchers can better characterize the disorders that could lead to the development of superior diagnostic and treatment practices.

Future Directions

ERP methods remain a strong tool for assessing brain function. Due to stability and reproducibility, ERPs are useful in assessing neuroplastic and functional changes that occur in normal course of recovery from neurological insults following stroke or traumatic brain injury. Additionally, ERPs could be a tool for monitoring changes induced by behavioral or pharmacological treatments (Polich, 2003). Despite the popularity of neuroimaging techniques, integrating temporal precision of electrophysiological measures with spatial localization of hemodynamic methods such as fMRI allows further specification of the brain processes.

ERPs are utilized for brain–computer interface systems (BCIs), which translate electrical signals in the brain to an output device (e.g., button press, keyboard, robotic arm) for communication and controlled movement. These devices are in high demand for patients with severe motor neuron disease, paralysis, and locked-in syndrome. P300-based BCIs are among the most common BCI systems and have been used for individuals with severe physical disabilities due to amyotrophic lateral sclerosis (McCane et al., 2015). Another type of BCI uses the N200 component to select letters and spell out messages. This type of technology could present limitless possibilities for individuals with severe communication and motor deficits.

Introduction

Research in neuroscience has slowly been trying to bridge the gap between understanding the disease processes. Many of the concepts in cognitive psychology and psychiatry are being rewritten as development and application of new technologies further our understanding of the brain processes. A particularly productive field of research has involved medical imaging that utilizes techniques such as proton magnetic resonance spectroscopy (^{1}H MRS), a non-invasive neurochemical assay that can directly measure neuronal activity, biochemical systems, and metabolic processes utilized by neurons. In this section, each brain chemical that can be directly quantified using ^{1}H MRS method is covered as well as examples of their roles in psychiatric diseases.

Physics of MRS

^{1}H MRS is a method typically employed by the organic chemist to define chemical structures; MRS can be applied to the human body, or more specifically to the human brain, providing quantitative and noninvasive studies of brain biochemistry. The physics behind the technique is similar to that utilized by the nuclear magnetic resonance (NMR): briefly, for a head scan, the patient slides inside the radiofrequency (RF) volume head coil that situates inside the bore of the magnet where there is a homogeneous static magnetic field such that free nuclei are oriented parallel and antiparallel to the magnetic field, according to their spin state. The nuclei are then excited by electromagnetic radiation in the form of a pulse sequence via a transmitter.

The nuclei absorb the energy, altering the nuclear spin. As the nuclei precess or 'relax' back to their original state, energy is released and detected by the receiver in the RF coil as a free induction decay, which is promptly fast Fourier transformed into the resulting spectra.

Each chemical resonates at established frequencies that upon Fourier transform results in peaks at specific locations, or chemical shifts, along the *x*-axis. The chemical shift of each chemical is governed by the structure of the chemical, in particular, the grouping of the hydrogen atoms as single or multiple peaks (singlets and multiplets) and proximity to other hydrogen-containing groups (*j*-coupling). These chemical shifts are often expressed as "parts per million," which can be confusing as it does not relate to the concentration of the chemical, but historically has been used to express the frequency. The use of this nomenclature is so that it is independent of the field strength of the magnet used. The concentration of the metabolite is expressed along the *y*-axis as the height of the peak such that higher concentrations result in higher peaks and vice versa. Quantitation of these peak heights can provide an objective measure of brain biochemistry that is similar to a blood test or lab analysis, which can then be used for diagnosis or disease characterization. More importantly, however, the role of each of the chemicals is tied to metabolic and physiological processes within the brain that directly relate to brain processes. The remainder of this chapter will be devoted to the major metabolites that are detected by MRS, along with their findings in psychiatric diseases.

MRS Methods

There are several data acquisition methods available for human application and can be found in several review articles (Alger, 2010). Single-voxel double spin echo MRS (SV PRESS MRS) is by far the method of choice for most human study due to the flexibility of placing the voxel of interest (VOI) anywhere in the brain where there is reasonable magnet homogeneity (Soher, Hurd, Sailasuta, & Barker, 1996). As a simple rule, short echo time of 30–35 ms is commonly used where brain metabolites with short and long T2 relaxation times are observed and can be used for initial disease diagnosis. With a minor modification of the standard PRESS MRS (Bottomley, 1987), there are TE-averaged SV MRS (Hurd et al., 2004), two-dimensional (2D) MRS (Thomas, Binesh, Yue, & DeBruhl, 2001), GluCEST (Cai et al., 2012), and MEGA-PRESS (Mescher, Merkle, Kirsch, Garwood, & Gruetter, 1998). Each of these methods offers MRS detection of metabolites that have low concentrations and strongly overlapped with the metabolites with higher concentrations such as gamma-aminobutyric acid (GABA) and glutathione (GSH). Long echo time(>130 ms) multivoxel approach (MRSI) offers an ability to acquire MRS data from multiple voxels at the same time but suffers numerous drawbacks (Tran et al., 2000) such as the inability to detect short T2 relaxation times such as myoinositol, glutamate, and glutathione.

MRS and Brain Chemical

N-Acetylaspartate

N-acetylaspartate (NAA) is an amino axcid derivative considered a putative "marker" of viable neurons, axons, and dendrites. Studies demonstrated that NAA was distributed throughout the neuron and axon and its concentration correlated with the number of neurons measured (Urenjak, Williams, Gadian, & Noble, 1992). The ability to quantifiably measure neuron populations allows MRS to provide a diagnostic tool that no other radiological technique can match: an ability to literally "count" the number of active brain cells using a completely noninvasive and quantitative technique by simply measuring the peak height or area of the NAA resonance in the MRS spectra. This can be utilized in practical ways. For example, every metabolite has a "normal" concentration that generates a pattern of peaks that is the same from person to person unless there is an underlying pathology. Diagnosis with MRS can, therefore, be made by either comparing the numeric values of metabolite concentrations or by recognizing abnormal patterns of peaks in the spectra. With either method, it is the increase or decrease in the concentrations of the metabolites that are diagnostic for neurodegenerative pathology as has been shown across a broad variety of diseases. However, it should also be noted that NAA is a cerebral metabolite that participates in some metabolic processes, and therefore the interpretation of NAA as solely a neuronal marker is somewhat of an oversimplification.

NAA in schizophrenia

A recent meta-review of spectroscopy papers in schizophrenia revealed 103 papers alone that focused on MRS that included a total of 2,067 subjects and 2,115 controls, of which the great majority of the studies focused on treated chronically ill patients (Kraguljac et al., 2012). All papers utilized either the single-voxel (SV) or multivoxel (MRSI) methods. Decreased levels of NAA were found all across the brain including structures such as the hippocampus, thalamus, and frontal and temporal lobes. While the temporal lobes showed the greatest decreases in NAA, the variability of measurements in the temporal lobe was also greater than any other area of the brain. The reason for this variability is due to the susceptibility artifacts that occur due to the air and bone tissue interfaces within this brain region that result in distortions and signal loss. The basal ganglia and frontal lobe showed the most consistent decreases in NAA. While whole-brain NAA measures have not been applied to schizophrenia, these global changes in NAA throughout the schizophrenic brain would indicate that this method would be sensitive to these changes.

NAA in dementia

Given the relationship between NAA and neuronal viability, NAA is a key biomarker for dementia. Dozens of papers have shown decreases in NAA in both cortical and white matter regions of the brain including the posterior cingulate gyrus, temporal lobe, and the occipital lobe (Graff-Radford & Kantarci, 2013). In combination with myoinositol (mI), a putative glial marker, NAA provides up to 90% sensitivity and 95% specificity for distinguishing Alzheimer's disease (AD) from healthy subjects. In a recent study, the ratio of NAA/mI predicted progression to mild cognitive impairment (MCI) or dementia in 214 subjects, which supports previous findings of reduced NAA in MCI patients. Furthermore, MRS is valuable in differentiating between different types of dementia such as Lewy body, frontal lobe, and vascular dementia. While the temporal lobe is often thought to be the ideal location for detecting AD, it is the posterior cingulate gyrus that has been shown to be the most sensitive to AD. While there may be a neuropathological role for the posterior cingulate cortex in AD, as has been shown in PET studies, this region of the brain is also one of the most homogeneous parts of the brain that results in spectra of superior technical quality, which would also contribute to the diagnostic sensitivity of MRS to AD and other dementias.

NAA in depression/bipolar disorder

Changes in NAA in bipolar disorder (BD) and major depression have also been studied extensively (Capizzano, Jorge, Acion, & Robinson, 2007). Several studies have shown reductions in

NAA/Cr in the temporal lobes as a result of BD. Some studies have also shown reductions in NAA/Cr in the frontal lobe in patients suffering from major depression; however there are also studies that were not able to replicate these results. This may be due to the fact that a majority of the studies used a ratio to Cr despite the fact that some studies have shown that Cr is altered as a result of major depression.

NAA in HIV

^{1}H MRS has been able to characterize the chemical pathology of HIV-related brain change at various disease stages. Changes in NAA have been found in HIV-positive individuals with numerous HIV-related brain pathologies (Chang et al., 2004). These studies indicate that NAA levels are reduced in both neurologically asymptomatic and impaired HIV-positive patients. This change is likely to be related to neuronal loss and neurocognitive dysfunction. However, NAA is unchanged in acute HIV infection when MRS examinations were performed approximately 14 days after initial infection with elevated choline to creatine ratio (Cho/Cr) (Sailasuta et al., 2012) implicating cellular inflammation in the absence of measurable neuronal injury.

Glutamate and Glutamine

Glutamate (Glu) is an amino acid with several important roles in the brain. First, it is the most abundant excitatory neurotransmitter in the human brain; it plays a major role in neurotransmission where it is released from presynaptic cells and then binds to postsynaptic receptors, thus inducing activation. As a result, Glu has many impacts on neurological and psychiatric diseases. In particular, dysfunction reflected in excessive glutamate Glu release or reduced uptake can lead to an accumulation of Glu, which results in excitotoxicity. This second mechanism not only is key to understanding the underlying pathophysiology of different brain disorders but also provides a potential pathway for disease treatment as there now exist numerous glutamate Glu agonist and antagonist pharmaceutical interventions that can be used to modulate glutamate Glu levels and thus provide potential treatments. Finally, Glu is a key compound in brain metabolism via the citric acid cycle and therefore also tightly coupled to brain energetics.

Metabolically, glutamate (Glu) is stored as glutamine (Gln) in the glia, and the balanced cycling between these two neurochemicals is essential for normal functioning of brain cells. Glu and Gln are compartmentalized in neurons and glia, respectively, and this chemical interconversion reflects an important aspect of metabolic interaction between these two types of cells. *In vivo* studies have revealed that the neuronal/glial Glu/Gln cycle is highly dynamic in the human brain and is the major pathway of both neuronal Glu repletion and astroglial Gln synthesis. Gln is released from astrocytes, accrued by neurons, and converted to Glu by the neuron-specific enzyme phosphate-activated glutaminase. Gln is the main precursor for neuronal Glu and GABA, but Glu can also be synthesized *de novo* from tricarboxylic acid (TCA) cycle intermediates.

Glutamate in Schizophrenia

It is thought that schizophrenia is related to a dysfunction in *N*-methyl-D-aspartate (NMDA) receptors, the major subtype of Glu receptors. Evidence from studies of NMDA receptor agonists such as phencyclidine and ketamine has shown decreased Glu levels as well as the psychotic symptoms observed in schizophrenia (Javitt & Zukin, 1991). A recent meta-review (Marsman et al., 2013) examined 28 publications for a total of 647 patients with schizophrenia compared with 608 healthy controls appears to support this hypothesis by showing evidence of reduced Glu. While several brain regions were explored including the medial frontal region, hippocampus, and thalamus, only significant differences were found in the medial frontal region with reduced Glu. Group-by-age associations showed that Glu decreased at a faster rate with age in patients with schizophrenia compared with controls. While there have been few longitudinal studies of Glu using MRS, the literature appears to reflect that first-episode schizophrenics show increased glutamate, whereas, in the chronic stage of disease, Glu is decreased. This provides the basis for the second hypothesis of excitotoxicity of Glu in schizophrenia. Proponents argue that initially Glu levels are increased leading to excitotoxicity, which in turn leads to neuronal death as reflected by decreases in NAA. In the chronic stages of the diseases, the neuronal loss would also be reflected in decreases in Glu.

Glutamate in Dementia

Several proton spectroscopy studies have demonstrated decreases in Glu in Alzheimer's dementia using traditional MRS methods (Ross, Bluml, Danielson, & Kanamori, 1997) as well as others such as GluCEST (Cai et al., 2012). Perhaps of greatest interest is that some studies in dementia patients have shown how Glu levels can be reversed using pharmaceutical interventions such as galantamine, a cholinesterase inhibitor, which showed that Glu increased after treatment in AD patients.

The role of Glu in AD has also been explored in detail using ^{13}C MRS. The initial study in AD utilized [1-^{13}C] glucose in patients clinically diagnosed with AD as well as age-matched controls. The results of the study showed reduced Glu neurotransmission as measured by examining the time course of enrichment of Glu via the TCA cycle as well as relative enrichment of Glu to Gln. The time course measurements reflect the neuroenergetics of the brain and effectively measure TCA cycle rates. In AD patients, these rates were found to be reduced. The measure of Glu and Gln enrichment is of particular interest as it is reflective of Glu neurotransmission in itself. For example, if the glial TCA cycle is operating faster, then an enrichment pattern with relatively increased Gln signal versus Glu signal would be expected. In this study, Glu/Gln ratios were found to be significantly decreased, reflective of decreased neurotransmission. More interestingly, when correlated with NAA measures as a surrogate marker for neuronal integrity, significant correlates were found with Glu/Gln ratios, further supporting the argument that this measure may be reflective of Glu neurotransmission in and of itself. As NAA or the number of neurons decreased, Glu/Gln decreased, thus demonstrating that Glu neurotransmission may be decreased as a result in the reduction of the number of functioning brain cells. Sailasuta et al. also found that using [1-^{13}C] acetate infusion that is preferential to glial glutamate metabolism, the third turn of the TCA cycle, which produces bicarbonate, is significantly slower in AD patients when compared with controls (Sailasuta, Harris, Tran, & Ross, 2011).

Glutamate in Anxiety Disorders

Several studies have demonstrated that Glu is increased in the anterior cingulate cortex as a result of general and social anxiety disorder (Pollack, Jensen, Simon, Kaufman, & Renshaw, 2008) when compared with healthy controls. Excess Glu in anxiety is not only found in group differences and correlations with anxiety severity. One study showed that when anxiety is induced using cholecystokinin tetrapeptide, Glu levels in the anterior cingulate markedly increase within 2–10 min of the challenge. Furthermore, when patients with anxiety are treated with medications, such as levetiracetam, Glu levels appear to decrease as a result of the treatment.

Glutamate in Depression

A recent meta-review (Luykx et al., 2012) examined 16 publications of Glu in major depressive disorders (MDD) using MRS for a total of 281 patients and 301 controls. The anterior cingulate cortex and the prefrontal cortex were the two primary brain regions examined by most studies. The result of meta-analysis showed that Glu and a combination of Glu and Gln (Glx) were found to be significantly decreased in the anterior cingulate in MDD subjects. However the literature remains mixed. For example, 2D COSY was used to study levels of metabolites in the dorsolateral prefrontal white matter regions to study MDD in the elderly. The study concluded that the depressed subjects had lower levels of NAA and higher levels of Glu/Gln, mI, and phosphoethanolamine (Binesh, Kumar, Hwang, Mintz, & Thomas, 2004).

Perhaps the strongest evidence of the importance of using MRS to measure Glu in MDD comes from neuropharmacological literature where MRS has been used extensively to measure the effects of medication on brain metabolites. A recent review identified 15 articles where MRS was used to assess MDD treatments, of which six specifically studied Glu and/or Glx. These findings showed several studies where Glx levels were initially decreased in MDD subjects, but after treatments such as electroconvulsive therapy and repetitive transcranial magnetic stimulation, Glx levels increased. These studies give rise to the hypothesis that Glu has a role in neuroplasticity (Sanacora, Treccani, & Popoli, 2012), thus clearly demonstrating that Glx is an important component of MDD and that MRS is an effective means by which one can monitor therapeutic interventions.

Glutamate in Bipolar Disorder

Given the role of Glu in psychosis and depression, there is also a body of literature that has explored the use of MRS in BD. Similar hypotheses of Glu neurotoxicity and neuroplasticity arise in the literature for Glu MRS of BD as discussed in a recent review (Gigante et al., 2012), where 17 studies were identified. In most studies, the frontal lobe was the focus of MRS in regions such as the anterior cingulate cortex and the dorsal lateral prefrontal cortex. The meta-analysis showed elevated levels of Glx in BD. It is particularly interesting that this remained the case regardless of whether the patients were medicated. This is in contrast to MDD studies where Glx levels were decreased and modified by treatment.

Glutamate in HIV

Chronic HIV-infected individuals with dementia had lower levels of Glx and Glx/Cr in the frontal white matter, which was associated with neurocognitive performance. With the development of TE-averaged PRESS, where the strongly overlapped Glu resonance can be directly quantified from other metabolites, elevated Glu was reported in the frontal white region of chronic HIV-infected adults (Sailasuta, Shriner, & Ross, 2009) and in perinatally infected youth but lower in the parietal gray matter of HIV-infected individuals with cognitive deficits (Ernst, Jiang, Nakama, Buchthal, & Chang, 2010).

γ-Aminobutyric Acid

The counterpart to Glu is GABA, the major inhibitory neurotransmitter in the brain. Interestingly, in the developing brain, GABA is initially excitatory and later shifts to its inhibitory role as glutamatergic functions develop. The balance between excitation and inhibition is reflected not only in the roles of these two neurotransmitters but also in their metabolism as Glu is a metabolic precursor of GABA. GABA is of particular interest given the availability of drugs that modulate the binding of GABA receptors, such benzodiazepines, which have helped elucidate the role of GABA across a broad range of psychiatric conditions such as anxiety, memory loss, depression, and pain. Similar to Glu, GABA is difficult to detect using MRS due to its overlap with the resonances of Glu and Gln, therefore requiring specific sequences to measure. Further, the concentration of GABA in the brain ranges from 1.3 to 1.9 mM and therefore is difficult to detect accurately and consistently given its low concentration. A novel metabolite editing method (MEGA-PRESS) has been used successfully to quantify GABA in several brain disorders.

GABA in Schizophrenia

Alterations in GABA neurotransmission underlying the pathophysiology of schizophrenia are evidenced by reduced GABA synthesis as reflected by decreased activity GAD67 in parvalbumin-staining cortical neurons (Gonzalez-Burgos, Hashimoto, & Lewis, 2010). Additionally, $GABA_A$ receptors may be upregulated, possibly reflecting a compensatory response to reduced GABA levels (Jarskog, Miyamoto, & Lieberman, 2007). Due to the relatively recent advances in MRS that have allowed for GABA measurements, MRS studies of GABA in schizophrenia are rapidly evolving. Using MEGA-PRESS, a study of chronic schizophrenics reported GABA to be 10% lower than healthy controls and also shown to correlate with the orientation-specific surround suppression, which is essentially a quantitation of the level of visual inhibition that is though be regulated by GABAergic pathways. A more recent study found a similar reduction of GABA in chronic schizophrenia in the anterior cingulate that also correlated with poor attention performance. In a study in early course schizophrenia, decreased GABA levels in the basal ganglia were also found. In contrast, however, another study found increases in GABA/Cr ratios in chronic schizophrenia. These discrepancies may have results from the use of Cr as studies have shown that Cr is reduced in schizophrenia, thus possibly elevating the ratio if the reduction is greater than the reduction in GABA. It is also clear that there are significant medication effects on the GABA measures as another study in schizophrenia showed that the measured GABA concentration in the anterior cingulate was significantly negatively correlated with the dose of antipsychotics. In this study, exclusion of patients on these compounds abolished the statistically significant effects.

GABA in Anxiety

There have only been a handful of studies that have used MRS for measuring GABA in anxiety. Comparing patients with panic disorder and healthy controls, MRS studies have found that GABA is reduced in the occipital cortex, anterior cingulate cortex, and medial prefrontal cortex (Goddard et al., 2001). Interestingly, upon administration of benzodiazepine, GABA levels in the occipital cortex did not change. Other studies however have not found differences in GABA levels in patients with panic disorder in the dorsal prefrontal or ventrolateral prefrontal regions. Similarly, there were no significant differences in patients with social anxiety disorder (Pollack et al., 2008). It should be noted however that measuring GABA is challenging and can often result in large variability in the measurement, which would result in the lack of significant findings but should not necessarily be interpreted as a lack of change in GABA.

GABA in Depression

A recent review cited 14 papers that utilized MRS to measure GABA levels in MDD where there are general findings of decreased GABA in the occipital cortex, anterior cingulate, and dorsal prefrontal cortex but not in the frontal white matter (Maddock & Buonocore, 2012). Furthermore, the review highlights four studies that examine the effect of treatment on GABA levels and show that treatments of selective serotonin reuptake inhibitors and electroconvulsive therapy both increased levels of GABA in the occipital cortex, although one study of cognitive behavioral therapy did not show increased levels.

GABA in Bipolar Disorder

Two studies have shown that patients with BD exhibit lower GABA in the anterior cingulate, parieto-occipital cortex, and occipital cortex (Brady et al., 2013). A CSI study, however, did not show any significant differences between patients with BD and healthy controls (Kaufman et al., 2009). It is likely that the low SNR of multivoxel MRS approach, as described earlier, resulted in the lack of statistical differences between the two cohorts.

GABA in HIV

Given the complexity of measuring brain GABA using conventional spectroscopy methods due to overlap with other metabolites, there are limited studies that directly measure GABA in HIV-infected individuals. Using a 2D correlated spectroscopy, which can disambiguate the GABA signal, Banakar et al. reported reduced GABA/Cr in chronic HIV-infected children. GABA systems play important roles in HIV infection with several studies documented inhibition of the GABAergic neurotransmission in HIV infection (Feligioni et al., 2003).

Glutathione

The primary role of GSH is as an antioxidant, providing the brain's defense system against damaging reactive oxygen species (ROS) that arise from oxidative stress such as super oxide, nitric oxide, hydrogen peroxide, and free radicals (Dringen, 2000). The damage caused by ROS include DNA modification, lipid peroxidation, and protein modification from which the brain is especially vulnerable due to the large quantity of ROS produced there, availability of lipids, and iron deposition that catalyzes ROS reactions. Oxidative stress is also strongly associated with neuroinflammatory processes (Agostinho, Cunha, & Oliveira, 2010). As a result, compromises in GSH metabolism have been found to play an important role in the pathogenesis across a wide variety of diseases such as neurodegenerative disorders as well as psychiatric disorders.

GSH is synthesized intracellularly by first combining Glu and cysteine to form γ-glutamylcysteine via synthetase enzyme followed by addition of glycine as catalyzed by GSH synthetase. Due to the limited supply of Glu, cysteine, and glycine, in different cell types, GSH is synthesized different between neurons, astrocytes, and glial cells, thus providing an interesting specificity to GSH measures to processes such as neuroinflammation. The thiol group on GSH is a reducing agent in that it can donate an electron to unstable molecules such as ROS. When ROS are present, GSH will reduce ROS by catalysis of glutathione peroxidase (GPx) to form glutathione disulfide (GSSG). GSSG can then regenerate GSH using glutathione reductase. GSSG resonates at a different frequency on the MRS spectrum (Satoh & Yoshioka, 2006), and therefore reductions in GSH concentrations as measured by MRS would provide a putative measure of brain oxidative stress and neuroinflammation. However, it is important to note that defects in GSH metabolism can also reduce concentrations of GSH and disruptions to GSH synthesis or GSH peroxidation can also reflect oxidative stress.

Glutathione in Schizophrenia

A review identified four studies that measure GSH in patients with schizophrenia (Matsuzawa & Hashimoto, 2011). The first study used double quantum coherence (DQC) approach to measure GSH in the medial prefrontal cortex in 14 patients including schizophrenia and schizophreniform disorder and compared them with 14 controls. GSH was found to be significantly lower, which was further confirmed by a decrease in CSF GSH levels. The second study utilized MEGA-PRESS and STEAM in the medial prefrontal cortex in 11 patients with schizophrenia and 9 controls, and although they found decreased GSH, the difference was not statistically significant between the two groups. The third study also utilized MEGA-PRESS in the medial prefrontal cortex, although they too did not find significant group differences between schizophrenic (n =20) and controls (n =16) and significant negative correlations between GSH measures and negative symptoms scores. Finally, the fourth study utilized LCModel with conventional PRESS (TE = 30 ms) in the bilateral temporal cortex in first-episode psychosis (n =30), of which 13 were neuroleptic naïve and had various diagnoses of schizophrenia, schizo psychosis, schizoaffective disorder, and depression with psychotic symptoms. Their findings are surprisingly contrary to previous studies where they show increased GSH in the schizophrenia group when compared with controls. It is important to note however the authors used the criteria of <50% CRLB that indicates that metabolite concentrations could range from zero to twice the estimated concentration. According to the LCModel guidelines, this would imply that the metabolite is undetectable. Coupled with findings of interference of Glu with GSH LCModel measures, it is likely that these results are not reliable.

Glutathione in Dementia

Two recent studies have utilized MRS to measure GSH in dementia. The first study utilized MEGA-PRESS and measured GSH in healthy young and old controls, 11 patients diagnosed with MCI, and 14 patients that suffered from AD (Mandal, Tripathi, & Sugunan, 2012). They explored several different brain regions including the frontal cortex, parietal cortex, hippocampus, and cerebellum. While the study found higher GSH in the young controls versus the elderly controls and patients, there did not seem to be any significant differences between the elderly controls and MCI or AD patients. The second study (Duffy et al., 2014), however, examined a much larger group of subjects (54 MCI and 41 healthy controls) using PRESS (TE = 35 ms) MRS and LCModel in the anterior and posterior cingulate gyri. They found elevated GSH levels in MCI patients when compared with age-matched healthy subjects in both brain regions. Furthermore, they also found the anterior and posterior cingulate GSH levels negatively correlated with executive and memory function, respectively. The authors hypothesize that the increased GSH may be a neuroprotective affect that arises from the upregulation of GSH in response to oxidative stress onset by MCI.

Glutathione in Bipolar Disorder

Fifty-three patients with BD (13 bipolar I, 25 bipolar II, 15 bipolar spectrum) and 51 age- and gender-matched controls were studied with PRESS (TE = 30 ms) in the anterior cingulate cortex and GSH measured using LCModel (Lagopoulos et al., 2013). In this case, CRLB was reported to be less than 20%. There were no significant differences found in the comparison of bipolar patients and controls, nor were there any significant correlations with clinical scores of depression or mania. The authors conclude that oxidative stress does not play a role in BD. It is interesting that an earlier paper from the same group utilizing the same methods but in a larger cohort ($n = 88$; mixed psychiatric disease including depression, bipolar, and psychosis) found that GSH was accounted for by the 40% of the clusters when cluster analysis was applied (Hermens, Lagopoulos, Naismith, Tobias-Webb, & Hickie, 2012). One of the clusters exhibited higher GSH; however, as a mix of different psychoses, it is difficult to determine the underlying pathophysiology, which might explain this finding.

Conclusion

MRS is a powerful imaging tool that can provide noninvasive, quantitative, and objective measures of several brain disorders. Highly complementary to other imaging tools, MRS can be used in conjunction to better understand the different brain functions such as neurodegeneration (NAA), excitotoxicity (Glu), inhibition (GABA), neuroinflammation (GSH), mitochondrial function (Cr), membrane turnover and demyelination (Cho), and gliosis (mI). In schizophrenia, reduced NAA, increased Gln, and variable Glu (dependent on chronicity, reduced GABA, GSH, and Cr) have been the major findings providing insight into the neuronal function and the influence of the major neurotransmitters upon the disease. In dementia, the primary findings are reduced NAA and Glu and increased mI, which are not only diagnostic for AD but also in predicting progression of dementia as well. Reduced NAA, Glu, and GABA are characteristic of depression. Those results provide an interesting contrast to BD where NAA and GABA are also reduced but Cho and Glu are increased and GSH does not appear to change. Anxiety disorder is probably the least explored by MRS but have shown increased Glu but decreased GABA, thereby demonstrating an imbalance between the major excitatory and inhibitory neurotransmitters in the brain. Numerous studies were reported in HIV infection before the introduction of highly antiretroviral therapy (ART) as well as after ART. In chronic HIV infection neuronal loss (NAA) is evidenced with elevated mI, and Cho confirmed neuronal and glial dysfunction. However, in the treatment naïve early infection (acute), NAA is unchanged indicating the virus inability to penetrate blood–brain barrier. As MRS clinical research is rapidly evolve through the various pulse sequences and post-processing methods that are more and more rapidly becoming available to neuroscientists, psychiatrists, psychologists, and physicians, MRS may eventually cross over into the realm of clinical diagnosis where it would be a valuable tool to provide mechanistic and physiological insight into psychiatric diseases much as genetics and pathophysiology have provided for other diseases.

The impressive amount of research in the field of neurodegenerative diseases that has characterized the last two decades has been directed in particular toward the establishment of accurate measures able to make an early diagnosis of the diseases. In particular, the greatest effort and the most promising findings have been collected for the early detection of Alzheimer's disease (AD).

AD is the most common form of dementia, in which memory problems are typically the first symptoms. The underlying pathophysiological mechanisms start several years before the clinical manifestation of the disease. Therefore, revised diagnostic criteria emphasized the role of the *in vivo* detection of biomarkers for the identification of different stages of AD (Albert et al., 2011; McKhann et al., 2011). There is a great promise that biomarker assessment will lead to an accurate diagnosis of AD. Two main groups of validated biomarkers have been categorized: (a) amyloid-beta deposition/plaque formation and (b) tau-protein neurodegeneration. Neuroimaging and cerebrospinal fluid measures have been proposed as useful tools for the detection of the underpinning pathophysiological process of AD. Among neuroimaging

techniques, magnetic resonance imaging (MRI) allows detecting the evolution of distinct patterns from early to late AD. Many recent studies showed that the atrophy of the hippocampal area as well as of the entorhinal cortex are considered to be indicators of the regional neuronal injury (Apostolova et al., 2010; Martin, Smith, Collins, Schmitt, & Gold, 2010).

Furthermore, behavioral data have been shown to provide an important contribution for the early and differential diagnosis of AD. Some cognitive scores collected during the assessment of patients could represent a useful marker of the clinical onset of AD. In particular, it has been pointed out that low performance at free and cued selective reminding test (FCSRT), even in presence of retrieval facilitation with cueing, can be a valid clinical marker of typical AD (Dubois et al., 2014). Low free recall at FCSRT could also represent a predictor of conversion to AD in MCI patients (Dubois et al., 2016). Other studies (e.g., Della Sala, Parra, Fabi, Luzzi, & Abrahams, 2012) showed memory binding as a successful predictor of conversion from mild cognitive impairment (MCI) to AD. Although many neuropsychological measures may appear promising, the definition of the best cognitive test is still controversial.

Recently, it has been proposed that multimodal markers can improve the sensitivity and specificity of diagnosis. In this scenario, it clearly emerges the importance to identify the best combination of biomarkers able to accurately detect the early stage of the disease or to predict the prognostic outcome in symptomatic patients at elevated risk.

Advances in the field of artificial intelligence have led to new approaches useful for the analysis of medical data. Among these approaches, multivariate analysis and machine learning (ML) have shown promising results.

Multivariate analysis is the analysis of data based on the principle of multivariate statistics. In contrast with univariate analysis, it involves the study of more than one statistical variable at a time. In this sense, multivariate analysis is able to extract information from distributed patterns of data, without requiring a priori knowledge of where it may be coded (i.e., of which variables of interest should be considered). A great consequence of this point is that this approach allows highlighting differences that might otherwise remain undetected, because—in general—no a priori choice of variables is necessary in this case.

ML is a subfield of computer science that includes all advanced computer methods able to learn from *experience*. Therefore, ML also comprehends multivariate techniques that are able to learn a specific task gathering information from multiple variables. There are two great advantages of ML techniques: the first is that they are able to deal with large amounts of data in a relatively short time, which is particularly useful in problems that require the use of a large number of variables or samples (e.g., in medicine), and the second is that ML methods are able to generate predictive models (learned from experience) that can be used to make predictions on new (unseen) samples. Specifically, this last characteristic represents the fundament of ML methods, which are—by their own nature—able to perform automatic single-subject classification, in contrast with traditional statistical techniques. The ability of learning from a given (finite) dataset on how to classify samples not belonging to that dataset is called *generalization ability*. Finally, another interesting characteristic of ML algorithms is that they can be used to find which features most influence the generation of the predictive model. For example, in a simple binary classification task, ML can be used to determine which features are the most important for the discrimination of two classes.

Because of these characteristics, multivariate ML techniques are becoming one of the main research topics in data science, given their applicability to different fields and, in particular, to medicine, where there is strong need of tools able to analyze big data in an objective way, to make accurate predictions about patients' status, and to automatically extract potential markers of diseases.

As a matter of fact, although we are still in a *research* phase, ML techniques have been widely and successfully applied in medicine to the diagnosis of AD. A paper by Klöppel et al. (2008) showed that computers—intended as *intelligent* algorithms—are suitable for the diagnosis of AD. Indeed, in this study, a particular ML algorithm, called support vector machine (SVM), classified AD using neuroimaging data with performances comparable with or higher than well-trained neuroradiologists, thus suggesting a primary role for computerized diagnostic methods in clinical practice.

According to the field of applicability, there are several studies showing promising results in the classification of AD patients. Concerning the neuroimaging field, MRI coupled to ML has been reported to be successful in performing the automatic classification of AD and MCI patients (e.g., Nanni, Salvatore, Cerasa, & Castiglioni, 2016; Salvatore, Cerasa, et al., 2015). A previous systematic review investigated the use of ML for the classification of AD through structural MRI (Salvatore, Battista, & Castiglioni, 2015), reporting median specificity and sensitivity for the conversion from MCI to AD of 66 and 75%, respectively. There are only few papers investigating the application of ML to positron emission tomography (PET). Pagani et al. (2015) found a specificity and sensitivity of 92 and 91% for the prediction of conversion to AD, respectively. Overall, these studies demonstrated that ML algorithms applied to biomedical imaging might aid in the diagnosis of AD, but these conclusions should be confirmed in samples coming from dementia clinics.

Advanced ML methods have been successfully applied also to biological studies of AD. Craig-Schapiro et al. (2011) revealed that CSF calbindin, in combination with CSF Aβ42 and age, predicts the risk of developing AD with 80% of sensitivity and specificity. Other results (Yang, Tan, & Qiu, 2012) coming from ML applied to biological data and neuroimaging indicate that abnormal values of CSF Aβ42 coupled with atrophy as measured using MR imaging precede clinical symptoms of AD with a sensitivity and specificity of 88 and 82%, respectively.

ML methods have also found their fruitful application in the automatic analysis of behavioral/neuropsychological data collected from AD patients. In particular, Weakley, Williams, Schmitter-Edgecombe, & Cook (2015) showed that neuropsychological measures alone are able to achieve good performance for the diagnosis of AD, above 80%. ML algorithms have been applied to the identification of the best neuropsychological measures for the diagnosis of AD (e.g., Battista, Salvatore, & Castiglioni, 2017; Cui et al., 2011, 2012). Specifically, decline of episodic memory and executive functions appear to be the most accurate measures. Fraser and colleagues (Fraser, Meltzer, & Rudzicz, 2015) found that ML algorithms coupled with measures of picture description tasks are able to distinguish AD from the healthy condition. Results showed that the mean length of sentences, the number of produced words and verbs, the frequency, and the familiarity of words are consistent measures of AD. ML coupled with linguistic markers is object of study also for the automatic diagnosis of pathologies involving language impairment as a first symptom, such as primary progressive aphasia (PPA) (Garrard, Rentoumi, Gesierich, Miller, & Gorno-Tempini, 2014).

In the last few years, a growing interest in the field of biomarker assessment through artificial intelligence techniques has been directed toward the combination of multiple sources of clinical information coming from structural, functional, metabolic, molecular neuroimaging, neurophysiology, neuro-biochemistry of CSF, and neurogenic sources (Cavedo et al., 2014). The use of multimodality markers is getting more consensus in the literature, showing that combining features from different modalities leads to higher diagnostic accuracy compared to the results of each modality alone (e.g., Dukart, Sambataro, & Bertolino, 2015), since this approach provides complementary information for the diagnostic process.

Although several biomarkers have been identified from the recent literature, these markers have to be considered with high attention. The definition of the ML algorithm and of the validation procedures associated with the accuracy of different measures can vary across studies, as well as the definition of the gold standards for the diagnosis and of the performance-evaluation metrics. Therefore, in order to improve the diagnostic power of ML techniques, it would be desirable to decrease the heterogeneity among studies, or—in other words—to make them comparable. This could provide a powerful and noninvasive tool not only for the diagnosis of AD but also for screening the efficacy of new drug treatments without the need for large and expensive clinical trials.

Finally, a new subfield of artificial intelligence is recently emerging from the computer-vision community (Krizhevsky, Sutskever, & Hinton, 2012). This subfield, known as deep learning, represents the most advanced frontier of ML, especially in terms of performance. Deep learning techniques are particularly useful for the automatic classification of images, for which they were originally designed, and they have been proven to outperform previous ML algorithms in most tasks (Razavian, Azizpour, Sullivan, & Carlsson, 2014). However, in order for deep learning algorithms to be trained preventing overfitting problems, a huge amount of data are needed. Namely, this translates in the need for datasets of thousands or millions of images. This is the reason why this technique has not been applied yet to the diagnosis of AD through biomedical imaging. The perspective of higher performance than those obtained by current ML methods is thus a strong motivation for the clinical community to collect big sets of medical data and to make them available in public repositories.

Overview

Transcranial magnetic stimulation (TMS) is a noninvasive technique to assess and alter excitability within the central nervous system. Through electromagnetism TMS generates activity within the cortex, which can indirectly depolarize corticospinal output neurons that ultimately activate peripheral muscle(s). This chapter focuses on the applications of TMS to index and modulate the neurophysiology of the motor system after a brain injury, specifically stroke. We will provide an overview of TMS, applications in healthy and neurologically injured populations to index cortical excitability and connectivity, along with the potential application to modulate excitability and connectivity to achieve a functional benefit (e.g., repetitive TMS [rTMS]). Throughout this chapter we will highlight limitations of a "one-size-fits-all" application of TMS to index and modulate the motor system. Together, this will support our concluding framework to develop a targeted assessment of cortical excitability and connectivity to foster application of an individualized rTMS treatment approach.

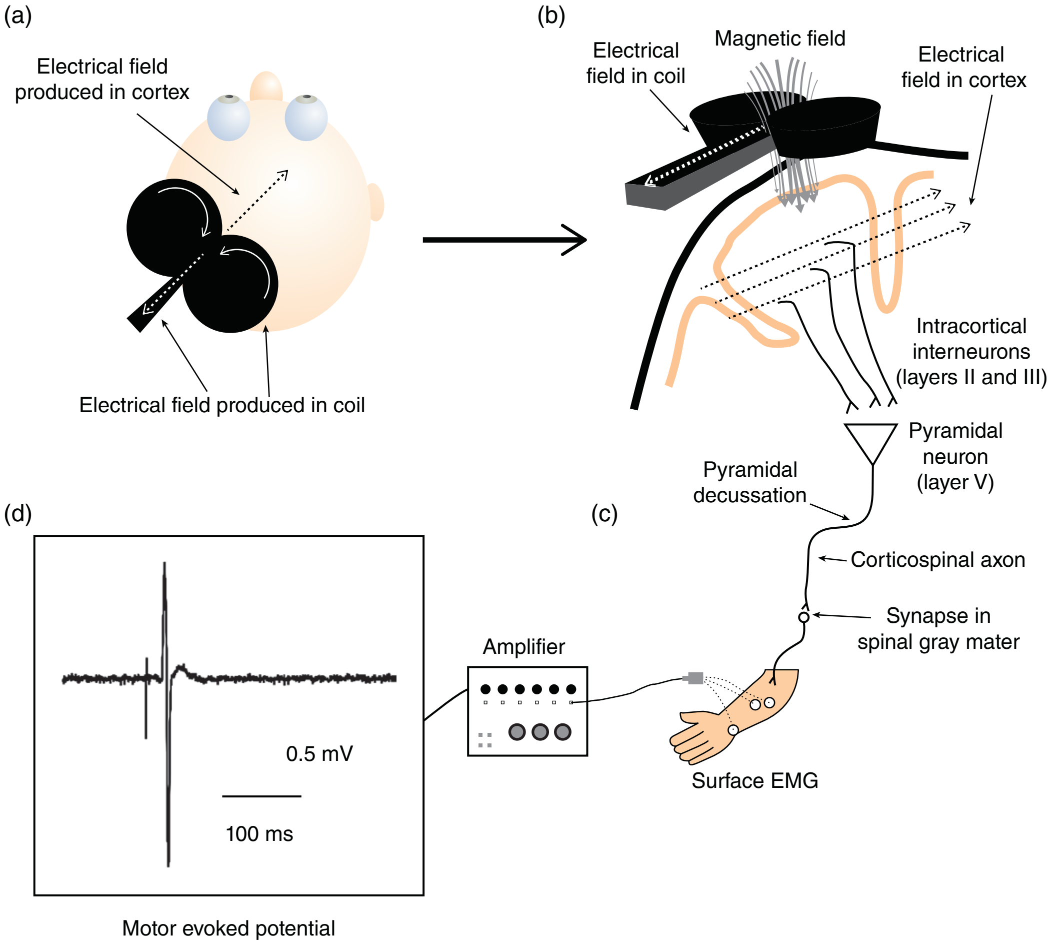

Figure 1 Schematic of transcranial magnetic stimulation (TMS). (a) A TMS coil placed over the scalp produces an electric field in the TMS coil, as well as in the opposite direction in the cortex. (b) Electric field produced by the coil induces a magnetic field traversing the skull and dura, producing electrical activity in the cortex in the opposite direction, which activates intracortical interneurons synapsing on pyramidal neurons and thus activates the corticospinal tract. The descending corticospinal tract then synapses on to a motor neuron in the spinal gray matter, which then carries the signal to the muscle. (c) The surface electromyographical (EMG) response resulting from TMS-induced activation of the corticospinal tract is captured via surface electrodes recording from the target muscle. (d) Amplified EMG is projected onto a computer screen for quantification of motor evoked potential (MEP) amplitude and latency.

Transcranial Magnetic Stimulation (TMS)

Transcranial magnetic stimulation (TMS) is a noninvasive technique to assess and alter excitability within the central nervous system (Auriat, Neva, Peters, Ferris, & Boyd, 2015; Brown, Neva, Ledwell, & Boyd, 2014; Chen et al., 2008). TMS operates under the principles of electromagnetism to activate cortical neurons. When activated electric current courses along the wires within the TMS coil, a rapidly changing transient magnetic field traverses the scalp and generates electrical activity within the cortex under the coil. If held over the primary motor cortex (M1) and with high enough intensities, a single pulse of TMS will result in transsynaptic activation of corticospinal output neurons. The corticospinal volleys activated by TMS reach the target muscle and can be recorded by surface electromyography (EMG), which is observed as a well-defined waveform called the motor-evoked potential (MEP) (see Figure 1). The amplitude (and sometimes latency) of the MEP is the primary outcome measure of corticospinal excitability using TMS (Chen et al., 2008; Di Lazzaro & Ziemann, 2013).

TMS can be used to index and modulate cortical excitability. Methods of single and paired pulse TMS are commonly used to index corticospinal and interhemispheric excitability in healthy and neurological populations (see Table 1 and comprehensive reviews by Brown et al., 2014 and Auriat et al., 2015). In contrast, repetitive delivery of TMS pulses (rTMS) can be used to modulate cortical excitability for a period of time (from minutes to ~1 hr) (Chen et al., 1997; Huang, Edwards, Rounis, Bhatia, & Rothwell, 2005). There has been a rapid expansion in the application of rTMS as an intervention to modulate cortical excitability. This is likely underpinned by the notion that rTMS is thought to mimic the early stages of long-term potentiation (LTP) and long-term depression (LTD)-like mechanisms, which are considered to be the basic neural processes underlying experience-dependent neuroplasticity in the brain (Di Lazzaro & Ziemann, 2013; Rioult-Pedotti, Friedman, & Donoghue, 2000). There has been growing interest to use rTMS as a potential therapeutic tool for healthy and neurological populations since it has been shown to cause lasting alterations in cortical excitability and behavior beyond that of the stimulation itself (Auriat et al., 2015; Brown et al., 2014; Chen et al., 2008). Today, researchers continue to use rTMS to test whether the application of stimulation alone, or in conjunction with motor training, can enhance rehabilitation benefits in people with neurological impairment (Auriat et al., 2015; Brown et al., 2014; Hsu, Cheng, Liao, Lee, & Lin, 2012). While rTMS may be applied in many neurological impairments (Brown et al., 2014), for the purposes of this chapter, we will focus on stroke given the high prevalence of people living with the effects of stroke coupled with the large body of research that has been completed to investigate the therapeutic potential of rTMS in stroke.

TMS to Assess Cortical Excitability and Connectivity After Stroke

Studies using multiple methods of TMS demonstrate altered brain excitability and connectivity during all phases post-stroke. Firstly, there can be changes in corticospinal and intracortical excitability. After stroke the ipsilesional hemisphere typically shows less corticospinal excitability with smaller, or even absent, MEPs. In contrast, the contralesional hemisphere often demonstrates equal or abnormally increased corticospinal excitability (Liepert et al., 1998; Sawaki et al., 2008; Stinear, Barber, Petoe, Anwar, & Byblow, 2012). Importantly, individuals that demonstrate an MEP elicited from the ipsilesional hemisphere soon after stroke generally show better motor recovery (Stinear et al., 2012) compared with those who do not (Trompetto, Assini, Buccolieri, Marchese, & Abbruzzese, 2000). Similarly, intracortical excitability can be altered in the ipsilesional hemisphere but remains relatively normal in the contralesional hemisphere (Manganotti et al., 2002). Together, these alterations in corticospinal and intracortical excitability suggest an imbalance between the ipsilesional and contralesional cortices that may underpin decreased capacity for motor function of the paretic limb (Liepert et al., 1998; Sawaki et al., 2008; Stinear et al., 2012).

Secondly, there can be alterations in connectivity between the two hemispheres, often referred to as interhemispheric inhibition (IHI). After stroke, asymmetry in the level of IHI between the two hemispheres is associated with the degree of functional recovery expressed.

Table 1 Summary of single, paired pulse and repetitive transcranial magnetic stimulation (TMS) measures of cortical excitability.

MEP, motor evoked potential; AMT, active motor threshold; RMT, resting motor threshold; RC, recruitment curve; CSP, contralateral silent period; iSP, ipsilateral silent period; CNS, central nervous system; SICI, short-interval intracortical inhibition; ICF, intracortical facilitation; LICI, long-interval intracortical inhibition; SICF, short-interval intracortical facilitation; SAI, short afferent inhibition; AF, afferent facilitation; LAI, long afferent inhibition; CMCT, central motor conduction time; IHI, interhemispheric inhibition; cTBS, continuous theta burst stimulation; iTBS, intermittent theta burst stimulation; PAS, paired associative stimulation.

Several TMS studies show that the ipsilesional M1 produces less IHI (Boroojerdi, Diefenbach, & Ferbert, 1996; Shimizu et al., 2002) and the contralesional M1 continues to show normal, or even increased levels of IHI (Duque et al., 2005; Murase, Duque, Mazzocchio, & Cohen, 2004). The net result is increased inhibition acting on the ipsilesional hemisphere that may decrease ipsilesional M1 excitability (Liepert et al., 1998) and interfere with corticospinal function and neuroplasticity in the ipsilesional cortex (Carey, Fregni, & Pascual-Leone, 2006; Taub et al., 2006). This pattern of asymmetric IHI has been associated with poorer motor function (Duque et al., 2005; Harris-Love, Chan, Dromerick, & Cohen, 2015; Murase et al., 2004). Collectively, these findings have given rise to the idea of the interhemispheric competition model (IHCM) (Auriat et al., 2015; Di Pino et al., 2014). This model assumes that the neurologically intact brain has mutually balanced inhibition between hemispheres, but the damage due to stroke in one hemisphere disrupts this balance. The IHCM posits that poor recovery of function after stroke is hindered by decreased excitability in the ipsilesional cortex and exacerbated by excessive inhibition from the contralesional hemisphere. The idea of the IHCM has generated much discussion surrounding the notion that the contralesional hemisphere is not a “friend” to recovery after stroke but rather a “foe,” hindering its potential to drive repair and recovery after injury.

Recent research that has stratified patients by severity of motor impairment would suggest that the IHCM might be too simplistic. Work that has investigated people with chronic stroke (>6 months post injury) has found *increased* IHI from the ipsilesional to the contralesional M1 (Borich, Neva, & Boyd, 2015). This is contrary to previous findings underpinning the IHCM (Auriat et al., 2015; Di Pino et al., 2014). Further work shows that *increased* inhibition from the contralesional hemisphere is associated with *less* impairment and *better* function (Mang, Borich, Brodie, & Boyd, 2015). Moreover, those with severe upper limb impairment after stroke show *less* ipsilesional IHI associated with *greater* function (Hayward et al., 2017). Collectively, these findings have generated renewed interest to understand the neurobiological role of the contralesional hemisphere to achieve motor recovery. The contralesional hemisphere may not be the “foe” to all that the IHCM suggests, but could be a “friend,” which aids in supporting recovery of function, potentially substituting for cortical networks lost after stroke.

rTMS as a Therapeutic Approach to Improve Recovery of Function After Stroke

rTMS is a potential therapeutic approach to aid in the recovery of motor function after stroke (Corti, Patten, & Triggs, 2012). Theoretically, rTMS can be used to either *increase* ipsilesional cortical excitability by directly applying excitatory rTMS over the ipsilesional hemisphere or *decrease* contralesional cortical excitability by applying inhibitory rTMS over the contralesional hemisphere to decrease the perceived abnormally enhanced inhibitory signals directed toward the lesioned M1 and thereby increase ipsilesional excitability (Auriat et al., 2015). Although both approaches of rTMS application after stroke have shown promise in enhancing ipsilesional excitability and improving motor function, with perhaps slightly more promise from inhibitory contralesional rTMS (Hsu et al., 2012), there is accumulating evidence that the response to rTMS is inconsistent and variable (Carey et al., 2014; Héroux, Taylor, & Gandevia, 2015; Meehan, Dao, Linsdell, & Boyd, 2011). Inconsistent and variable effects are noted regardless of what form of rTMS is employed (Carey et al., 2014; Meehan et al., 2011) and irrespective of the targeted brain area or hemisphere (Carey et al., 2014; Hsu et al., 2012;

Meehan et al., 2011) (Table 1). Further, varied responses to rTMS are not explained by simple demographic factors such as age, sex, time post stroke, or stroke severity (Carey et al., 2014; Hsu et al., 2012). This supports a rationale for developing a framework to individualize the application of rTMS to achieve optimal modulation of cortical networks.

The Need for an Individualized Approach to rTMS Application After Stroke

Despite its broad use in healthy and stroke populations, a comprehensive understanding of the neurophysiological effects of rTMS on brain and behavior is lacking. Although some work has provided evidence for identifying how healthy individuals may respond to specific types of rTMS (Hamada, Murase, Hasan, Balaratnam, & Rothwell, 2013), at present there is no single measure that can accurately predict an individual's response to rTMS, particularly in neurological populations including stroke. This likely reflects the large complexity of brain connections and function and highlights the need for new approaches that attempt to categorize an individual response to rTMS interventions based on measures of their neurophysiology and anatomy. There are multiple indices of cortical excitability and connectivity via TMS (mentioned above; see Table 1) that may assist in navigating the pathway to selection and application of rTMS for an individual to respond optimally.

To date stroke recovery research has focused almost entirely on M1 in the *ipsilesional* hemisphere as the target location of cortical repair and augmentation with brain stimulation applying excitatory rTMS (Auriat et al., 2015; Plow, Cunningham, Varnerin, & Machado, 2014). The focus on M1 is likely underpinned by previous research suggesting that patients with damaged M1 generally have worse recovery and those with spared M1 have better recovery (Bhatt et al., 2007). Yet, there is growing evidence that association motor-related areas can take over the function of M1, such as the premotor cortices (Frost et al., 2003; Plow et al., 2014). These areas, anterior to M1, which include the supplementary motor area (SMA) and the dorsal (PMd) and ventral (PMv) premotor cortices, greatly influence and contribute to M1 corticospinal output. Recent work has suggested that premotor areas may be viable options for brain stimulation (e.g., rTMS) to potentiate recovery, particularly in those with more severe impairment (Plow et al., 2014). We not only agree with this hypothesis and suggestion, but we also suggest that these association motor-related areas may be tested for corticospinal excitability via single and paired pulse TMS in addition to M1 to assist in guiding the therapeutic application of rTMS. If indeed areas like PMv can compensate for the function of M1 as shown by previous work (Frost et al., 2003), then it is possible that these areas could be indexed by TMS.

Except for a very small number of studies (Brodie, Meehan, Borich, & Boyd, 2014; Meehan et al., 2011), the vast majority of research employing *contralesional* rTMS has focused solely on M1. Since there is evidence that interhemispheric connectivity is not as simple as the IHCM may suggest after stroke, this possibly suggests that other non-primary motor areas (i.e., premotor and prefrontal areas) may contribute to maintaining or compensating for altered interhemispheric connectivity following stroke. This notion is further supported by the fact that interhemispheric connectivity has been demonstrated between non-M1 areas such as primary somatosensory cortex (S1), PMd, and dorsolateral prefrontal cortex (DLPFC) to the contralateral M1 in healthy individuals (Ni et al., 2009). If this interhemispheric connectivity exists before the onset of a stroke, it is possible that some of these connections remain after damage due to stroke, which may be useful to assess spared connectivity and be exploited for the repair and recovery of function.

Personalized Therapeutic rTMS Application After Stroke

The development of a TMS assessment protocol that indexes cortical excitability and connectivity of multiple brain regions in an attempt to build a comprehensive understanding of an individual's neurophysiology after stroke via TMS assessment is the next challenge for the field. This information would be used to inform the optimal location of stimulation, along with the type, dose, and intensity of rTMS applied to modulate cortical output. While work in this field is slowly emerging (Plow et al., 2014), we propose three steps to support the development of an individualized approach. First, there is a need to consider ipsilesional excitability of primary motor and other higher-order motor-related (e.g., PMd) areas via TMS. If ipsilesional premotor cortices are compensating for decreased M1 excitability, this may indicate that excitatory rTMS over premotor cortices may be a viable option for individuals to enhance the endogenous cortical reorganization taking place to promote better motor recovery. Second, we propose it is vital to take into account if the ICHM applies to an individual after stroke, as this would greatly impact the potential positive (or negative) response to inhibitory rTMS over the contralesional M1. If in fact the contralesional hemisphere is a "friend" after stroke, assisting in recovery of function, then suppressing contralesional M1 activity with rTMS would possibly be counterproductive to motor recovery (Bradnam, Stinear, Barber, & Byblow, 2012). Third, it is warranted to assess interhemispheric communication from non-M1 areas that may be compensating for a lack of connectivity between ipsilateral and contralateral M1, potentially due to obliteration of ipsilesional M1 in more severe stroke. Such regions include PMd, S1, and DLPFC. Since this type of IHI has been demonstrated in healthy individuals (Ni et al., 2009), and that greater inhibition from the contralesional hemisphere can be associated with greater motor function (Mang et al., 2015), it is possible that other related non-M1 areas could be modulated, and this interhemispheric connectivity may be critical to functional recovery after stroke. By determining the cortical excitability and interhemispheric connectivity profile of an individual via TMS assessment, an individualized rTMS intervention that seeks to either exploit the endogenous reorganization of the brain or assist in enhancing excitability or connectivity in the area that is needed to increase the effects of therapy in individuals with stroke can be developed.

Concluding Remarks

TMS can be used to assess and alter cortical excitability and interhemispheric connectivity in healthy and clinical populations (e.g., stroke). Increasingly, rTMS is studied for its ability to augment behavioral interventions in individuals who have had a stroke with some degree of success. Unfortunately, there is a large amount of variability in response to rTMS in individuals with stroke. We propose the use of multiple indices of cortical excitability and interhemispheric connectivity in both M1 and non-M1 areas in order to guide and inform rTMS application. This will support the formulation of an individualized approach to rTMS application that is tailored to positively modulate cortical excitability and interhemispheric connectivity to increase response to therapy and motor function after stroke.

Introduction

One of the most exciting developments in clinical neuroscience is the conceptualization of the brain as an interconnected network or (mathematically speaking) a graph. This new area of study called connectomics has already yielded invaluable insights into brain function and dysfunction in the context of neuropsychiatric diseases. This chapter will introduce the reader to the topic of connectomics followed by an overview of key findings associated with a few neuropsychiatric disorders studied using this innovative technique.

What Is Connectomics?

Connectomics refers to an innovative school of methods that allow us to study system properties of the human brain by constructing comprehensive maps of brain connectivity, both structural and functional, based on noninvasive neuroimaging modalities. Mathematically, such "connectome" studies model the brain as a "graph," composed of the nodes or "vertices" (cortical and subcortical gray matter regions) and the connections or "edges" (defined using either structural or functional information) connecting these nodes. In this context, the term connectomics refers to a collection of mathematical and computational approaches to the study of the brain, as it is represented as a network composed of the aforementioned nodes and edges. As an

example, a structural "tractography"-derived connectome has edges that are defined by white matter connectivity extracted using diffusion tensor imaging (DTI), which allows one to quantify the number of white matter "fiber" tracts between brain regions. By contrast, edges in a functional magnetic resonance imaging (fMRI)-derived connectome are typically defined based on the correlation of the blood oxygen level-dependent (BOLD) signals in fMRI between brain regions or nodes. Similarly, another form of noninvasive functional connectome can be defined using electroencephalography (EEG), where edges are defined as the correspondence (based on signal's power spectrum, phase information, etc.) between EEG signals from electrodes. Once the brain has been modeled in this manner, various graph theory-based metrics can be calculated in order to better elucidate the functional and structural organization of the brain (Rubinov & Sporns, 2010) as a result of the interactions among all connections connecting different areas in the brain (instead restricted to a select few regions or white matter tracts as was commonly done prior to the advent of connectomics). Common metrics described in the literature include path length and global efficiency (both measures of network integration), clustering coefficient (a measure of network segregation), and centrality (a measure of nodal importance or influence). From here, the next level of graph connectome analysis can be applied in order to understand the modular or community structure of a connectome. Indeed, just as social networks can be divided into cliques that describe modes of association (family, school, etc.), a connectome can be divided into modules or communities.

To measure how efficient two nodes of a connectome communicate with each other, one computes the graph distance or shortest path length between them. Calculated by averaging the lengths of shortest paths between all pairs of nodes, the characteristic path length (CPL) (Rubinov & Sporns, 2010) is commonly used to measure overall network integration (node-level path length is defined similarly by averaging the shortest paths connecting an index node to all other nodes in the network). By contrast, the clustering coefficient is a measure of network segregation and reflects the tendency of a node's neighbors to be connected to each other. Highly connected nodes have a high degree of centrality, that is, a large proportion of all edges pass through a given node. Sporns and colleagues have identified brain regions with typically high centrality, which they called the "rich club" (van den Heuvel & Sporns, 2011). These nodes have been shown to be particularly important when examining specific diseases from a network perspective.

Connectomics of Psychiatric Disorders

Schizophrenia

The largest body of work in the emerging field of connectomics and psychiatry comes from studies of schizophrenia. Even before the advent of connectomics, researchers have long-conceptualized schizophrenia as a connectivity disorder (Bullmore, Frangou, & Murray, 1997). In recent years, several investigators have discovered brain network abnormalities consistent with this notion of schizophrenia as a connectivity disorder. One of the first studies of connectomics and schizophrenia published by Lynall et al. revealed that participants with schizophrenia had reduced network strength and increased variance of functional connectivity strengths, among other network alterations (Lynall et al., 2010). The authors concluded that in schizophrenia, brain networks were less integrated with decreased influence of "hub" nodes. Altered hub nodes were also noted in a study that examined rich club organization in schizophrenia; here the authors found a reduced density of highly connected rich club nodes that linked frontal, parietal, and insular regions and thus resulted in reduced global communication capacity (van den Heuvel et al., 2013).

How might some of these network alterations be related to one of the cardinal symptoms of schizophrenia, hallucinations? In a study of patients with the 22q11.2 deletion syndrome, hallucination symptom severity was significantly associated with local efficiency in speech centers like Broca's area and Wernicke's area (Ottet et al., 2013). Further, two recent studies have identified that abnormal connectome properties in the default mode network are associated with hallucinations. Chang and colleagues showed that auditory–visual hallucinations were especially associated with abnormal bilateral connectivity of the default mode network and inferior frontal gyrus (Chang et al., 2015). A similar pattern was identified by Wang et al. showing increased connectivity between the default mode network and heteromodal association areas (Wang, Zeng, et al., 2015). While these studies demonstrate connectome alterations associated with specific symptoms and the syndrome of schizophrenia in general, one area that requires further study is the impact of antipsychotic treatments on connectome properties and whether there are connectome-based predictors of treatment response.

Mood Disorders

Connectomics has been extensively studied in the area of mood disorders. Studies of structural connectomes in late life depression have revealed impaired network efficiency, both in the active and remitted state of the disease (Ajilore et al., 2014; Bai et al., 2012). Furthermore, it has been shown that late life depression is associated with impaired network resiliency that is partially mediated by white matter hyperintensity burden (a common radiological finding in LLD) (Ajilore et al., 2014; Mak, Colloby, Thomas, & O'Brien, 2016). In examining alterations in hub regions in both late life depression and bipolar depression, there is evidence of altered network influence and network organization implicating key regions in the default mode network (Ajilore et al., 2014; Charlton et al., 2015; Gadelkarim et al., 2014). Examining functional connectomes with fMRI, late life depression is associated with reduced edge strength in circuits involved in emotion regulation and reward processing (Tadayonnejad, Yang, Kumar, & Ajilore, 2014).

Connectomic studies in bipolar disorder have revealed impaired white matter integrity in the corpus callosum that is related to impaired global network segregation and integration. Furthermore, like unipolar depression, patients with bipolar disorder exhibited decreased global network efficiency and interhemispheric efficiency (Leow et al., 2013). Demonstrating how these structural alterations relate to function, it has been shown that these structural connectome properties mediate abnormalities in fMRI activation and cognitive performance in euthymic bipolar I patients (Ajilore et al., 2015).

The impact of treatment on connectome alterations in mood disorders has been demonstrated in several studies across different therapeutic modalities. For example, betweenness centrality (a measure of "hubness") of the subgenual cingulate distinguished transcranial magnetic stimulation (rTMS) responders from nonresponders (Downar et al., 2014). Antidepressant treatment has been shown to reduce functional connectivity strength in the bilateral dorsomedial prefrontal cortex and increase hippocampal functional connectivity strength (Wang, Xia, et al., 2015). Additionally, electroconvulsive therapy (ECT) treatment response is associated with structural connectome changes in limbic regions such as the amygdala and parahippocampus and with nodal strength increases in paralimbic regions (Zeng et al., 2015).

Anxiety Disorders

Compared with schizophrenia and mood disorders, there have been fewer studies in anxiety disorders. A recent study by Servaas et al. showed that people with high levels of neuroticism had more randomly organized brain networks compared with those with low levels of neuroticism

(Servaas et al., 2015). Furthermore, these participants had relatively higher efficiency in an affective subnetwork. In a connectome-wide analysis study by Satterthwaite and colleagues, anxiety was associated increased connectivity between ventromedial prefrontal cortex and the amygdala (Satterthwaite et al., 2016).

In obsessive–compulsive disorder (OCD), there have been several interesting studies examining the impact of treatment on connectomics measures. For example, it has been shown that cognitive behavioral therapy (CBT) can enhance functional network efficiency in OCD (Feusner et al., 2015). Additionally, pharmacological treatment with selective serotonin reuptake inhibitors (SSRI) has been shown to impact brain network characteristics in OCD. Shin and colleagues found that participants with OCD had reduced functional network efficiency that increased with SSRI treatment. Furthermore, they found that treatment response correlated with changes in network connectivity of the right ventral frontal cortex (Shin et al., 2014).

Future Directions

The majority of studies described above have primarily used a single modality such as fMRI or DTI to generate connectomes. However, combining multimodal neuroimaging techniques allows for more complete models of brain function and dysfunction. In a study using a multimodal fusion technique called functional-by-structural hierarchical mapping, it was shown that combining two modalities enhanced the power to detect significant differences compared with either modality alone (Ajilore et al., 2013).

In addition to incorporating multiple modalities, studies are currently underway to improve how we characterize functional connections in brain networks. Current fMRI methods typically use Pearson correlations as a measure of connectivity. However, this method may overestimate the number of "true" functional connections. Using partial correlations and other information theory-based methods may lead to more accurate functional connectomes (Cassidy, Rae, & Solo, 2015).

Another advance in the characterization of functional connectomes derives from the recognition that resting-state fMRI does not truly reflect the brain at rest but instead, brain activity is very dynamic at all times. Novel connectomics methods, such as time-resolved functional connectivity and sliding-window techniques, are being developed to capture these dynamics. Along this line, work by Bassett and colleagues has shown how network dynamics relate to cognitive function and adaptive flexibility (Bassett et al., 2011; Braun et al., 2015).

Conclusion

Understanding the brain as a network has tremendous implications for how we characterize neuropsychiatric disorders. Rather than conceptualize diseases as arising from dysfunction in a few select brain regions, we understand that these complicated disorders often arise from disruptions in connectivity between regions. By thinking of the brain as a complex network of nodes and connections, novel treatments can be designed to target key nodes in the network defined by connectivity patterns. As described above, innovative neuroimaging and integrative techniques employing multimodal synthesis of imaging data and graph theory-based network analysis help to characterize the impact of disrupted tracts, networks, and whole-brain connectivity in neuropsychiatric diseases. Identifying abnormal circuits in this population and variances at the individual level could be used to develop patient-specific targets for future interventions, such as brain stimulation techniques or psychotherapies designed to engage, augment, or bypass these circuits.

Asperger Syndrome

Introduction

Asperger syndrome (AS) has two independent lives. One is based on popular psychology, pervading TV series and crime literature presenting socially awkward, highly intelligent characters with ritual habits and acute deductive skills. The other is an ephemeral, almost clandestine one based on science, concerning a neurodevelopmental condition included in the autism spectrum. Within current scientific understanding, AS still has an ambiguous existence, based on the decisions of its inventors, re-inventors, or committees' manufacturing consensus, without acknowledging that some people profoundly recognize themselves as having or *being* it. This unstable existence has resulted in an unavoidable circularity between its changing definitions and the reported findings of its characteristics. Here, we present the history of AS, its delineation within and outside of the autism spectrum, its neurobiological and psychiatric counterparts, and AS during childhood development and adulthood and conclude with the reciprocal relations that AS people may engage in with non-autistic people in the modern world.

History: The Four Ages of Asperger Syndrome

Discovery

In 1944, Hans Asperger, a Wiener pediatrician whose career partially overlapped with the years of the Nazi regime, published a series of four case studies of what he called "autistic psychopathy." Asperger's detailed description of their atypical social interactions included an abnormal gaze and voice, reduced facial expressions, atypical language and conversation, and self-absorption. These manifestations were associated with several challenges (attention and learning difficulties, stereotypic behaviors, clumsiness, reduced autonomy, and, in some cases, acts of delinquency), as well as advantages, such as creativity, outstanding mastery of speech, logical

thinking, and an at least normal level of general intelligence. Circumscribed interests, a hallmark of the condition, were considered to be useful and beneficial to the person. Up to one-fourth of AS individuals have various specific, above average abilities. Autistic psychopathy was considered to be a lifelong condition, genetically determined, with an onset before the age of 2 years, and was predominately found in males.

Rediscovery

Most important features of autistic psychopathy were identical to Kanner's description of autism 1 year earlier, except for the absence of "autistic language" features, the addition of attention-deficit clumsiness, and the genetic origin (in this latter aspect, Asperger was in advance of Kanner). In the quarter century following Asperger's description, there was an unequal competition of quotations between him and Kanner. Asperger quoted Kanner several times, whereas Kanner ignored him. Asperger's writings were virtually unquoted in non-German literature until 1981, despite the striking similarity between his autistic psychopathy and Kanner's autism, until L. Wing, an English psychiatrist, described 34 individuals that she personally diagnosed, roughly corresponding to Asperger's initial description. She also coined the term Asperger syndrome (Wing, 1981). Wing admittedly modified many important AS features and priorities. In particular, she attenuated the differences between Asperger's and Kanner's description and introduced her own beliefs. She particularly emphasized the sex ratio, clumsiness, and atypical social reciprocity, along with learning difficulties. She assumed a misunderstanding of other's nonverbal expressions, "lack of ability to understand and use the rules governing social behavior," and a lack of empathy. Most of the people that Wing described in her paper would have been classified as autistic based on further DSM-IV criteria, due to the presence of signs now included in the definition of verbal autism. These included early signs, such as overt, reduced interest and pleasure in human company, and the absence of pretend play during the first year, and later signs, such as pronoun reversal, stereotypical language, delayed echolalia, and a perceptual fascination with spinning objects. She minimized the role of genetics, in favor of acquired neurological conditions.

Among the changes introduced to Asperger's definition in that of Wing were an emphasis on the negative aspects of the syndrome and a generally more severe and pessimistic view of AS people. Although 76% of the individuals in her group had specific interests, their recognized skills were limited to rote memory, chess play, and music, despite that some may had the ability to follow careers in their domain of interest. She minimized the specific relation that AS people have with language and negatively described their language abilities. She was also highly critical of their originality and creativity in her description, as well as the notion of their high intelligence. These potentially positive assessments were replaced by an overall "lack of common sense." The study emphasized psychiatric co-occurring conditions, especially depression. Finally, she presented the reaction of others to AS people as varying "between compassion and exasperation."

Wing's paper generated great interest in Western countries and inaugurated a self-organized nosographic period where numerous important figures in autism research, liberated by Wing's first attempt to describe the condition and by the absence of a biological or symptomatic gold standard, produced their own sets of criteria (Gillberg & Gillberg, 1989; Szatmari, 1992; Szatmari, Bartolucci, & Bremner, 1989). The operationalization of some of these criteria in short and nonspecific questionnaires contributed to the popularity of AS but undermined the specificity of its initial description—foreshadowing the future loss of the information signal detected by its inventor.

Transient Life as an Official Entity (1994–2013)

In a concerted but awkward attempt to restore some order to the AS field, the DSM-IV committee tried to establish consensual criteria to capture the specificity between Asperger's and Kanner's initial descriptions. They re-separated the criteria merged by L. Wing into two distinct entities. The DSM-IV committee defined autism by three groups of symptoms (social, communication, and restricted interests and repetitive behaviors [RIRB]) and AS by only two (social and RIRB), which were identical to those of autism. They also proposed a priority rule: anybody satisfying criteria for autism could not be considered to have AS. The diagnosis of AS could be used only in the absence of a delay in the onset of speech, cognition, or autonomy.

Many were dissatisfied with the DSM-IV criteria during its era of application. The exclusion of language signs from the definition of AS combined with a priority rule was unfortunate. Language use is clearly atypical, even in prototypical AS. Prosody, quantity and rhythm, the amount of information provided, formalism, and topic adjustment are altered in AS, but the structural aspects of language use may be of very high quality. As a consequence, all clinically defined AS satisfied the criteria for DSM-IV-defined autism and disappeared. Moreover, the use of identical RIRB signs to diagnose AS and autism did not take into account that RIRB may take a different form, depending on whether or not the onset of speech is delayed (e.g., perceptual fixations in autism, thematic interests in AS). Another aspect that highlighted the unreliability of the autism vs. AS distinction was the reported absence of distinctive cognitive profiles. Its demonstration would have required a clear behavioral distinction between the two subgroups, which was not possible using the DSM-IV criteria.

Official Disappearance and Resistance (2013 to the Present)

The DSM-5 committee (American Psychiatric Association, 2013) took a very different view and merged the precedent subcategories of pervasive developmental disorders (autism, Asperger, and pervasive developmental disorders not otherwise specified) into an autism spectrum, possibly more specific than that of the DSM-IV. The DSM-5 recommendations introduce speech and intelligence levels among the clinical specifiers, merging the pervasive developmental disorder subgroups of the DSM-IV into an infinite number of possible clinical pictures within the autistic spectrum. It follows a "build your own autistic" strategy to cope with the presumed heterogeneity of the spectrum. However, the DSM-5 suggests keeping the old diagnoses and not recoding them according to the new criteria. The ICD-10 maintains the category but blurs it, disregards it, and poorly influences research decisions: "A disorder of uncertain nosological validity, characterized by the same type of qualitative atypicalities of reciprocal social interaction that typify autism, together with a restricted, stereotyped, repetitive repertoire of interests and activities. It differs from autism primarily in the fact that there is no general delay or retardation in language or in cognitive development. This disorder is often associated with marked clumsiness. There is a strong tendency for the abnormalities to persist into adolescence and adult life. Psychotic episodes occasionally occur in early adult life."

The disappearance of AS had been in preparation since the late 1980s by the diagnostic instruments (ADI and ADOS) that operationalize the DSM diagnostic criteria. Accordingly, there was no accepted standardized instrument to diagnose it, consistent with the doubt of the independent existence of the AS category. ADI and ADOS either merged AS people into a unique autism category by giving them an autism diagnosis or failed to detect it. The ADI questionnaire and the ADOS observation scale are indeed not sufficiently sensitive concerning communication to detect AS people, who speak fluently and do no present *major* communication issues. Either the person has sufficient communication issues to be considered autistic, or, more frequently, this is not the case, and the person is considered to be subthreshold. In both cases, AS disappears as an independent entity.

A strong scientific (Lai, Lombardo, Chakrabarti, & Baron-Cohen, 2013) and journalistic reaction between the pros and cons of the DSM-5 decision followed and is still active, sometimes fueled by information on Asperger's role during World War II (Czech, 2018). However, Asperger's inexcusable attitude toward the Nazi occupants is irrelevant to the scientific validity of his description of the condition, although it may play a role in the decision to attach his name to it. There remains an as yet unresolved contradiction between the weak scientific consensus still plaguing AS and the strong self-recognition of it by numerous individuals. As a result, research focused on AS has diminished considerably. Another detrimental consequence of including AS within autism is that it has allowed the inclusion of a more heterogeneous population in research studies than during the DSM-IV era, with the obvious result: the marked absence of major discoveries in prototypical autism, AS, or even autism spectrum disorders in brain imaging studies and genetics during the last 10 years.

Our Position

Our position in 2016 is that a sufficiently large number of individuals present prototypical AS of a sufficiently similar form to justify its autonomous designation. Despite its fuzzy definition, the condition still exists. Within the autistic spectrum, the co-segregation of the absence of a speech onset delay (SOD) with strong, verbally defined interests and a unique profile of cognitive strengths justifies its recognition. The spectrum of RIRB of AS people is also different from those with autism: when people diagnosed with autism at school age, who have access to oral speech, are stratified according to whether or not they had an SOD (or at least, clearly defined echolalia and stereotyped language), self-injury, preoccupation with parts of objects, or manual stereotypies are found only in those with an SOD. In contrast, AS people present stronger and different motor atypicalities than autistic individuals.

Despite controversies concerning its validity and diagnostic borders, AS exists in a prototypical form and is well characterized by the DSM-IV criteria, granted one withdraws the rule giving priority to autism, adds the possibility of minor communication atypicalities, and gives greater weight to the cognitive profile. A conservative view of the verbal autism vs. AS distinction is that when faced with an autistic clinical presentation as an adult, different predictions and clinical symptoms can be expected depending on whether the patient had an SOD or not. A prototypical presentation of AS involves a past history of reduced sharing of interests (theirs or his) with peers, self-consciousness of being different beginning at school age, and strong intellectual and emotional investment in thematic domains developing in coherent networks, together with normal or higher syntactic and vocabulary abilities and the absence of an SOD.

We have been able to arrive to this conclusion, despite the notorious difficulty in finding criteria that distinguish the two subgroups, ultimately resulting in the DSM-5 decision. It is possible to unravel the roots of the neurocognitive differences between *clinically defined* autistic and AS individual by comparing strictly defined individuals who are equivalent in their magnitude of social atypicalities and differ only by the presence or absence of an SOD (SOD vs. no SOD). Typical versus delayed speech acquisition milestones predict better developmental (Mayo, Chlebowski, Fein, & Eigsti, 2013) and language (Kenworthy et al., 2012) outcome in the autism spectrum. Concerning cognition, individuals with an SOD exhibit faster visual processing (Barbeau, Soulières, Dawson, Zeffiro, & Mottron, 2013), better dexterity and bimanual coordination (Barbeau, Meilleur, Zeffiro, & Mottron, 2015), superior auditory discrimination but impaired motion discrimination, and increased visual pursuit latency (Takarae, Luna, Minshew, & Sweeney, 2008) than individuals without an SOD. One fMRI study reported greater activity in the auditory-processing region for individuals with an SOD vs. greater activity in the language-processing region in those without an SOD when listening to nonspeech sounds. The AS cognitive profile also presents a higher VIQ than PIQ. DSM-5 autistics with or without SOD display distinct cognitive profiles by standard Wechsler intelligence profiling, with SOD individuals presenting superior visual and visuospatial performance relative to baseline, whereas individuals without SOD display distinct abilities in similitude and vocabulary (Sahyoun, Soulieres, Belliveau, Mottron, & Mody, 2009). The loss of this information, which was subsequently never replicated, results from the clinical definition of the participants, mixing verbal autistic adults with and without a history of SOD. Distinguishing individuals with or without SOD on the basis of their cognitive strengths and superior cortical reallocation suggests that autism is a condition that exhibits enhanced cortical plasticity, for which the targets, perception or language, differ according to subgroups, and suggests that AS individuals are speech experts (Samson, Zeffiro, Doyon, Benali, & Mottron, 2015).

Epidemiology

We are certain that prototypical AS individuals exist and are similar to each other, but the epidemiology of AS is still hazardous because of its fuzzy definition and ill-defined boundaries. If we limit AS to autistic individuals without SOD, its prevalence is still dependent on the level of atypicality required for the diagnosis of AD itself. For example, do we include the Japanese hikikomoris (close to the socio-communicative aspects of AS) or otakus (close to the RIRB aspects of AS) within AS? The difference between narrow and wide case ascertainment substantially affects the resulting prevalence. The occurrence of autistic people without SOD is, by definition, less frequent than the autism spectrum in its entirety, but also probably less frequent than autistic people with SOD. The recent emergence of a possible difference of AS according to gender, and the unavoidable circularity between case ascertainment based on gender and gender-specific criteria, prevents establishing a final sex ratio. Asperger's files following the war that could be studied (1950–1986) show the sex ratio for autistic psychopathy to be as high as 24/1. Another issue that prevents epidemiology from providing reliable numbers is the lack of a consensus regarding whether or not to exclude alternative diagnoses, the over-inclusivity of diagnostic instruments, and their lack of specificity. Many autism experts only know autism and fail to apply an "economy principle" when faced with ambiguous diagnoses. The prevalence of AS that they diagnose is therefore inversely correlated to their level of ignorance of other conditions.

Genetic Issues

An association between AS and autism was suspected before DSM-5. The clinical similarity between the broader autistic phenotype and the sociocognitive atypicalities evident in the first-degree relative of autistic and AS individuals contributed to the unification of the various forms within the autism spectrum. Twenty-five years ago, the common opinion was that familial genetic mechanisms were even more important in the AS than autism subtype. Asperger was convinced of this due to the apparent male transmission and high sex ratio. The broadening of the criteria and the return of syndromic autism (were *de novo* mutations are predominant) as a heuristic way to investigate neurobiological aspects of autism made this notion disappear. We predict that it will come back, in the same way that macrocephaly, evident for Kanner, was rediscovered 50 years later. Despite strong claims to the contrary, the role of environmental factors (beyond the intrinsic relation between gene expression and environment) has not been empirically demonstrated and has only been demonstrated for a few limited syndromic, para-autistic clinical presentations. Similarly, *de novo* mutations produce mostly intellectual disability syndromes for which the link with the presentation of prototypical AS is, at least, a matter of debate.

Differential Diagnoses

The absence of gold standards for determining whether patients fall into the autism spectrum or not leads to unavoidable disagreement on the actual diagnoses of people at the margin of prototypical descriptions. Confusing AS with "mild" autism within the autistic spectrum puts the patient at risk of missing that intelligence and better speech abilities may increase the risk for depressive thoughts. AS is not mild when things go wrong, and severity (in terms of well-being) and marginality (distance from the prototypical non-autistic phenotype) should be clearly distinguished.

The most frequently evoked diagnoses outside of the autism spectrum are schizoid personality, obsessive–compulsive personality, and social anxiety. There is disagreement concerning the distinction between the schizophrenic galaxy and AS. Wing recognized the possibility of hallucination in AS but carefully drew a distinction with schizophrenia, based, in particular, on the contrast between "local" AS thought and the "delusional and vague woolliness" of schizophrenic thought. However, she incorporated Wolf's schizoid personality with AS, although, in our opinion, there are crucial differences. These differences are well captured by the DSM-IV description, distinguishing between AS people, whose positive emotions are specifically triggered by a narrow range of interests, and people with schizoid personality who display a reduced range of positive and negative emotions. It can be difficult to distinguish between the negative symptoms of schizophrenia and the reduction of social interest in AS in the absence of knowledge of the individual's developmental history. Indeed, AS patients do not present progressive lessening of their cognitive ability, which is also the hallmark of simple-type schizophrenia. Other confusion is possible between AS and various personality disorders, such as avoidant and obsessive–compulsive personality. There is even more confusion in diagnosing girls due to our ignorance of a possibly distinct feminine AS phenotype. TDAH, anxiety, and depression are considered to be frequent comorbidities rather than differentially diagnosed, which they can still be.

The Basis of Social "Impairment" in AS

Wing's contribution led to the scientific and public recognition of AS in the non-German world, but at the cost of losing some of the signal detected by its discoverer, and increased pathologization. Wing's ideas had a considerable influence on further cognitive neuroscience for better and for worse. In the 1990s, during the golden age of cognitive models, the supposedly broken module was the theory of mind and the understanding of implicit rules of social behavior. This was premature, especially in light of numerous studies demonstrating intact subcomponents of social function in the autism spectrum. AS people do not follow social rules and a typical style of conduct, but it does not necessarily mean that they do not *process* them. Their introspection and ability to describe their own psychosocial functioning is usually excellent and not related with their capacity to modify it according to society's demands. This suggests that the social issues of AS people are the product of reactions to their differences by those around them as well as the idiosyncratic ways that thought and action function in a person with AS. It may not result from a *misunderstanding* of social rules, but of atypicalities in relative priorities, as well as in language–action and emotion–perception relationships (for an alternative view see Klin, 2000). Cognitive scientists are now more prudent and do not directly conclude a defect of function based on the reduction or atypicality of a behavior. They also criticize compensation models where the overdevelopment of one function is believed to compensate for an impaired function. An alternative understanding of AS people could focus on their strengths, for example, language expertise, rather than on modeling their negative aspects (Samson et al., 2015).

Developmental Course and Educational Issues

A diagnosis of AS is generally possible only after 5 years of age, when limited to early talkers and clearly distinguishable from that of autistics who become verbal as adults. A frequent error is to mistake children with AS as gifted non-autistic children due to their early speech and grammatically complex sentences, together with sophisticated scientific or historical interests. AS people have a normal distribution on the intelligence curve, but a distinct profile. Even if they often appear to be geniuses, they may or may not be.

The social problems of AS people depend on the nature and intensity of their social demands. Bullying and conflict at school are frequent, with the results ranging from depression to hetero-aggressivity, as in neurotypical kids. School performance is also extremely variable, from being excellent when the methods and domain suit one particular schoolboy to school refusal at the opposite extreme. The level of autonomy given to the child is crucial, as well as the availability of a rational explanation of what school is useful for. Individual variations in temper/personality are more important than a diagnosis of AS, with some children being passive and easy learners, whereas others are strong opponents to irrelevant material. Over-logical thought may enter in conflict with illogical presentation of the content to be learned. Temporary home education may be the necessary solution in some cases.

The effect of AS people on non-autistics, such as irritation due to excess demands or dependence, must be taken into account, but should not justify segregation. Segregation can be prevented by adapting how pedagogical content is transmitted and how the child's performance is assessed. Individualized learning, tolerance for atypical learning strategies, teaching methods to match the person's intelligence, the surveillance of schoolmates, the possibility to withdraw during unstructured situations, and quick referral to a qualified problem solver are required. Adaptation of the school curriculum and the selection of academic domains according to the person's expertise and specialization are not allowed in most countries, but should be applied to the same extent as they are for other learning or motor disabilities (e.g., dyslexia, sensory impairments). School success and the obtention of a diploma are essential as many AS people will pursue university training and need these years to learn how to cope with the non-autistic world.

Employment and Adult Outcome

Despite the triumphalism of press claims, the employment of people diagnosed with AS is still rare (with a good outcome for only 1/4, Howlin, 2003). Unemployment is far more frequent together with a poor family life. Women with AS are less negatively affected than men with AS. This pessimistic figure is influenced by the "hidden cohort" issue. It is possible that more AS people are employed but are undetected because of the large number of individuals predicted by prevalence studies, but not currently identified. Quality-of-life studies as adults, as well as studies on its predictors during childhood, are also lacking. There are, however, indications that self-recognition as a person with AS and their association with other AS people or verbal autism, through self-organized web groups, improves quality of life. Most knowledge on the adult life of AS people should, however, be considered to be provisional at best and is based on poor quality information. Consequently, as for school integration, we have very little knowledge of the social and employment outcome of AS people in a lifelong context, as well as their support and tolerance by others.

Treatment and Support Issues

The concept of treatment is not straightforward when applied to a condition that overlaps with the personality of the individual themselves. It assumes that the AS phenotype should be normalized to satisfy social constraints and improve quality of life. This has been gradually recognized over the last 40 years, to the point that the dominant belief is that AS should not and cannot be cured, but that its comorbidity should. Even this cannot be taken for granted, as a large part of the so-called comorbidity of AS originates from reactions to external constraints. The belief by the scientific community that anxiety and depression are comorbidities of AS overlooks the specific relation that AS people have with conflicts. Modifying reality (which would, for a psychotic person, be criticized as sharing delusions with the patient) is an option in family, school, or employment crises involving a person with AS, when this reality is unbearable. For example, "depression" related to bullying should be primarily treated by policing the bully's conduct and/or by temporarily withdrawing the bullied child from school, unlike the treatment of endogenous depression, which may, of course, nevertheless occur.

It was acknowledged that behavioral modification "involved heroic effort and (…) limited results" (Frith, 1991, p. 16). Nonetheless, the conviction dominating the 1980s was that AS people do not understand other people's intentions and emotions and should learn them, leading to the development of social skills training groups. Their purpose was somewhere between training a supposedly missing function and providing help for crisis situations. The results were disappointing due to disinterest or overapplication of the learned rules. Moreover, social skills training is centered on the demands of people other than the patient himself, diminishing their interest for the person with AS. Focusing instead on differences between them and the world around them, and how to pursue their own interests, while avoiding conflict with the outside world, may restore self-esteem, while maintaining motivation for support.

Individual psychological support is recommended, but its purpose is yet to be determined. The necessity to abandon the psychodynamic framework threw psychologists in ready-made cognitive therapy, which AS people may find naïve and trivial. We suggest that "skills" learning should be replaced by a mechanistic learning of how the social world works. Two messages have to be transmitted: other people do not function like they do, and non-autistic people are stronger and more numerous. AS people may benefit from establishing compromises between their own needs and modes of functioning and those of others, as well as from opportunistic problem solving strategies (half psychological support, half intervention *in situ*). It is beneficial for them to have a resource person, in whom they have gained confidence, to solve administrative, financial, or employment imbroglios in which they are trapped. Choosing the right treatment targets is essential, as for autism, and the basic model of global assessment, detecting deficits, and providing training is not valid. For example, motor clumsiness is not a suitable target of intervention when it does not interfere with the person's interests.

Conclusion

AS history reflects an interaction between scientific, historical, and personal issues. It spans from its discovery on a clinical basis, its merging with autism, and its transient status under an ill-conceived American and psychiatric centered definition to its official disappearance under questionable scientific principles and has led to its current semi-clandestine existence. Confronting the shifting foundations of modern psychiatry, it exemplifies how uncertain, arbitrary, and unstable the delineation of a psychiatric category is when it does not coincide with the discovery of its neurobiological mechanisms. Aside from its historical journey, AS also confronts important aspects of human neuroscience and psychology, the ongoing evolution of human rights, and the biological and ethical nature of human society. The questions raised by a diagnosis of AS, as well as those by AS people themselves, have participated in the progress of all of these domains. While it is justified to question the nature of its boundaries, the diagnosis of AS remains essential for the virtual community of people who recognize themselves to be in it. Their confidence in having a place among human society is anchored in the name other humans give to them.

Neurobiology of Down Syndrome

Stella Sakhon and Jamie Edgin

Department of Psychology, The University of Arizona, Tucson, AZ, USA

Down syndrome (DS/trisomy 21) is the most common genetic cause of intellectual disability, occurring in 1/700 live births (Parker et al., 2010). The syndrome involves the triplication of over 300 genes and is associated with characteristic facial features, delays in physical growth, and impairments in intellectual and adaptive function (Epstein et al., 1991). The cognitive and behavioral phenotype is well characterized (Dierssen, 2012; Edgin, 2013; Fernandez & Reeves, 2015; Grieco, Pulsifer, Seligsohn, Skotko, & Schwartz, 2015), but more information is required about the trajectories of cognitive and neural development in the syndrome and the bases for individual differences, which are extensive (Karmiloff-Smith et al., 2016).

The study of DS is associated with some notable "firsts" in biological science. In 1959, it was the first chromosomal abnormality to be discovered (Lejeune, Gautier, & Turpin, 1959), just 4 years after Tjio discovered the total number of human chromosomes (Tjio & Levan, 1956). This discovery paved the way for other notable accomplishments in medical genetics (Patterson & Costa, 2005). DS is also among the first intellectual disability syndromes to have representative animal models (the Ts65Dn mouse model, Davisson et al., 1992), allowing for substantial advances in the understanding of the neurobiology of the condition as well as the development of therapeutic treatments (Bartesaghi et al., 2015; Fernandez et al., 2007). Further, neural and cognitive development across the lifespan in DS may be of great interest to the broader scientific community. People with DS advance through the developmental period while bearing significant β-amyloid burden linked to the triplication of the amyloid precursor protein (APP) gene and harboring certain medical comorbidities (i.e., including sleep disturbance). In fact, DS stands as the condition with the greatest risk for the early onset of Alzheimer's disease (AD), demonstrating risk of the disease decades in advance of the general population (Wiseman et al., 2015). DS is currently regarded as a population with significant potential for successful pharmacological and behavioral treatments, both in the infant period and in aging adults who are susceptible to AD-related decline (Bartesaghi et al., 2015; Rafii et al., 2015). Findings from studies examining sleep disorders in this group suggest additional avenues of treatment, based on remediation of sleep deficits (Breslin et al., 2014;

Edgin et al., 2015). We will now overview the wealth of findings on the neurobiology of DS to date, including our current understanding of brain development and aging in humans and animal models of the condition.

Brain Structure Across Development in Down Syndrome

There are rich sets of structural brain data from individuals with DS, primarily collected postpartum. Less *in vivo* neuroimaging data exist with DS, and most have focused on the adult period in reference to AD cognitive-related decline. It is known that brain alterations start during the fetal period (by the second trimester) and progress through adulthood (Ábrahám et al., 2012; Guidi et al., 2008; Wisniewski, 1990). During prenatal development (17–21 weeks of gestation), individuals with DS show altered neurogenesis and reduced cell numbers in the hippocampus and parahippocampal cortex, including the presence of apoptotic cell death (Guidi et al., 2008).

Differences in the DS brain become more pronounced across the first year of life (Ábrahám et al., 2012). One study examining brain development in 101 individuals with DS from birth to age 5 years found delays in myelination and proposed that delays could alter the function of the hippocampal circuitry. Although at birth, the brain shape in infants with DS did not differ from non-DS infants, around 3–5 months of age, the anterior–posterior diameter was shorter, the frontal lobes were reduced, the occipital poles were flatter, and the brain stem and cerebellum were smaller in DS infants compared with non-DS infants (Wisniewski, 1990). Wisniewski (1990) also reported decreases in neurons of layers II and IV and myelination delay in 22.5% DS and only 6.8% non-DS children.

Structural neuroimaging studies have also confirmed structural brain abnormalities in DS, including reduced global brain volume (Lee et al., 2015; Pinter, Eliez, Schmitt, Capone, & Reiss, 2001; White, Alkire, & Haier, 2003). A voxel-based morphometric study found reductions in gray matter (GM) volume, with significant decreases in the CA2/CA3 region of the left hippocampus (White et al., 2003). A structural neuroimaging study by Lee et al. (2015) found a 7% reduction, specifically, in cortical GM volume (frontal, temporal, and occipital) in individuals with DS. They found a 12% reduction of cortical surface area (SA) but a 4% reduction of cortical thickness (CT) in DS, suggesting that reduced cortical volume may be driven by cortical SA rather than CT. Another study using automatic measurements of CT from structural MRI found a negative correlation between CT and age in the bilateral frontal, temporal, and parietal lobes and cingulate gyrus in nondemented individuals with DS (Romano et al., 2016), suggesting brain regions associated with age-related decline are impacted before the onset of any symptoms of dementia.

Several studies have also suggested major alterations in white matter (WM) development. Using diffusion tensor imaging (DTI), researchers found adults with DS had significantly reduced WM pathways in the frontal lobes compared with controls (Powell et al., 2014). One study examining the differences in myelination in the hippocampus, in fetuses and patients with DS from midgestation to adulthood, showed that those with DS differed in the number and density of myelinated fibers compared with age-matched controls. The difference in fiber density was subtle in the first few months after birth but became more evident across age (Ábrahám et al., 2012). Recent work has shown that genes regulating oligodendrocyte differentiation and myelination display altered expression in DS, suggesting that poor myelination may contribute to slow neural transmission and perhaps even underdevelopment of some later-developing brain structures (Edgin, 2013; Olmos-Serrano, Kang, et al., 2016).

In addition to structural brain abnormalities, individuals with DS show aberrations in functional connectivity. A study testing resting-state functional connectivity showed significantly greater between-network connectivity in individuals with DS as compared with a typically developing (TD) group (Vega, Hohman, Pryweller, Dykens, & Thornton-Wells, 2015). Another study examined neural activation between individuals with DS and a TD group when listening to a short story. Significantly greater activation in midline regions of the frontal lobe and cingulate cortex in DS suggested altered functional neural organization during language processing compared with TD individuals (Jacola et al., 2014).

In comparison to the general population, individuals with DS have a higher risk of developing AD and present AD neuropathology at much younger ages (Malamud, 1972). Almost all individuals with DS over 35–40 years of age develop β-amyloid (Aβ) plaques and neurofibrillary tangles (characteristic of AD neuropathology), evidenced by autopsied patient data and PET imaging with β-amyloid markers (Zigman & Lott, 2007). Recent work seeks to address whether the presence of amyloid deposition or associated biomarkers could predict AD neuropathology before the development of dementia (Handen et al., 2012; Head et al., 2011; Rafii et al., 2015; Teipel & Hampel, 2006). Head et al. (2011) suggested that levels of plasma Aβ could help predict variation in cognitive function in DS with or without dementia; however, group differences in plasma Aβ did not predict early signs of AD neuropathology in DS. A recent study by Rafii et al. (2015) sought to identify AD biomarkers. They successfully collected volumetric MRI, amyloid positron emission tomography (PET), fluorodeoxyglucose (FDG) PET, and plasma Aß data that are consistent with preclinical AD in DS. While evidence is accumulating to suggest links between sleep disturbance and the development of AD in the general population, there is little extant work relating these risk factors in DS, and some have hypothesized poor sleep to be an important predictor of this group's progression to dementia (Fernandez & Edgin, 2013).

Mouse models of DS (e.g., Ts65Dn and Tc1) have also provided insight to the neurobiology of DS and numerous potential pharmacological therapies (Bartesaghi et al., 2015). Recent work has further refined the profile of hippocampal dysfunction in these models, a profile consistently demonstrated from decades of work (Reeves et al., 1995). Specifically, the Tc1 mouse model displays reduced entorhinal cortex input to the dentate gyrus (DG) and abnormal DG–CA3 connectivity, coupled with impaired information processing in CA3 and CA1 networks (Witton et al., 2015). A recent longitudinal behavioral study from birth to adulthood in the Ts65Dn mouse model found reversal learning impairments across the lifespan and evidence for an age-dependent decline, findings suggesting that early behavioral markers may be predictive of later cognitive status (Olmos-Serrano, Tyler, Cabral, & Haydar, 2016). More information is needed regarding the longitudinal profiles of specific cognitive and neural deficits from animal models, such as the data gathered from the elegant lifespan approach employed by Haydar and colleagues. These data would help to guide early interventions for improving cognitive function in humans with DS.

Also important to understanding the neurobiology of DS are approaches that incorporate the influence of health and environment on these brain and cognitive phenotypes. DS is not a homogeneous condition, but is characterized by extensive variation in developmental trajectories and cognitive end points that may reflect individual differences in health, environmental resources, or background genetics. For instance, individual differences in sleep among people with DS, including diagnosed obstructive sleep apnea (present in approximately 50%), significantly correlate with variation in verbal IQ and executive function across a wide range of ages (Breslin et al., 2014). Other studies have suggested that the behavioral profile of DS may also relate to background genetics in addition to chromosome 21 variation, including risk alleles for attention deficit hyperactivity disorder (ADHD; Mason, Spano, & Edgin, 2015). Further, individuals with DS are embedded within a social environment, and some groups have shown a better response to intervention in the context of environmental enrichment (Catuara-Solarz et al., 2015). We believe that the study of DS offers a wealth of information to inform how sleep may impact learning (Edgin et al., 2015) and clues to the development of AD. However, a careful examination of these links requires the field to fully recognize the multisystem complexity and profiles of individual differences associated with trisomy 21.

Future Directions and Conclusion

Work already conducted in humans and animal models of DS provides us with a wealth of information regarding brain development in a population at great risk to develop both AD and sleep disturbance. Open questions include when may individuals with DS suffer from the impact of AD progression and what factors, including variability in health, genetics, and environment, may predict those with different developmental trajectories. Future studies that provide more information about the developmental trajectories in DS may influence pharmacological and behavioral treatments.

Stella Sakhon is a graduate student in Cognition and Neural Systems at the University of Arizona. Stella is investigating alternative language learning mechanisms in individuals with Down syndrome. The results of her work could have applications for designing intervention programs for language learning deficits in Down syndrome and will provide additional information about the influence of attention and sleep on word learning. Ms. Sakhon is a 2016 Galileo scholar in the University of Arizona, College of Science.

Jamie Edgin, PhD, is an assistant professor of Cognition and Neural Systems program at the University of Arizona. He is an assistant professor and the director of the Memory Development and Disorders Laboratory in the Department of Psychology at the University of Arizona. Her research centers on typical and atypical memory development and sleep. Currently she is creating a new computerized battery for the assessment of memory in preschoolers and special populations. She has received awards for her work on Down syndrome, including the Inaugural David Cox Rising Star Award for Down Syndrome Research from the LuMind Research Down Syndrome Foundation and the Charles Epstein Award. She is a fellow of the Psychonomics Society and holds grants from the LuMind Research Down Syndrome Foundation, the NIH, and the Bill and Melinda Gates Foundation.

Vascular Dementia

Vascular dementia (VaD) defines impaired cognitive function due to cerebrovascular disease. VaD is most common in older individuals (Middleton, Grinberg, Miller, Kawas, & Yaffe, 2011) and accounts for 15–20% of all forms of dementia (Gorelick et al., 2011). Alzheimer's disease (AD) is the most prevalent etiology of age-related dementia; however a combination of VaD and AD (i.e., mixed dementia) is the dominant form of neuropathology in postmortem studies of aged individuals with antemortem diagnoses of dementia (Lee, 2011). The differences in prevalence observed in clinic versus autopsy have led some groups to suggest that cerebrovascular disease is a primary driver of AD-related pathology, though the position is not universally endorsed.

In addition to advanced age, VaD risk factors include low educational attainment, family history of dementia, diabetes, cardiovascular disease, and lipid abnormalities (Gorelick et al., 2011). The impact of gender as a risk factor remains unclear since the historic literature prioritized outcomes in males (Desmond et al., 2000; Korczyn, Vakhapova, & Grinberg, 2012; Lee, 2011). By contrast, racial/ethnic differences are more well defined. Compared with Caucasians, African Americans and Asians have higher risks of VaD, with a 50% increase in risk reported in some studies (Fitzpatrick et al., 2004).

Subtypes of Vascular Dementia

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is the dominant genetic subtype. CADASIL is related to a mutation on the Notch-3 region of chromosome 19 (Desmond, 2004). First symptoms appear between the ages of 20 and 40 and typically include cognitive impairment, migraine with aura, and/or mood disorders. While the young age of onset can lead to misdiagnosis, CADASIL is believed

to account for a minority of VaD cases (Chabriat, Joutel, Dichgans, Tournier-Lasserve, & Bousser, 2009).

Large vessel cerebral infarcts account for approximately 15% of VaD cases and typically reflect an embolic etiology (Korczyn et al., 2012). One-third of older individuals who experience a large cortical stroke meet diagnostic criteria for VaD within 3 months of the infarct (Desmond et al., 2000), particularly when the language network is damaged (Jellinger, 2008). Ischemia can also cause cortical injury when insufficient blood exchange occurs in the "watershed" or border zone regions along the dorsal surface of the cortical mantle (Korczyn et al., 2012).

Small vessel ischemic disease results from the occlusion of penetrating arteries that provide blood to the deep structures and white matter pathways (Desmond, 2004), which are evidenced on magnetic resonance imaging as white matter hyperintensities (WMH). These vascular injuries are common in individuals over the age of 65 and correlate with the degree of cognitive impairment. Increased burden of WMH correlates with cardiovascular disease (Korczyn et al., 2012) and is believed to involve microangiopathy, venous collagenosis, and Wallerian degeneration (Korczyn et al., 2012). Significant ischemic injury in subcortical brain regions perfused by the lenticulostriate arteries is sufficient to result in dementia. Unfortunately, many individuals with subcortical ischemia are prone to additional cortical and subcortical infarcts due to the underlying cardiovascular disease (Jellinger, 2013; Korcyzn et al., 2012; Lee, 2011).

Symptoms of Vascular Dementia

Symptoms may appear gradually over time, or suddenly after a first cortical or strategically located subcortical stroke. The typical VaD cognitive phenotype includes prominent executive dysfunction characterized by abnormalities in divided attention, planning, multitasking, sequencing, etc. (Sachdev et al., 2014). However, other symptoms may be present depending on the location and amount of brain tissue involved, including classic stroke syndromes (e.g., neglect, prosopagnosia, aphasia, etc.). Physical symptoms include motor abnormalities and gait disturbance that mimic other etiologies (e.g., Parkinson's disease, normal pressure hydrocephalus) that complicate the differential diagnosis.

Treatment of Vascular Dementia

Clinical intervention for VaD includes two parallel paths. The first is to treat the underlying mechanisms, which typically includes a focus on the cardiovascular system. Aspirin, medications (e.g., antihypertensives), exercise, smoking cessation, and weight management can reduce the risk of additional cerebrovascular events. The second line of treatment targets brain mechanisms using medications originally developed for AD. Cholinesterase inhibitors provide modest therapeutic benefit in terms of cognitive symptoms and apathy (Erkinjuntti et al., 2002; Wilkinson et al., 2010). By contrast, glutamate receptor antagonism is not effective (McShane, Areosa Sastre, & Minakaran, 2006).

Future Directions

For the majority of cases caused by ischemic injury, VaD can be difficult to differentiate from other etiologies with high base rates in the elderly population (Gorelick et al., 2011; Jellinger, 2013). This is particularly true when symptom onset is slow and insidious as in the majority of subcortical ischemic disease (Lee, 2011). Further, the near ubiquitous nature of WMH on neuroimaging among older individuals requires a determination if the vascular burden exceeds expectations for age. Refining the diagnostic process represents a critical future direction. Novel neuroimaging methods using diffusion-based MR sequences and multimodal approaches offer enhanced opportunities to improve diagnostic accuracy (Attems & Jellinger, 2014). Further, non-pharmaceutical interventions, such as direct current magnetic stimulation, are needed to improve cognitive and psychiatric symptoms associated with vascular injury. Direct current stimulation is an exciting therapeutic modality to support compensatory recruitment of healthy (non-infarcted) brain tissue.

Frontotemporal dementia (FTD) is the collective term for the various clinical presentations resulting from frontotemporal lobar degeneration (FTLD). This pathological process involves progressive neuronal loss primarily in the frontal and temporal lobes. Unlike Alzheimer's disease, FTD is particularly prevalent in individuals aged 65 or younger. The current diagnostic framework identifies three core syndromic diagnoses: one that presents with prominent behavioral changes (behavioral variant) and two that initially present as changes to the understanding and production of language (primary progressive aphasia [PPA]; semantic variant and nonfluent variant). FTLD can also present as predominantly motor syndromes including corticobasal syndrome (CBS), progressive supranuclear palsy (PSP-S), and motor neuron disease (MND). Although individuals tend to meet criteria for one syndrome in the early stages, as the neurodegeneration inevitably spreads, signs and symptoms of two or more syndromes can emerge (Boxer et al., 2012). In addition to the existence of multiple FTD clinical syndromes, the underlying molecular pathology (e.g., different strains of tau or TDP-43 aggregates) is heterogeneous.

Clinical Presentations

Behavioral variant FTD (bvFTD) is the most common clinical FTD syndrome and is marked by severe behavioral and personality changes often in the context of relatively preserved global cognitive functioning (Lanata & Miller, 2016). A diagnosis of possible bvFTD requires the emergence of three out of the following six behavioral/cognitive changes as the first symptom: behavioral disinhibition, apathy or inertia, loss of sympathy or empathy, perseveration or

stereotyped/compulsive/ritualistic behavior, hyperorality, and deficits in executive tasks with relative sparing in episodic memory and visuospatial skills (Rascovsky et al., 2011). Behavioral disinhibition may be described as inappropriate and impulsive reactions manifesting as disregard for social conventions that are out of character for the individual. Examples may include cursing, telling offensive jokes, new onset of substance abuse, urinating in public, or committing criminal behavior. Apathy or inertia is a lack of interest or engagement in activities, exhibiting reduced motivation or concern for what was once important. This may include poor hygiene or disregard for social responsibilities (Lanata & Miller, 2016). Loss of sympathy or empathy is typically detected when the patient demonstrates indifference to the suffering of a loved one or an inability to interpret or process others' emotional experience. Examples of perseveration or stereotyped behavior may include simple, motoric movements such as tapping, humming, or rubbing. Compulsive behaviors may also be more complex such as detailed routines, counting, or verbalizing repetitive phrases. Hyperorality is commonly associated with an increased affinity toward sweet foods to the extent of weight gain.

While the behavioral changes described above are most prominent in bvFTD, cognitive changes can also emerge, especially later in the disease course. These changes include difficulty with multitasking, poor working memory, and mental rigidity (Rascovsky et al., 2011). Since changes in behavior, emotional expression, and personality typically present before the onset of measurable cognitive impairment in middle-aged individuals, bvFTD is often misdiagnosed as a psychiatric disorder rather than a neurodegenerative disease (Lanata & Miller, 2016). This can lead to increased distress due to inappropriate treatment and a delayed proper diagnosis (Woolley, Khan, Murthy, Miller, & Rankin, 2011). Therefore, continued education and awareness of this syndrome across mental health and medical settings is critical to accurately and swiftly diagnose this disorder earlier in the disease process. In fact, it is recommended that middle-to-late life patients with new onset of neuropsychiatric symptoms be considered for a neurodegenerative evaluation (Woolley et al., 2011).

PPA is the other major subset of FTD, which is defined as the insidious onset of communication difficulties as the predominant source of disability in the early stages of the disease process. At the early stages of PPA, communication deficits are isolated, and focal atrophy can be observed on brain imaging. However, as the disease progresses, other cognitive, behavioral, and motor problems can emerge (Gorno-Tempini et al., 2006). PPA is broken down into three subtypes: nonfluent variant (nfvPPA), semantic variant (svPPA), and logopenic variant (lvPPA). The underlying neuropathology of nfvPPA and svPPA subtypes is FTLD, whereas Alzheimer's pathology is most commonly associated with the logopenic subtype. Therefore, the current entry will focus on the first two subtypes.

The nonfluent variant of PPA is characterized by effortful, halting speech with inconsistent speech sound errors and distortions (apraxia of speech) and agrammatism in language production. Brain imaging typically shows atrophy localized to the frontoinsula region at the early stages of the disease (Gorno-Tempini et al., 2011). These impairments are typically in the context of spared single-word comprehension and spared object knowledge (naming and semantics). Apraxia of speech, meaning deficits in planning the articulation of words or inconsistent speech sound errors with distortions, is often the first symptom of this syndrome (Caso et al., 2013). Later in the disease process, more agrammatism emerges. Agrammatism in the production of speech may involve impairments in the accuracy of tense use (i.e., "buyed" instead of "bought") or the progressive reduction in use of prepositions, resulting in speech that primarily consists of nouns (Thompson & Mack, 2014). Inability to comprehend grammar may also be present, such as the diminishing ability to understand syntactically complex sentences (i.e., "went to the store after eating lunch"; Charles et al., 2014). These speech impairments increase throughout the disease process until the affected individual becomes mute (Gorno-Tempini et al., 2006).

Semantic variant (svPPA) is characterized by the loss of semantic knowledge for low-frequency nouns, inability to name objects, and impaired single-word comprehension (Gorno-Tempini et al., 2011). This variant is highly localized to the anterior temporal lobes (ATL), with atrophy typically more severe on the left side in comparison with the right (Mesulam et al., 2014; Wilson et al., 2010). However, individuals that do have pronounced atrophy in the right ATL also commonly struggle with identifying well-known faces and knowing information associated with those people (Kamminga et al., 2015). Patients with svPPA may present with overly general and empty speech and the use of nonspecific words when referring to objects (i.e., "apple" when referring to any fruit). Due to semantic knowledge loss, individuals may also have surface dyslexia, meaning that they lose the ability to read irregular words (e.g., knight, island) due to the loss of meaning associated with the word. Loss of semantic knowledge commonly occurs within the context of preserved repetition and speech production (Gorno-Tempini et al., 2011).

Related Frontotemporal Dementia Syndromes

Other clinical syndromes associated with FTLD can present with primary changes in motor control and sensorimotor integration, though this presentation is less common among the FTLD syndromes (Lanata & Miller, 2016). These symptoms can emerge early in the disease course or can accompany one of the behavioral or language syndromes. In fact, approximately 18% of bvFTD cases show movement changes, while these findings are rarely seen in svPPA (Park & Chung, 2013). When motor changes present as the first clinical symptom, PSP-S, CBS, or MND should be considered.

Progressive supranuclear palsy (PSP) is an atypical parkinsonian disorder characterized by abnormal vertical saccades (supranuclear gaze palsy) and postural instability with frequent falls (Litvan et al., 1996). The reason for falls may be multifactorial, including postural instability, impaired eye movements, and impulsivity. Since slowed movement and impaired postural reflexes are also typically present among individuals with PSP, falls can be particularly dangerous since these individuals have difficulty catching or protecting themselves. Cognitive symptoms can also be present with predominant executive dysfunction along with reduced mental speed, attention deficits, and possible personality changes (Donker Kaat et al., 2007).

CBS is also classified as an atypical parkinsonian syndrome. To meet criteria for CBS, individuals must present with an insidious onset and gradual progression of at least two motor symptoms within two separate clusters. The first cluster includes limb rigidity or loss of power for voluntary movement, abnormal muscle tone, and jerky muscle contractions. The second cluster includes inability to perform planned movement, sensory loss, and alien limb syndrome (condition in which limbs move without conscious control; Armstrong et al., 2013). Some CBS patients might also show signs of executive dysfunction, behavioral or personality changes, visuospatial deficits, or nonfluent language changes such as effortful, agrammatic speech.

Several overlapping symptoms within PSP and CBS complicate the diagnostic process. More than 50% of autopsy-confirmed cases of PSP are misdiagnosed as CBS prior to death (Wadia & Lang, 2007). Overlapping presentation includes rapid disease progression, parkinsonism that responds poorly to levodopa treatment, ocular abnormalities, and cognitive symptoms (Litvan et al., 1999). Furthermore, although asymmetry is classically associated with CBS, asymmetric motor symptoms can occur in both PSP and CBS and are not necessarily more common in CBS (Armstrong et al., 2013).

MND is typically associated with amyotrophic lateral sclerosis (ALS) (Lou Gehrig's disease). To meet criteria for MND, individuals must show signs of neuronal abnormalities in both the upper and lower extremities on physical examination or electromyogram (EMG) (Geevasinga et al., 2016). Typical presentation involves fasciculations, muscle weakness, and difficulty with swallowing (Olney, Spina, & Miller, 2017). While MND can present with any of the core clinical FTD variants, it is most common in individuals with bvFTD. However, the survival rate among those with both MND and bvFTD is lower since individuals with bvFTD are less likely to be compliant with treatment recommendations (Olney et al., 2005).

Epidemiology of FTD

FTD is one of the most common causes of dementia with onset prior to age 65 and might be even more prevalent than AD in those under age 60 (Knopman, Petersen, Edland, Cha, & Rocca 2004). The average age onset of FTD is 56 years old and typically emerges between the ages of 45 and 64. However, cases of younger onset have been cited (Mercy, Hodges, Dawson, Barker, & Brayne, 2008). FTD can occur as early as within the second decade of life with 13% of cases occurring before the age of 50 (Onyike & Diehl-Schmid, 2013). Earlier onset cases more commonly present with svPPA or bvFTD, and later onset typically presents with the nfvPPA syndrome (Flanagan et al., 2015). In general, FTD progresses faster than Alzheimer's disease, but the rate of decline in FTD varies based on the syndrome. The svPPA subtype has the longest course, with estimates of approximately 12 years of life on average after diagnosis. The survival rate of nfvPPA and bvFTD are similar, ranging from 8 to 9 years on average (Kansal et al., 2016). Nevertheless, a small subset of individuals progress very slowly and may live up to 20 years after diagnosis (Suhonen et al., 2015).

The true prevalence of FTD is difficult to estimate within the general population given that it is easily confused with or confounded by psychiatric disorders and evolving diagnostic criteria. According to the most recent estimates, between 10 and 46 incidences per 100,000 individuals aged 45–64 are currently diagnosed with FTD. This translates to an estimated point prevalence of about 20,000–30,000 individuals in the United States (Knopman & Roberts, 2011). Of those with FTLD, approximately 50–60% present with a bvFTD syndrome, and up to 40% present with a PPA disorder (Johnson et al., 2005; Rohrer et al., 2011). Less than 5% of cases with FTLD manifest as a motor syndrome (i.e., CBS, PSP-S, MND), making these presentations rare. Although few studies report a higher prevalence in males (Johnson et al., 2005), most studies consider FTLD to be equally prevalent among males and females (Hogan et al., 2016; Onyike & Diehl-Schmid, 2013).

Neuropsychological Assessment

Neuropsychological assessment can be a helpful tool to distinguish clinical presentations of FTD. In the early stages, some bvFTD patients show executive functioning deficits, while others may have relatively intact cognition. As the disease progresses, executive dysfunction becomes more evident, while episodic memory, language, and visuospatial functioning remain more intact (Piguet & Hodges, 2013; Rascovsky et al., 2011; Seeley et al., 2008). For instance, they may perform poorly on tasks of working memory, phonemic verbal fluency, set shifting, and inhibition (Bott, Radke, Stephens, & Kramer, 2014). Inability to monitor errors on testing has also been associated with bvFTD. For instance, bvFTD patients are more likely to make a higher number of repetition and rule violation errors on testing than patients with other neurodegenerative diseases (Carey et al., 2008; Possin et al., 2012). They may also have deficits in emotion recognition (Kumfor & Piguet, 2012) and theory of mind (Gregory et al., 2002).

Since the hallmark feature of svPPA is loss of object knowledge, these patients typically have profound impairment on tasks of confrontation naming without benefit from phonemic or semantic cueing (Gorno-Tempini et al., 2011). They also show impairment in semantic verbal fluency, in which they are asked to generate as many words related to a specific category (i.e., animals, boys' names) as they can within 1 min. This becomes a challenging task for individuals with svPPA due to the loss of conceptual meaning of the category presented. Performance on tasks related to single-word comprehension and reading irregular words is also commonly impaired (Hodges & Patterson, 2007; Mesulam et al., 2009). Episodic memory for nonverbal information (Irish & Piolino, 2016), executive functioning (Marra et al., 2007), and visuospatial abilities (Seelaar, Rohrer, Fox, van Swieten, & Pijnenburg, 2011) are relatively spared.

The hallmark features of agrammatism and effortful, halting speech in nfvPPA are accompanied by neuropsychological deficits primarily related to language and executive functions. These individuals may show slowed word retrieval, commit errors in relation to word retrieval, exhibit an inability to understand complex syntax, and have difficulty repeating words (Leyton et al., 2014; Rohrer et al., 2010). Mild to moderate executive dysfunction may also be present, such as impairment on tasks of phonemic fluency, working memory, set shifting, and inhibition (Gorno-Tempini et al., 2004; Libon et al., 2007). In comparison with svPPA, nfvPPA individuals have spared single-word comprehension and spared object knowledge and therefore are expected to benefit from cueing on confrontational naming tasks, for example (Kertesz, Blair, McMonagle, & Munoz, 2007). These individuals also have relatively spared episodic memory and visuospatial processing early in the disease (Gorno-Tempini et al., 2004; Murray et al., 2007).

Treatment Planning and Safety Considerations

The cognitive, behavioral, and movement changes place individuals with FTD at increased risk for injury and functional decline. Therefore, careful planning and consideration for safety is crucial as the disease progresses. Caregivers of those with bvFTD should be aware of the unique challenges associated with this disease process that differ from Alzheimer's disease and other variants of FTD. For instance, poor judgment, impulsivity, and disinhibition may lead to reckless conduct including overspending or inappropriate social behavior. Environmental controls are needed, including limited access to bank accounts, keys to vehicles, and dangerous medications. Additionally, individuals with FTD benefit from routines and familiar settings (e.g., restaurants where the individual is already known; Manoochehri & Huey, 2012). Hyperorality can be managed through increased supervision during meals to avoid excessive weight gain or dangerous placement of objects in the mouth (Manoochehri & Huey, 2012). Furthermore, removal of dangerous items from the home such as firearms and weapons is important (Merrilees, Klapper, Murphy, Lomen-Hoerth, & Miller, 2010). Clinicians are encouraged to use high-frequency words to enhance comprehension and improve communication (Gorno-Tempini et al., 2011). Additionally, due to agrammatism in speech comprehension in patients with nfvFTD, it is recommended that clinicians use simple grammar, ideally with one verb per sentence, in order to optimize communication. Engaging speech-language pathologists into the clinical care plan helps to tailor communication styles to accommodate for the patient's deficits. Additionally, family members of individuals diagnosed with FTD benefit from strategies to reduce defensiveness and emotional turmoil related to socially and personally distressing symptoms (Kortte, Stevenson, Hosey, Castillo, & Wegener, 2012).

For individuals experiencing weakness and any changes in movement, clutter on the floor, rugs, furniture, and unnecessary height discrepancies on the ground should be minimized as much as possible to protect against injury (Merrilees et al., 2010; Talerico & Evans, 2001). Lack of insight into the presence and/or severity of cognitive/motor symptoms and the poor impulse control increase fall risks. In severe cases, seatbelts on wheelchairs are needed to limit unsupervised ambulation.

Addressing caregiver burnout is especially important for those caring for a loved one with FTD. Several studies have shown that the stress associated with caring for an individual diagnosed with FTD is greater than those caring for a loved one with Alzheimer's disease (Boutoleau-Bretonnière, Vercelletto, Volteau, Renou, & Lamy, 2008; Mioshi, Bristow, Cook, & Hodges, 2009; Rascovsky et al., 2011). This stress is related to physical demand, disease progression, and depression (Mioshi et al., 2009). Caring for a loved one with bvFTD is particularly challenging due the emotional and personality changes that disrupt the bond and empathy within the relationship. Consistent with this point, empirical studies demonstrate that caring for an individual with bvFTD induces greater distress burden than caring for a loved one with svPPA or nfvPPA (Mioshi et al., 2009, 2013). These caregivers typically experience poorer sleep quality, apathy, and reduced daytime activity (Merrilees et al., 2013). Recommendations to address caregiver burden and improve quality of life include engaging the whole family system in care to relieve one family member of sole responsibility, identifying rewarding aspects of caregiving, reminiscing about positive memories, and seeking outside assistance for skills-based care if the financial means are available (Caceres et al., 2016). Referrals to support groups or individual therapy may also promote healthy coping for caregivers (Mioshi et al., 2013), as well as assist family members to develop realistic expectations of their loved one's cognitive, behavioral, and physical limitations (Caceres et al., 2016).

Introduction

Traumatic brain injury (TBI) is a significant public health problem facing all industrialized countries. Estimates of TBI in the United States suggest that as many as 4 million brain injuries occur per year (Coronado, Johnson, Faul, & Kegler, 2006; Silver, McAllister, & Yudofsky, 2005), resulting in over 1 million hospital emergency department visits, 300,000 hospitalizations, and 50,000 deaths result from TBI annually (Rutland-Brown, Langlois, Thomas, & Xi, 2006).

This chapter will provide an overview of TBI across the spectrum of severity. Particular focus will be placed on evaluation and management of mild traumatic brain injury (mTBI), given (a) its high incidence relative to moderate and severe TBI and (b) the importance of understanding the complex array of neurobiological, psychosocial, and environmental factors known to influence recovery and outcome from mTBI. The behavioral approaches to managing persisting symptoms following mTBI should be of interest to neuropsychologists or other mental health providers involved in care delivery for mTBI patients in a variety of settings.

Definition/Classification

TBI is commonly defined as *an alteration in brain function, or other evidence of brain pathology, caused by an external force, and characterized by the following: 1) any period of loss or decreased level of consciousness (LOC), 2) any loss of memory for events immediately before (retrograde) or after (posttraumatic) the injury, 3) any neurological deficits, and/or 4) any alteration in mental state at the time of injury (National Institute for Neurologic Disorders and Stroke [NINDS]*

Evidence of TBI can include visual, neuroradiologic, or laboratory confirmation of damage to the brain, but TBI is more often diagnosed on the basis of acute clinical criteria. Modern structural (e.g., diffusion tensor MRI) and functional imaging (resting-state functional MRI) techniques show promise as emerging tools to evaluate TBI, and it is possible that other sensitive biomarkers may be developed in the future.

Common mechanisms of TBI include the head being struck by an object, the head striking an object, the brain undergoing an acceleration/deceleration movement, a foreign body penetrating the brain, or forces generated from events such as a blast or explosion. Motor vehicle crashes have consistently been cited as the most common cause of TBI, accounting for 40–60% of all TBIs annually (Kraus & Chu, 2005). All forms of transportation, however, are common causes of TBI, including motorcycle crashes, bicycle accidents, and pedestrian injuries. Certainly, there has been an increased focus on the high frequency of concussion or mTBI encountered by athletes participating in contact and collision sports at all competitive levels.

Numerous systems have been developed over the years to define and classify TBI severity along a continuum from mild to moderate to severe. The Glasgow Coma Scale (GCS) (Jennett & Teasdale, 1981) is the most recognized and widely used method for grading TBI severity and can often be retrieved from hospital records. The GCS provides an indicator of gross neurologic status by assessing motor function, verbal responding, and the patient's ability to open his or her eyes voluntarily or in response to external commands and stimuli. Other classification systems that use multiple severity indicators improve the sensitivity in the detection of mTBI, while also taking into consideration traditional acute injury characteristics that have been presumed to predict outcome following mild and moderate brain injury (see Table 1 for example).

Functional Neuroanatomy of TBI

Focal Brain Injury

In more severe forms of TBI, structural brain damage after trauma can be categorized based on clinical and neuroradiologic findings. Common forms of focal brain injury include skull fracture, contusions and lacerations, intracranial hematoma, epidural hematoma (EDH), subdural hematoma (SDH), and brain damage due to increased intracranial pressure. Contusions are the most common brain damage due to TBI and have a characteristic distribution preferentially affecting the pole of the frontal lobe, the inferior aspect of the frontal lobes, the temporal poles, the lateral and inferior aspects of the temporal lobe, and the cortex above and

below the operculum of the Sylvian fissures. Intracranial hematoma is the most common cause of clinical deterioration and death in patients who were initially lucid after TBI. SDH is a common occurrence in TBIs of any severity, especially among older adults, which is often associated with swelling of the ipsilateral cerebral hemisphere and can cause secondary complications from mass effects.

Diffuse Brain Injury

Acceleration/deceleration and rotational forces often produce effects that are microscopic and distributed widely in the brain. The most common of these, and essentially the signature injury in mTBI, is traumatic axonal injury (TAI). TAI, which historically has been referred to as diffuse axonal injury (DAI), occurs when the brain is deformed from traumatic forces causing axons to be stretched sufficiently to produce at least a transient disruption in neural functioning.

Secondary Brain Injury

Primary traumatic damage to the brain may be further complicated by secondary insults that occurred acutely or subacutely. In patients with severe brain injury, hypoxia is considered the most common secondary insult. Other forms of secondary injury may include diffuse (multifocal) vascular injury, focal or widespread cerebral swelling, or disruption of normal brain electrical activity that may cause posttraumatic seizures.

Pathophysiology of mTBI or Concussion

Collectively, the underlying pathophysiological processes of concussion have been characterized as a "neurometabolic cascade," which has been eloquently characterized by Hovda and colleagues (Giza & Hovda, 2001). The clinical manifestation of concussion signs and symptoms results from sequential neuronal dysfunction due to ionic shifts, altered metabolism, impaired connectivity, or changes in neurotransmission. A concussion or mTBI does not typically result in identifiable structural injury to neurons and axons or any measureable cell death. The time course of this physiological disruption is considered to generally parallel that of clinical symptoms and recovery time.

Traumatic Brain Injury and Depression

Depression is frequently diagnosed after brain injury, with symptoms of dysphoria, anhedonia, and fatigue. Additionally, patients with TBI typically report lower life satisfaction (Jacobsson, Westerberg, & Lexell, 2010), and individuals with TBI frequently have more difficulty reintegrating back into social roles. Although TBI patients appear at risk of developing depression following their injury, the relationship between depression and injury severity is not well characterized. For example, while there is data to suggest that TBI severity groups do no differ on emotional domains like depression, anxiety, or irritability, even when cognitive differences are accounted for (Malec, Testa, Rush, Brown, & Moessner, 2007; Rapoport, McCauley, Levin, Song, & Feinstein, 2002), it would not be disputed that the psychology of neurobehavioral change following mild versus severe brain injury differs. Regardless, it is well recognized that depression following all-severity TBI has some neurobiological underpinnings. Nevertheless, mood and adjustment following injury is strongly related to patient perception about success resuming important psychosocial roles (Ownsworth et al., 2011). The nuances associated with emotional functioning across the spectrum of brain injury that are moderated by patient variables and other psychological and social factors need further investigation.

Treatment of Mild Traumatic Brain Injury

It is estimated that 70–90% of all treated traumatic brain injuries are mild in severity based on acute injury characteristics (Cassidy et al., 2004). For the majority of individuals with mTBI, the symptoms of PCS gradually resolve within a few weeks of injury. For a subset of individuals with mTBI, however, symptoms can persist well beyond expectations (i.e., months). The term post-concussive disorder (PCD) has been proposed for diagnostic use when symptoms following mTBI such as neurologic, cognitive, behavioral, or somatic complaints persist beyond the acute and subacute periods and become chronic (Iverson, Zasler, & Lange, 2007), often operationalized as persisting beyond three months. In most studies, brain injury severity characteristics are not strongly associated with risk of PCS. Rather, factors such as pre-injury adverse life events or stress or post-injury psychological factors (e.g., anxiety, attributions) are often more associated with persistent symptoms.

McCrea (2008) and Ruff and colleagues (Ruff, Camenzuli, & Mueller, 1996; Ruff & Richardson, 1999) highlight the complexity of the issues associated with PCD by stressing that PCD is not a unidimensional brain-based condition but rather an outcome influenced by cognitive, emotional, medical, psychosocial, and motivational factors, now referred to as the neurobiopsychosocial model of PCD (Iverson et al., 2007). Because of this complexity, treatments targeting PCD-related symptoms need to be equally diverse (e.g., they should follow an integrated model of care). Additionally, patients are frequently referred to behavioral health providers such as neuropsychologists, rehabilitation psychologists, health psychologists, and/or psychiatrists for a variety of reasons, but particularly when they are experiencing cognitive, emotional, or behavioral changes that accompany PCD.

Behavioral health intervention for PCD is not a singular treatment approach but should be conceptualized in three distinct ways: (a) symptom management (e.g., symptom reduction), (b) cognitive restructuring, or (c) preventative treatment. Treatment for PCD, like many treatments in medicine, is often geared toward *symptom management*. Behavioral health specialists help patients develop a behavioral program to facilitate symptom management (e.g., reduction of pain, improving sleep hygiene, using moderation during daily activities) of persistent symptoms. For example, patients with chronic daily headache or neck pain may benefit from learning progressive muscle relaxation or biofeedback procedures from a qualified health psychologist. Patients with mood disorders (e.g., depression), anxiety disorders (e.g., posttraumatic stress disorder), or adjustment reactions may benefit from psychiatric consultation or time-limited cognitive behavioral therapy (CBT) to increase patients' awareness of factors contributing to psychiatric difficulties, reduce their symptoms, or help them develop appropriate short- and long-term goals post-injury.

Because the symptoms of PCD are nonspecific to PCD and because they are so prevalent in normal, healthy non-brain-injured persons, some patients with PCD may be misattributing symptoms to their injury that are better explained by another source (i.e., highlighting importance of *cognitive restructuring* treatment). For example, attention and memory concerns post-injury may be related to chronic pain, psychoactive medications, or a posttraumatic stress reaction, rather than his or her mTBI in isolation. Iverson et al. (2007) reviews cognitive errors or biases exhibited by patients with PCD that can complicate recovery and promote disability.

While symptom management and cognitive restructuring approaches are very important for patient health and quality of life, treatment approaches focusing on *prevention* of PCD are ideal. Early preventative interventions for PCD essentially inoculate patients against a purely neurobiological perspective of concussion, which helps them take personal control over aspects of their recovery that are modifiable and view their injury, recovery, and symptoms as objectively as possible (Ferguson & Mittenberg, 1996; Miller & Mittenberg, 1998; Mittenberg, Canyock, Condit, & Patton, 2001; Mittenberg & Fischera, 1993; Mittenberg, Tremont, Zielinski, Fichera, & Rayls, 1996). Because psychological and social factors of disease (and PCD) are clearly modifiable variables (e.g., the patient, the provider and the patient's environment can influence outcome), it should not be surprising that mTBI patients who receive brief behavioral health treatments very early post-injury (hours or days) report fewer and less severe PCD-related symptoms months later relative to control patients with mTBI who do not receive these interventions (Borg et al., 2004; Comper, Bisschop, Carnide, & Tricco, 2005; Mittenberg et al., 1996; Ponsford et al., 2002).

Conclusion

TBI is a major public health problem worldwide that is associated with significant morbidity and mortality. Moderate and severe TBI present the highest risk for serious and permanent disabilities. The overwhelming majority of TBIs are classified as mild in severity, and major scientific advances have emerged to inform the underlying pathophysiology, assessment techniques, and therapeutic interventions to facilitate recovery, improve outcome, and reduce disability for those who have persisting symptoms following mTBI. TBI of any severity can be associated with neuropsychiatric sequelae (e.g., depressive disorders), but further research is needed to better understand the nuance of how injury severity is associated with risk of psychological health problems. Additional research is also needed to improve outcomes for those with the most intractable symptoms, as etiology may be complex and multifactorial. Including neuropsychologists and behavioral health professionals in the treatment of mTBI and PCD is empirically supported by research exploring the efficacy of psychoeducational and cognitive behavioral treatment paradigms for preventing or reducing PCD-related symptoms.

This chapter is intended to serve as a quick reference guide on chronic traumatic encephalopathy (CTE). CTE is a progressive neurodegenerative disease that results in a decline of clinical function (McKee et al., 2013; Mez et al., 2017; Stern et al., 2013) and is believed to be the consequence of exposure to repetitive head impacts (RHI), both concussive and subconcussive injuries (Montenigro et al., 2016). CTE was first recognized in 1928 by Harrison Martland who published a paper coining the phrase "punch drunk" to describe a series of behavioral and cognitive disturbances in Olympic prize fighters (Martland, 1928). Clinical dysfunction (e.g., behavior, mood, cognitive, and motor disturbances) (Millspaugh, 1937), as well as neuropathological evidence of neurodegeneration (e.g., hyperphosphorylated tau [p-tau]) (Corsellis, Bruton, & Freeman-Browne, 1973), was evident in boxers throughout the twentieth century. CTE, however, did not emerge as a public health concern and topic of lay conversation until 2005, following the publication of a case study of a former professional American football player who had progressive cognitive and behavioral/mood problems during life, as well as evidence of CTE neuropathology at postmortem (Omalu et al., 2005). Since 2005, CTE has been discovered in a variety of contact sports athletes (e.g., American football players, boxers, rugby players), as well as military veterans, victims of domestic violence, and other individuals with a history of RHI exposure (McKee et al., 2013, 2016; Mez et al., 2017). Over the past decade immense progress has been made in research and

awareness of CTE, and CTE may represent a major public health concern. This chapter will provide an overview of the neuropathological and clinical presentation of CTE and discuss targets of ongoing and future research.

Neuropathology of CTE

McKee et al. at the Boston University (BU) CTE Center and the Veterans Administration-BU-Concussion Legacy Foundation (VA-BU-CLF) brain bank have refined and validated the neuropathology of CTE. In 2013, as part of a National Institute of Neurological Disorders and Stroke (NINDS)-funded study known as "Understanding Neurologic Injury in Traumatic Encephalopathy (UNITE)" (PI: Ann McKee) (Mez et al., 2015), McKee et al. proposed neuropathological diagnostic criteria for CTE (McKee et al., 2013). A NINDS and National Institute of Biomedical Imaging and Bioengineering (NIBIB)-sponsored conference of 7 independent neuropathologists with expertise in neurodegenerative disease evaluated McKee and colleague's proposed criteria using 25 selected cases of various tauopathies. There was strong agreement among the panel for the neuropathological diagnosis of CTE (kappa = 0.78), with the pathognomonic lesion defined as an irregular perivascular deposition of p-tau at the depths of the cortical sulci. The neuropathology of CTE was distinct from any other neurodegenerative disease, including Alzheimer's disease (AD).

The neuropathology of CTE involves a diverse range of progressive macro- and microscopic alterations (McKee et al., 2013; Mez et al., 2017). Although gross pathology is generally unremarkable in the early stages of CTE, widespread cortical and subcortical neural degeneration is evident with the progression of the disease, in addition to dilation of the lateral and third ventricles, septal abnormalities (e.g., cavum septum), and pallor of the locus coeruleus and substantia nigra. Microscopically, perivascular p-tau neurofibrillary and astrocytic tangles are initially localized to the sulcal depths of the superior, dorsolateral, and inferior frontal cortices. As the disease advances, the p-tau becomes widespread throughout the cortex and subcortex (including the medial temporal lobe [MTL]) and extends into the diencephalon, brain stem, and spinal cord. Axonal degeneration, fiber loss, white matter disease, neuroinflammation, and extensive deposition of the TAR DNA-binding protein 43 (TDP-43) can also be found in the majority of CTE cases. Mez et al. (2017) found beta-amyloid protein deposits in a subset of participants at all stages of CTE pathology, and in stage IV CTE, deposition occurred in 91% of cases. However, beta-amyloid protein deposits are often diffuse, and not neuritic, plaques and associated with age and the APOE ε4 allele (Mez et al., 2017; Stein, Montenigro, et al., 2015). CTE is frequently comorbid with other neurodegenerative diseases, including AD, Lewy body disease (LBD), motor neuron disease (MND), and FTLD (Ling et al., 2017; McKee et al., 2013; Mez et al., 2017). Recent research proposes argyrophilic grain disease and Parkinson's disease as potential comorbidities of CTE as well (Armstrong, McKee, Stein, Alvarez, & Cairns, 2016).

RHI Exposure and CTE

RHI seems to be a necessary risk factor for CTE. However, it is not sufficient as not all individuals exposed to RHI develop CTE. There are a number of other risk factors thought to interact with RHI that may contribute to the development of CTE and clinical decline. A few potential factors include cumulative exposure to RHI (Montenigro et al., 2016), early age at first exposure (Alosco, Kasimis, et al., 2017; Schultz et al., 2017; Stamm, Bourlas, et al., 2015; Stamm, Koerte, et al., 2015), presence of the *APOE* genotype (Stern et al., 2013), older age (McKee et al., 2013, Mez et al., 2017), cognitive reserve (Alosco et al., 2016), and cerebrovascular health (Alosco, Koerte, et al., 2017). Despite common belief, recurrent subconcussive head trauma, not concussion, seems to play a prominent role in the development of CTE (McKee et al., 2013; Mez et al., 2017; Stein, Alvarez, & McKee, 2015). In a Mez et al. (2017) case series of 202 deceased former American football players, 3 of 14 high school (21%), 48 of 53 college (91%), 9 of 14 semiprofessional (64%), 7 of 8 Canadian Football League (88%), and 110 of 111 National Football League (NFL) (99%) players all showed evidence of CTE neuropathology. All three former high school players had mild pathology (stages I and II), and the majority of higher level players had severe pathology (stages III and IV) (Mez et al., 2017). Additionally, a recent study by Ling et al. (2017) hypothesized that CTE in retired soccer players may be related to their prolonged exposure to repetitive subconcussive head impacts from heading and head-to-player collisions. The concussion rate was limited in 6 of the 14 cases to one event during their careers; however, all cases developed a progressive dementing illness in later life. All six of the histological examinations revealed some features supportive of CTE, including characteristic tau pathologies, dilation of the third ventricle, and septal abnormalities (Ling et al., 2017). Research from the Mayo Clinic brain bank supports the relationship between RHI exposure and CTE (Bieniek et al., 2015). The contact sports history of 1,700 brain donation cases was ascertained from the Mayo Clinic brain bank and was correlated with their neuropathology. The brains of sixty-six males who participated in contact sports at the amateur level (34 of which played American football) were neuropathologically examined, revealing that 21 of the 66 donation cases had the diagnostic lesion of CTE (Bieniek et al., 2015). CTE neuropathology was *not* present in 198 age- and disease-matched men and women who did not have a history of contact sports participation. The findings presented by the Mayo Clinic are remarkable in that they are not limited by sample ascertainment bias due to recruitment of subjects with a history of RHI exposure and suspected neuropathology or CTE.

Clinical Presentation of CTE

Stern et al. (2013) performed retrospective family telephone interviews and medical record reviews for 36 contact sports male athletes (29 American football players, 3 professional hockey players, 1 professional wrestler, and 3 former boxers) who were neuropathologically diagnosed with *only* CTE in order to describe the clinical presentation of the disease. Of the 36 subjects, a subgroup of 22 exhibited initial declines in behavior and mood at a mean age of 35, primarily characterized by explosivity, impulsivity, and physical and verbal violence, in addition to depression and related symptoms (e.g., apathy, suicidality). This group ultimately developed cognitive symptoms; however, there was a second subgroup of 11 subjects who had cognitive difficulties as the initial symptom at a mean age of 60, especially in episodic memory and executive function. This subgroup tended to develop dementia and had more advanced CTE neuropathology. Three subjects were asymptomatic, potentially because one was only 17 years old and had early-stage CTE neuropathology (stage I), and the other two had very high cognitive reserve (based on their advanced graduate degrees and professional success). Despite previous research on boxers describing motor disturbances (e.g., parkinsonism) as a prominent feature of CTE, Stern et al. found little evidence of this feature in a sample of mostly former American football players. This is consistent with previous research indicating that boxers tended to have more pathology in brain regions (e.g., cerebellum) that cause parkinsonism (McKee et al., 2013). This may be due to differences in type and angle of force related to the biomechanics of head trauma, in which boxers receive focal stress to the brain stem and cerebellar regions.

A recent study by Mez et al. (2017) further describes the clinical presentation of CTE in 111 cases of former American football players. Both mild and severe cases of CTE pathology reported a progressive clinical course, and there were no asymptomatic cases. Impulsivity, depression, apathy, and anxiety, among other behavioral or mood symptoms, were frequently reported in 26 (96%) mild cases and 75 (89%) severe cases. Cognitive symptoms such as memory, executive function, and attention difficulties were also frequently reported in 23 (85%) mild cases and 80 (95%) severe cases. Both motor symptoms and dementia were common only in severe cases. Among the 111 CTE cases with standardized informant reports on clinical symptoms, 47 (42.3%) initially presented with cognitive symptoms, 48 (43.2%) initially presented with behavior or mood symptoms, and 16 (14.4%) initially presented with both. These clinical observations confirm and expand on previous reports of clinical presentations of CTE (Stern et al., 2013).

Clinical Research Diagnostic Criteria

CTE cannot currently be detected during life. A number of different research groups (Jordan, 2013; Montenigro et al., 2014; Victoroff, 2013) have proposed provisional research diagnostic criteria for the clinical syndrome associated with CTE and/or exposure to RHI, most recently being traumatic encephalopathy syndrome (TES) (Montenigro et al., 2014). The purpose of the TES criteria, and other proposed criteria, is to facilitate clinical research investigations on CTE and is not intended for clinical diagnostic purposes. TES is based on the clinical features of neuropathologically confirmed cases of CTE. A TES diagnosis requires a history of multiple impacts to the head (e.g., from contact sports participation, military service, domestic violence), including concussions, subconcussive injuries, and/or moderate to severe traumatic brain injury (TBI). Based on signs and symptoms found in a majority of neuropathologically confirmed CTE cases (Stern et al., 2013), at least one of three core clinical features must be present: (a) behavioral disturbances (e.g., aggression, impulsivity), (b) mood dysfunction (e.g., depression), and (c) cognitive decline, particularly in executive function and episodic memory, that is corroborated by standardized testing. Two supportive features (impulsivity, anxiety, apathy, paranoia, suicidality, headache, motor signs, documented decline, delayed onset) are also required for a TES diagnosis, as well as a symptom duration of at least 12 months. No other neurological disorder can fully account for the clinical features. These core features form four distinct TES diagnostic variants: behavioral/mood, cognitive, mixed, and dementia. For all diagnostic variants, motor disturbances and the clinical course (i.e., “stable,” “progressive,” or “unknown/inconsistent”) must be indicated. TES dementia requires a progressive clinical course and functional impairment.

TES is used to describe the clinical syndrome associated with exposure to RHI and is not intended to indicate underlying neuropathology. TES can be a manifestation of other neurological conditions and/or neurodegenerative diseases associated with head trauma. If an individual meets TES diagnostic criteria, the next step is to indicate the likelihood of CTE being the etiology through the designations of “probable CTE,” “possible CTE,” or “unlikely CTE.” A “probable CTE” diagnosis requires the presence of an *in vivo* biomarker that is suggestive of underlying CTE neuropathology. Without confirmation of a biomarker, only a diagnosis of “possible CTE” can be made.

Proposed *In Vivo* Biomarkers of CTE

Although validated *in vivo* biomarkers of CTE are not yet available, several have been proposed based on the neuropathology of CTE and preliminary biomarker studies in subjects at high risk for CTE, that is, former professional American football players. Various magnetic resonance imaging (MRI) technologies/approaches (i.e., high-resolution T1 anatomical MRI, diffusion tensor imaging [DTI], functional MRI [fMRI], arterial spin labeling [ASL], single-photon emission computed tomography [SPECT], MR spectroscopy [MRS]) have been examined in former professional American football players and provide support for the following as potential "proxy" markers of CTE neuropathological changes, but not of p-tau deposition: *cavum septum pellucidum* (Gardner et al., 2016; Koerte et al., 2016), *cortical atrophy and thinning* (Adler et al., 2016; Coughlin et al., 2015; Strain et al., 2015), *white matter alterations* (Alosco, Koerte, et al., 2017; Goswami et al., 2016; Strain et al., 2013), *cerebral hypoperfusion and functional hypoactivity* (Ford, Giovanello, & Guskiewicz, 2013; Hampshire, MacDonald, & Owen, 2013; Hart et al., 2013; Terry, Adams, Ferrara, & Miller, 2015), and *neurochemical alterations* (Lin et al., 2015).

Currently, the most promising method for the *in vivo* detection of underlying CTE neuropathology (i.e., p-tau) is positron emission tomography (PET) amyloid and tau imaging. In the case of AD, the Food and Drug Administration (FDA) has approved PET ligands that bind to amyloid (e.g., [(18)F]-florbetapir) and are used for the detection of amyloid uptake. There is preliminary support for the use of p-tau PET ligands in CTE, such as FDDNP (Barrio et al., 2015; Small et al., 2013) and [(18)F]-flortaucipir (also known as AV-1451 and T807) (Mitsis et al., 2014). Of particular interest is flortaucipir because of its improved specificity to p-tau, in general, and to paired helical filament (PHF) tau isoforms seen in CTE (e.g., 3R/4R). Not only will the combination of amyloid and tau PET imaging play a critical role in the detection of CTE during life, but it will also help in differentiating from similar neurodegenerative diseases (e.g., AD).

Fluid biomarkers, such as blood, saliva, and cerebrospinal fluid (CSF), are practical alternatives to PET imaging that can detect underlying AD neuropathology (Olsson et al., 2016) and may have similar applications in CTE. Recent research in symptomatic former NFL players and controls provides preliminary evidence for plasma exosomal tau (Stern et al., 2016) and plasma total tau (t-tau) (Alosco, Tripodis, et al., 2017) as candidate biomarkers for CTE. Alosco, Tripodis, et al. (2017) examined plasma t-tau in the blood of symptomatic former NFL players and revealed that a higher exposure to RHI predicted greater plasma t-tau later in life. However, plasma t-tau did not predict clinical function. CSF measures of t-tau, p-tau, and beta-amyloid are also of particular interest as potential biomarkers of CTE. Analysis of CSF concentrations in deceased professional American football players with neuropathologically confirmed CTE found a trend for increased CCL11, a protein previously associated with age-associated cognitive decline (Cherry et al., 2017). There was also an association between CSF CCL11 levels, and the number of years exposed to football was observed independent of age (Cherry et al., 2017). These biomarkers require more research but may ultimately become a simple diagnostic measure of CTE.

Conclusions and Future Directions

CTE is a distinct, debilitating, and progressive neurodegenerative disease associated with exposure to RHI. Given millions of contact sports athletes, military personnel, and domestic violence victims exposed to RHI each year, CTE may become a major public health concern. Research on the disease is still in its early phases. Provisional clinical research diagnostic criteria have been proposed, that is, TES (Montenigro et al., 2014), but require refinement and validation until it can be used for clinical diagnostic purposes. It is currently not possible to detect CTE during life, partially because validated *in vivo* biomarkers do not yet exist, and the clinical presentation of CTE remains ill defined (Asken et al., 2017; Iverson et al., 2017). More research needs to be done in order to assess the risk factors and epidemiology of CTE, as well as testing of proposed pathophysiological mechanisms that underpin the association between RHI and exposure and CTE (Cherry et al., 2016). A NINDS-funded, 7-year multicenter study, referred to as “Diagnostics, Imaging, and Genetics Network for the Objective Study and Evaluation of Chronic Traumatic Encephalopathy (DIAGNOSE CTE) Research Project” (PIs: Robert A. Stern [Contact PI], Jeffrey Cummings, Eric Reiman, Martha Shenton) is aiming to fulfill some of these needs. DIAGNOSE CTE is a longitudinal examination (baseline and 3-year follow-up) of symptomatic and asymptomatic former NFL players, symptomatic and asymptomatic former college football players, and an asymptomatic control group without a history of brain trauma or contact sports participation. At each time point, subjects complete clinical exams (neurological, motor, neuropsychological, neuropsychiatric, and daily functioning), neuroimaging (PET tau and amyloid, MRI, fMRI, DTI, MRS), lumbar puncture, and blood draw for DNA extraction and blood protein analysis. The ultimate endpoint for DIAGNOSE CTE is to develop and refine methods and criteria to diagnose CTE during life in order to initiate clinical trials and to facilitate epidemiological studies on CTE.

Dr. Michael L. Alosco, PhD is an assistant professor of neurology at the Boston University School of Medicine (BUSM). He completed his undergraduate studies at Providence College, and he earned his doctoral degree in clinical psychology, with a focus in neuropsychology, in 2015 from Kent State University. He completed his clinical internship in neuropsychology at the VA Boston Healthcare System. Dr. Alosco then completed a 3-year postdoctoral fellowship at the BU Alzheimer’s Disease (AD) Center and CTE Center, initially through the NIA-funded T32 Alzheimer’s Disease Translational Research Training Program, followed by a National Institute of Neurological Disorders and Stroke-funded Ruth L. Kirschstein F32 National Research Service Award (NRSA). Dr. Alosco’s research focuses on risk factors and biomarkers of neurodegenerative conditions, with a focus on AD and CTE. Dr. Alosco is particularly interested in the contribution of cerebrovascular disease to the clinical and neuropathological presentation of AD and CTE. He is additionally involved in research examining the relationship between exposure to repetitive head impacts and long-term neurological consequences. Dr. Alosco plays a critical role in several large-scale *in vivo* and *ex vivo* studies on AD and CTE at the BU AD and CTE Center. Dr. Alosco has accumulated >100 peer-reviewed publications, has written numerous book chapters, serves as an ad hoc reviewer for several journals, and has received several honors and awards.

Ms. Alyssa Phelps, BA completed her undergraduate studies at Cornell University where she graduated with honors in psychology. Her undergraduate research focused on integrative neuroethology and cognitive neuroscience. Since graduating, Alyssa transitioned to the Boston University (BU) Alzheimer’s Disease (AD) and CTE Center where she is an intern working on the Longitudinal Examination to Gather Evidence of Neurodegenerative Disease (LEGEND) Study. In the future, Alyssa hopes to pursue a doctoral degree in clinical psychology.

Dr. Robert L. Stern, PhD received his PhD in clinical psychology from the University of Rhode Island. He completed his predoctoral internship training under Dr. Edith Kaplan at the Boston VA Medical Center and his postdoctoral fellowship at the University of North Carolina School of Medicine. He is currently professor of Neurology, Neurosurgery, and Anatomy and Neurobiology at Boston University (BU) School of Medicine, where he is also director of the Clinical Core of the NIH-funded BU Alzheimer's Disease Center and director of Clinical Research for the BU Chronic Traumatic Encephalopathy (CTE) Center. A major focus of his research involves the long-term effects of repetitive head impacts in athletes, including the neurodegenerative disease, CTE. He is the lead co-principal investigator of a $16 million NIH grant for a multicenter longitudinal study to develop methods of diagnosing CTE during life as well as examining potential risk factors of the disease. Dr. Stern's other current major area of funded research involves the diagnosis and treatment of Alzheimer's disease. He has published on various aspects of cognitive assessment and is the senior author of the *Neuropsychological Assessment Battery* (NAB), as well as the *Boston Qualitative Scoring System for the Rey–Osterrieth Complex Figure*. He has received numerous NIH and other national grants, and he is a Fellow of both the National Academy of Neuropsychology and the American Neuropsychiatric Association. Dr. Stern has over 175 peer-reviewed publications, is on several journal editorial boards, and is the co-editor of two upcoming books: *Sports Neurology* (part of the Handbook in Clinical Neurology series published by Elsevier) and *The Oxford Handbook of Adult Cognitive Disorders*. Introduction

For more than a century, neuropsychological assessment has provided an objective method to quantify brain integrity. This approach overcomes limitations of subjective report of cognitive status, which are vulnerable to bias. The severity of cognitive impairment is often inflated in the context of concurrent mood disruption. By contrast, individuals with neurological brain injury are prone to underestimate the severity of cognitive impairment. Lack of insight into cognitive impairment is frequently associated with Alzheimer's disease (AD), yet the feature is neither universal nor specific to the neuropathogenic mechanisms of AD. For example, recent studies indicate poor self-awareness of cognitive impairment among younger adults infected with human immunodeficiency virus (HIV). The inherent limitations of self-reported cognitive function underscore the importance of objectively defined assessment regardless of the underlying disease or mental health condition.

Anatomical Substrates of Neuropsychological Performance

The field of neuropsychology is based on the central tenet that biology and behavior are intertwined and inseparable. These relationships were established through empirical studies of individuals with natural and iatrogenic brain damage (Kolb & Wishaw, 2015). More recently, neuroimaging using high-resolution magnetic resonance imaging (MRI) and positron emission tomography (PET) allows *in vivo* examination of brain–behavior links. Advanced imaging

techniques such as MRI and PET (among other modalities) have revolutionized the brain sciences, yet neuroimaging studies neither define nor reliably predict functional capacity. Reliable estimates of the functional integrity of the underlying anatomy require a comprehensive approach to cognitive testing using measures sensitive to the primary networks of the brain (Yeo, Krienen, Chee, & Buckner, 2014). Inconsistencies exist in the literature, but most groups agree that these networks can be defined as five to seven relatively unique cognitive domains (attention, information processing speed/psychomotor speed, working memory/executive function, language, learning and memory, visuospatial, and motor). Analyses of the behavioral patterns observed within and across these domains produce rich insights into brain structure and function. This process is referred to as cognitive phenotyping.

Cognitive testing alone cannot reliably determine the etiology of isolated neuronal damage. However, the sensitivity of cognitive phenotyping to detect abnormalities in regional or brain-wide networks is quite good. Neuronal disruption that is largely confined to the cellular layers of the cortical ribbon is expressed behaviorally as deficit driven by the affected cortical region (e.g., language, memory, and motor). By contrast, neuronal damage predominately affecting the subcortical white matter fasciculi or the deep subcortical gray matter nuclei (caudate, globus pallidus, putamen, thalamus) produces a pattern of deficits most consistent with frontal lobe dysfunction (Cummings, 1993). Such anatomical specificity for associated cognitive impairment is most likely to be observed during the early stages of neurodegenerative conditions. By contrast, advanced stages of neurological conditions typically involve both cortical and subcortical brain regions and therefore produce a mixed pattern of cognitive symptoms.

Cortical Versus Subcortical Cognitive Phenotypes

The cortical cognitive phenotype includes amnestic memory loss, apraxia, agnosia, and anomic aphasia. This pattern was originally modeled after the prototypical expression of AD. Processing speed, working memory, and executive function are also affected in AD, but the level of impairment is typically less severe than the early and profound impairment in memory retention. Other neurodegenerative conditions that produce a cortical cognitive phenotype include semantic dementia, argyrophilic grain disease, and posterior cortical atrophy (Benson, Davis, & Snyder, 1988; Ferrer, Santpere, & van Leeuwen, 2008; Hodges, Patterson, Oxbury, & Funnell, 1992). The exact nature of the accompanying phenotype differs in these conditions, yet each shares a predilection for early involvement of cortical gray matter regions and a cognitive signature consistent with at least one cortical syndrome. An exception to this model can be seen among individuals with the frontal variant of frontotemporal dementia (FTD). Executive dysfunction is present early in FTD, and the behavioral deficits associated with poor behavioral regulation dominate the clinical presentation. Individuals under 65 with a marked change in personality and self-regulation are likely to meet diagnostic criteria for FTD.

In contrast to the cortical phenotype, subcortical cognitive phenotypes are characterized by abnormalities in attention, working memory, executive function, information processing, and psychomotor speed. This pattern reflects a predilection for disease mechanisms to impact deep subcortical gray matter nuclei (e.g., small vessel ischemia), white matter fasciculi (e.g., multiple sclerosis [MS]), or both gray and white matter regions (HIV) (Cummings, 1993; Rao, 1986; Woods, Moore, Weber, & Grant, 2009). Parkinson's disease, Huntington's disease, and "normal aging" also produce a cognitive pattern consistent with a subcortical profile. Neuropathology may exist in cortical regions (e.g., Parkinson's disease) or in gray–white matter junctions (MS), but the preponderance of cellular damage is concentrated in white matter tracts and/or the basal ganglia. An interesting example of disconnection is evident among individuals with damage to the cerebellum (e.g., from stroke). The cerebellum is connected to the dorsolateral prefrontal cortex by a long-range fasciculus, and when damaged, affected individuals exhibit significant executive dysfunction (Strick, Dum, & Fiez, 2009). These cases of distant/remote brain damage provide clinical evidence that the behavioral expression of frontal impairment results from damage to the subcortical neural pathways.

Individuals with a subcortical cognitive phenotype often exhibit memory impairment, but the profile differs from what is observed in AD. Subcortical memory dysfunction is characterized by shallow learning and poor delayed recall of newly learned information. The restricted learning curve is a downstream consequence of poor attention, working memory, and/or executive skills needed to organize and learn the information. Long-term free recall is reduced as a function of the poor initial learning, but individuals usually do not exhibit a total loss of information. As such, subcortical etiologies spare recognition memory (discrimination of targets from foils) except when performance is confounded by positive or negative response sets (e.g., cases of stimulus-bound individuals). By contrast, individuals with AD do not benefit from recognition trials because the critical brain structures necessary for encoding and retention are damaged (i.e., medial temporal lobe). The ability to detect these unique memory phenotypes, therefore, is dependent on the specific memory measures included in the test battery. Memory tests that do not include a recognition trial will not differentiate retrieval from retention deficits.

Limitations to Phenotype Modeling

Neuropsychological phenotyping is not a perfect science. As described in the example of memory profiles above, the pattern of results is highly influenced by test selection (sensitivity, coverage), limited time windows to complete testing (e.g., when embedded in a demanding research study), access to appropriate normative data, and availability of alternate and equivalent forms for repeat testing (Kolb & Wishaw, 2015; Lezak, Howieson, Bigler, & Tranel, 2012). Additionally, stimulus confusion resulting from the administration of multiple tests can artificially create behavioral failures due to poor test administration procedures. A related problem is confusion that occurs when language measures are administered during the interval between final learning trials and delayed recall trials on verbal memory tests. These details are not intuitive, yet the quality of data available for phenotyping is intimately linked to sound implementation procedures. Unfortunately, efforts to fully standardize the process (e.g., NIH Toolbox; Gershon et al., 2013) have not been widely adopted, largely because the value of such an approach remains undefined. We expect change in the future, with more ready uptake of standardized cognitive assessments and application of predictive modeling using artificial intelligence algorithms (e.g., machine learning).

Opportunities for Future Research in Cognitive Phenotyping

Neuropsychological tests generate many indices of brain function. Depending on final test selections, the total number of dependent variables obtained from a comprehensive evaluation can easily exceed 50 or more indices. Structural and functional neuroimaging assessments generate many more variables of interest. Aggregating these outcomes into global measures by cognitive domain (e.g., executive function, information processing) or brain region (frontal lobe volume, white matter volume) to reduce the total number of dependent variables reduces the sensitivity of the outcome measures as areas of relative weakness are masked by relative strengths. An alternative approach is to simply ignore select data outputs based on a priori hypotheses related to regions believed to be relevant to the clinical or research question. This approach avoids reduced and restricted sensitivity due to averaging, but the outcomes are entirely dependent on the accuracy of the a priori hypotheses. It can be argued that this traditional data-reduction approach to clinical neuroscience has contributed to the slow pace of innovation in the field. Thus, a new approach is greatly needed.

Artificial intelligence systems adapted from private industry offer a fresh approach. Rather than intentional omission of potentially important indices of brain function, artificial intelligence incorporates all data input features into models to define the latent variance structure. Groups, including ours, apply these methods to integrate multimodal neuroimaging data, comprehensive neuropsychological performance indices, and laboratory markers, without aggregation of scores by cognitive domains or brain regions and without discarding data based on assumptions. Work conducted to date clearly defines that value of this approach to define the most salient variables that define group classification, as well as inform which variables can be adjusted to reduce risks associated with specific conditions. It is expected that data-driven approaches using artificial intelligence algorithms will transform the field and establish new paths for personalized medicine, inclusive of treatment and cure strategies across a broad spectrum of neurological conditions.

Author Biographies

Robert H. Paul is a board-certified clinical neuropsychologist. He serves as director of the Missouri Institute of Mental Health and professor of psychological sciences at the University of Missouri–St. Louis. His research program is focused on mechanisms of brain dysfunction in health conditions that primarily impact brain structures located deep beneath the surface of the cerebral cortex. He has special interest in clinical neuroscience capacity building in resource-limited environments.

Carissa L. Philippi, PhD, is an assistant professor in the Department of Psychological Sciences at the University of Missouri–St. Louis. Her research takes a dimensional approach to understanding the behavioral (e.g., negative self-related thought) and neural correlates of neuropsychiatric conditions, such as depression. For example, in a recent study, she identified associations between subclinical depression severity and resting-state functional connectivity of the anterior cingulate cortex that mirrored neural circuit dysfunction in major depression.

Gregory Dahl is a graduate research assistant in the Behavioral Neuroscience Program at the University of Missouri–St. Louis. He completed his undergraduate work in Psychology and Philosophy in May of 2015 and began working with client data/statistics for a not-for-profit mental health clinic. Upon entry to graduate school, he began working with Professor Philippi on the cognitive and affective neurobiology of self. His research interests include the neurobiology of memory and the cognitive/behavioral/environmental factors that can affect memory.

Mild Traumatic Brain Injury and Posttraumatic Stress Disorder: Diagnostic and Neurobiological Signatures of Comorbidity

Jacob Bolzenius

Missouri Institute of Mental Health, University of Missouri–St. Louis, St. Louis, MO, USA

Traumatic brain injury (TBI) is one of the most common conditions of acquired brain dysfunction, with estimates reporting 1.7 million cases per year in the United States alone (Faul & Coronado, 2015). While treatment for and survivability from more severe TBI has improved markedly over recent decades, mild TBI (mTBI), also commonly described as "concussion," presents a fairly unique symptom profile and recovery prognosis. Moreover, prevalence of this condition in certain stressful scenarios (e.g., military service, assault, motor vehicle accidents) leaves the individual prone to psychiatric disorders such as posttraumatic stress disorder (PTSD). This commonly comorbid disorder challenges clinical judgment and treatment strategies, particularly as patients progress past the acute injury phase. Optimized methods for identification of mTBI and PTSD, especially when presenting together, have thus been the subject of intense investigation over recent years. This chapter aims to delineate characteristics of both mTBI and PTSD and review evidence regarding the neurobiological bases of these disorders that may guide clinical care decisions.

Diagnosis and Characteristics of mTBI

Severity of TBI is classified as mild, moderate, or severe based on several criteria, including loss of consciousness (LOC), alteration of consciousness or posttraumatic amnesia (PTA), Glasgow Coma Scale (GCS) score, level of care or hospitalization required, and presence of acute neuroimaging abnormalities if available (Department of Veterans Affairs/Department of

The Wiley Encyclopedia of Health Psychology: Volume 1: Biological Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editor: Robert H. Paul.

Defense, 2016). mTBI is defined as a GCS of 13–15, LOC less than 30 min, and alteration of consciousness or PTA less than 24 hr. Most cases have unremarkable neuroimaging findings (i.e., CT or MRI) and require no significant hospitalization or prolonged care. The accuracy of these criteria and immediate care decisions, however, are largely dependent on self-report as well as information from collateral sources, if present. The most common causes of civilian mTBI include falls and motor vehicle accidents (Bazarian et al., 2009). Among military populations in modern conflicts, blast injuries or blast-related injuries represent the most common cause of mTBI (Helmick et al., 2015; Terrio et al., 2009).

Unlike moderate to severe TBI, which leads to marked and prolonged cognitive deficits, cognitive and behavioral difficulties from mTBI tend to resolve within a couple weeks. Meta-analyses have suggested that reductions in cognitive function are evident in the acute phase of mTBI, particularly in memory, fluency, and processing speed. However, these changes are dependent on the post-injury interval and tend to resolve with time, usually returning to near average within about 90 days (Belanger, Curtiss, Demery, Lebowitz, & Vanderploeg, 2005; Frencham, Fox, & Maybery, 2007; Schretlen & Shapiro, 2003). Injury-related litigation has been identified as one key factor to residual or worsening cognitive performance beyond this time point (Belanger et al., 2005). While the majority of individuals with mTBI fully recover, around 10–15% continue to experience symptoms past the 3-month window related to the injury. These chronic symptoms are known as post-concussion syndrome (PCS) (Iverson & Lange, 2011), recently reclassified as *major or mild neurocognitive disorder due to TBI* in the *5th edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5)* (American Psychiatric Association, 2013). Symptoms of PCS may take weeks to months to emerge following mTBI and can include a host of secondary effects, including orthopedic pain, headaches, psychiatric conditions, and sensory dysfunction (Leddy, Sandhu, Sodhi, Baker, & Willer, 2012). Treatment options include a variety of pharmacologic, physical, and psychological methods, with evidence supporting the use of early, brief psychological intervention including symptom attribution education, complemented by resumption of physical activity and medication when appropriate (Mittenberg, Canyock, Condit, & Patton, 2010).

Work is ongoing to identify biomarkers that can detect biological correlates of continued cognitive or subjective symptoms in these individuals. Volumetric MRI studies have described cortical thinning (A. P. Michael et al., 2015) and global and focal atrophy to both white and gray matter at 1-year post-injury that relates to cognitive changes and PCS symptoms (Zhou et al., 2013). Diffusion tensor imaging (DTI) has demonstrated sensitivity to sequelae of mTBI and ability to distinguish patients from controls (Hulkower, Poliak, Rosenbaum, Zimmerman, & Lipton, 2013). The advantage of DTI resides in the sensitivity to microstructural detail of neuronal components that are affected by the shearing forces (e.g., traumatic axonal injury) sustained during mTBI, particularly to white matter. As a result, DTI has become the neuroimaging method of choice for examining brain markers of mTBI, especially as this scan sequence is already commonly available on most commercial MRI scanners. Research has suggested that DTI may be more sensitive than cognitive testing to subacute mTBI changes and that these changes normalize longitudinally as injury-related physiological disruption normalizes (Mayer et al., 2010). In individuals with symptoms of PCS, DTI abnormalities in the subacute stage after mTBI have been related to greater white matter structural impairment at 6-month follow-up in patients compared with non-PCS controls (Messé et al., 2012). This is supported by animal research confirming the link between DTI changes and altered neuronal histopathology in mTBI models (Bennett, Mac Donald, & Brody, 2012; Hylin et al., 2013). Additional structural MRI sequences such as susceptibility-weighted imaging (SWI) and fluid-attenuated inversion recovery (FLAIR) provide help detecting micro-hemorrhages, and together usage of SWI and/or DTI detects mTBI abnormalities in up to one-third of those with negative CT scans on day of injury (Bigler, 2013; Shenton et al., 2012). Functional MRI (fMRI) sequences have also shown promise in differentiating mTBI from controls (Bryer, Medaglia, Rostami, & Hillary, 2013), suggesting that functional network integrity can be leveraged as a marker of both acute and chronic mTBI.

Diagnosis and Characteristics of PTSD

PTSD is a disorder characterized by emotional, behavioral, and cognitive symptoms that develops in response to a severe stressor or threat to life or well-being. Some of the most common clinical assessment tools for PTSD updated for *DSM-5* criteria include the Clinician-Administered PTSD Scale (CAPS-5) (Weathers et al., 2013), the PTSD Symptom Scale—Interview (PSS-I-5) (Foa et al., 2013), and the Structured Clinical Interview for *DSM-5* (SCID-5) (First, Williams, Karg, & Spitzer, 2015). Symptoms of PTSD are grouped diagnostically among several criteria clusters. These include reexperiencing or intrusive thoughts, avoidance behaviors, negative mood or altered cognitive ability, and arousal or reactivity. These diagnostic clusters reflect a change implemented in the *DSM-5*, which separated avoidance and negative alterations in cognition and mood, thus requiring identifiable presence of both of these symptoms for diagnosis. Symptoms can extend well beyond the acute recovery period and lead to continued cognitive difficulties, observable brain abnormalities, and altered quality of life and disability (Seedat, Lochner, Vythilingum, & Stein, 2006). PTSD is especially prevalent among military veterans, presenting in up to 20% of those returning from service (Hoge et al., 2004), and is associated with poor post-deployment health and occupational outcomes compared with non-symptomatic counterparts (Hoge et al., 2008).

While PTSD is generally viewed and treated as a disorder of fear conditioning dysregulation, it is also characterized by changes to objective neuropsychological performance. Individuals with PTSD exhibit greater attention to, and more difficulty disengaging from, emotionally laden stimuli (Christianson, 1992; Paunovi, Lundh, & Ost, 2002; Vythilingam et al., 2007). PTSD has been linked to long-term changes in several cognitive domains such as verbal and visual memory compared with controls (Johnsen & Asbjørnsen, 2008; Vasterling, Aslan, et al., 2018). Further, detriments in areas of executive function are shown to affect memory formation and retrieval for both neutral and emotionally laden content (LaGarde, Doyon, & Brunet, 2010; Williams et al., 2007). In addition to these various types of explicit memory, implicit memory shows differential effects in PTSD, with evidence of facilitated priming for high valence stimuli compared with controls (Kleim, Ehring, & Ehlers, 2011; T. Michael & Ehlers, 2007; T. Michael, Ehlers, & Halligan, 2005). Attention bias to trauma-related words in an emotional Stroop task relates to a diagnosis of PTSD (El Khoury-Malhame et al., 2011) as well as PTSD severity (Fleurkens, Rinck, & van Minnen, 2011). Additionally, these individuals exhibit impaired reward processing as effort expenditure to reach a positive reward varies greatly from patterns demonstrated by controls (Hopper et al., 2007). Thus, there is sufficient evidence substantiating the effects of altered cognitive functions, particularly as they relate to emotionally laden content.

PTSD disrupts normal function of the hypothalamic–pituitary–adrenal axis. These are marked by decreased cortisol and increased levels of corticotropin-releasing hormone that create a sensitized negative feedback inhibitory loop (Sherin & Nemeroff, 2011). To identify the neurocircuitry behind the disorder, prior work has demonstrated links to various markers of brain volume, integrity, and network connectivity. This includes disruptions in frontal networks necessary for inhibiting vigilance to trauma-related stimuli and extinguishing response patterns, overactive amygdala function that facilitates the learned and habituated aspects of the fear response, and decreased hippocampal activation leading to impaired association with and retention of less emotionally volatile information (Rauch, Shin, & Phelps, 2006). Volumetric MRI studies have related PTSD to smaller volumes in the hippocampus (Smith, 2005; Villarreal et al., 2002), anterior cingulate cortex (Kitayama & Quinn, 2006; Woodward et al., 2006), and amygdala (Karl et al., 2006) compared with healthy controls. DTI research has demonstrated consistent white matter disruptions associated with PTSD, particularly in tracts related to emotional regulation (Long et al., 2013; Schuff et al., 2011). Functional neuroimaging, including PET and fMRI, have also provided evidence for network disruption and altered blood flow patterns in response to emotional stimuli in individuals with PTSD (Bremner et al., 1999; Lanius et al., 2003; Patel, Spreng, Shin, & Girard, 2012). Elevated activation of the amygdala and hippocampus has been observed using fMRI while encoding and recalling negative stimuli in PTSD relative to trauma-exposed non-PTSD individuals (Brohawn, Offringa, Pfaff, Hughes, & Shin, 2010).

Characteristics of Comorbid mTBI and PTSD

Overlapping presentation of symptoms represents one of the chief challenges of comorbid PTSD and mTBI. Clinical determination of differential diagnosis is challenged by the need to rely on self-reported symptom complaints. Acute injury details may be irretrievable due to memory loss related to the traumatic event, making attribution of deficits ambiguous between sequelae of psychological and brain trauma. Both disorders share chronic symptom complaints including insomnia, slowed or foggy thinking, headache, and difficulties with attention, and additional comorbidities may arise including depression, substance use, and somatic problems. Due to variations in injury-related factors such as loss or alteration of consciousness that impact the subjective experience of the event, individuals with mTBI tend to be at higher risk for development of PTSD than more severe head injuries (Klein, Caspi, & Gil, 2016).

Military populations in particular are at elevated risk for exposure to trauma resulting in mTBI and PTSD. A large-scale study demonstrated a threefold increase in the rate of PTSD among veterans exhibiting positive symptoms of TBI compared with those exhibiting no symptoms (Carlson et al., 2010). Studies focusing on mTBI have shown that a significant portion of service members (up to 40% or higher) experiencing symptoms of mTBI also exhibit symptoms of PTSD (Hoge et al., 2008). These elevated rates are likely due to combat environments creating pre-injury states of heightened stress and hypervigilance that expose the individual to PTSD-inducing stimuli prior to onset of brain trauma (Kennedy et al., 2007). Additionally, variations in psychiatric profiles, including higher premorbid PTSD symptoms and lower cognitive function, military combat, and post-deployment stress, predict PTSD development following trauma exposure (Boasso, Steenkamp, Larson, & Litz, 2016; Sørensen, Andersen, Karstoft, & Madsen, 2016). Disentangling these disorder profiles and identifying optimal treatment regimens remain a critical goal, as history of TBI is a prominent risk factor for suicidal ideation (Wisco et al., 2014) and nearly two dozen US veterans die from suicide each day (Department of Veterans Affairs, 2016).

Research shows that presence of PTSD can impact the presentation and severity of the mTBI and vice versa. TBI and PTSD are both independently related to subjective post-injury symptom reporting (Vasterling et al., 2012). Symptoms of PCS in particular overlap notably with those of PTSD; thus treatment of some nonspecific symptoms (e.g., anger, impaired concentration) (Vasterling, Jacob, & Rasmusson, 2018) may improve outcomes of either condition. In the acute phase, symptoms of PTSD and mTBI (e.g., confusion, disrupted attention, disorientation) can resemble each other, and in the post-acute stage, PCS may be endorsed by individuals with non-trauma disorders (Donnell, Kim, Silva, & Vanderploeg, 2012) or even healthy controls (Iverson & Lange, 2010). Studies have described independent associations between both mTBI and PTSD with PCS, with evidence supporting an additive burden of adversity for those with both mTBI and PTSD (Brenner et al., 2010; Brenner, Vanderploeg, & Terrio, 2009). Data suggest that psychological distress related to PCS and PTSD are predictors of cognitive status regardless of TBI history, but history of mTBI is linked to higher rates of clinical morbidity (Donnelly, Donnelly, Warner, Kittleson, & King, 2017). Further, rates of PTSD are nearly twice as likely one year after mTBI compared with non-TBI civilian trauma (Bryant et al., 2010). Objective cognitive profiles are difficult to ascribe to one single condition, as both affect several of the same domains (e.g., executive function, learning, memory) (Scott et al., 2015), though some research suggests PTSD relates to poorer performance in cognitive domains of reaction time, learning, and memory after adjusting for TBI status (Vasterling et al., 2012). Subjective complaints regarding cognitive function often exceed measurable dysfunction (Spencer, Drag, Walker, & Bieliauskas, 2010; Zatzick et al., 2010).

Few neuroimaging studies have focused on both mTBI and PTSD. One study suggested that PTSD severity was more strongly related to measures of white matter integrity than mTBI, but subclinical symptoms of mTBI moderate the development of PTSD (Bazarian et al., 2013). Research has also shown that PTSD relates to white matter changes using DTI after accounting for mTBI status (Davenport et al., 2016; Schuff et al., 2011). Another study demonstrated greater white matter integrity in PTSD than mTBI, particularly in high-complexity regions (Davenport, Lim, & Sponheim, 2014), supporting the idea of mTBI as a disorder of diffuse brain disruption (Bolzenius et al., 2018; Hu et al., 2016). Other methods, such as single-photon emission computed tomography (SPECT), have revealed greater regional activation in PTSD compared to a mixed-severity TBI group, suggesting that PTSD symptoms in the presence of TBI produce a different signature than when considering either condition alone (Amen et al., 2015). fMRI research has also implicated altered connectivity between prefrontal and hippocampal regions that relates to disruptive reexperiencing of PTSD symptoms. Other studies report altered connectivity between prefrontal and basal ganglia regions, providing a potential neural substrate associated with abnormalities in working memory and maintenance networks that exacerbate PTSD symptoms(Spielberg, McGlinchey, Milberg, & Salat, 2015). Overall, these studies present intriguing interactions between symptom profiles of mTBI and PTSD, but additional research is needed to further tease apart the unique contributions of each condition. Advances in computational data science and predictive modeling algorithms based on artificial intelligence offers the potential to delineate the biology, symptoms, and treatments for PTSD and mTBI as separate entities.

Author Biography

Jacob D. Bolzenius earned a PhD (2014) in Psychology with an emphasis in behavioral neuroscience from the University of Missouri–St. Louis and has held several appointments, currently at the University of Missouri-St. Louis. His research has focused on using novel neuroimaging techniques, including diffusion tensor imaging and volumetric shape analysis, to assess biological correlates of brain disease or insult (e.g., traumatic brain injury, healthy aging). Currently he is applying diffusion basis spectrum imaging methods to infer markers of cellular inflammation and neuronal integrity associated with delirium in older adults. This research has promise to validate *in vivo* cellular pathology associated with brain disease that can inform the understanding of brain disease progression in later life to apply to prevention and treatment strategies.

Caloric Restriction, Cognitive Function, and Brain Health

Introduction

An increasingly large body of evidence suggests that lifestyle factors, including diet and exercise, play an important role in either mitigating or accelerating the neuropathological processes, leading to the development of Alzheimer's disease (AD) and other forms of late life dementia (Solfrizzi & Panza, 2014). Although previously conceived of as a disease developing in the later stages of life, AD in particular has been found to develop over the course of decades (Jack et al., 2010), emphasizing the importance of chronic lifestyle practices on the progression of subtle, insidious neuropathological changes.

Among the lifestyle characteristics examined, physical activity and dietary practices have been most extensively studied (Scarmeas et al., 2009). Although many studies have examined patterns of dietary behavior, such as the Mediterranean and Dietary Approaches to Stop Hypertension (DASH) diet, caloric restriction has consistently been an area of interest, owing to a large body of animal evidence demonstrating that it is the only known intervention to consistently increase lifespan across species. In addition, several lines of evidence among humans suggest that more limited intake of energy may confer reduced risk of dementia. For example, multiple studies have suggested that lower weight in midlife is associated with substantially lower risk of AD and other forms of dementia. Similarly, several randomized trials have provided evidence, albeit preliminary, that intentional caloric restriction may improve cognitive performance (Witte, Fobker, Gellner, Knecht, & Floel, 2009) and improve neuroimaging markers of brain health (Espeland et al., 2016). Nevertheless, multiple studies have suggested that lower weight, particularly underweight, is associated with worse outcomes among older adults, in contrast to the protective effects demonstrated in midlife.

Epidemiological Data

Accumulating evidence suggests that lower levels of caloric intake may be associated with improved cognitive performance and reduced rates of dementia. Although several recent examinations have been conducted in humans, this relationship has been studied extensively among animals. Despite relatively limited evidence in humans linking caloric restriction directly to brain outcomes, multiple, indirect lines of evidence support the notion that restricted energy intake may have salubrious effects. For example, multiple studies have demonstrated that being overweight or obese, particularly in midlife, is a risk factor for dementia (Kivipelto et al., 2006). Gustafson, Rothenberg, Blennow, Steen, and Skoog (2003) found that every 1.0 increase in BMI at age 70 was associated with a 36% increased risk of AD over an 18-year follow-up of nondemented, Swedish women. Similar results were found in a sample of Japanese men, with every 2.9 point increase in BMI conferring a 21% increased risk of vascular dementia (VaD) (Kalmijn et al., 2000). Although genetic factors no doubt play a prominent role in the development of AD, twin studies nevertheless demonstrate a similar relationship, with midlife obesity conferring more than a threefold increased risk of dementia (Xu et al., 2011). Although the mechanisms linking obesity to dementia are likely multifactorial (Craft, 2009), recent studies have suggested that the presence of obesity in midlife is associated with neuropathological correlates of dementia, including neurofibrillary tangles (Chuang et al., 2016) and total brain volume loss (Debette et al., 2011). Despite these findings, it must also be noted that not all studies have shown an association between obesity and increased risk of dementia, a phenomenon that has come to be referred to as the “obesity paradox” (Driscoll et al., 2016).

Independent of studies examining obesity, a separate line of evidence suggests that more modest caloric intake is associated with improved longevity and that excess energy intake is associated with adverse cognitive outcomes. For example, among nearly 1,000 participants in the Washington Heights-Inwood Columbia Aging project, Luchsinger, Tang, Shea, and Mayeux (2002) found that greater caloric intake was associated with increased risk of AD, particularly among individuals with APOE-4 genotype. A well-known association has also been documented between chronic, markedly diminished caloric intake and improved longevity among Okinawans, who have a high prevalence of centenarians and relatively low rates of dementia (Willcox et al., 2007). In an archival analysis of centenarian Okinawans, participants even reported a 10.9% energy deficit during their 30s, a pattern that was maintained over subsequent decades of life.

Randomized Trials

Relatively few randomized trials have directly tested the impact of caloric restriction in human participants. In one of the most positive findings reported, Witte et al. (2009) examined the effects of caloric restriction on cognitive performance among 50 healthy, elderly subjects at either normal weight or mildly overweight. Participants were randomly assigned to either caloric restriction, increased intake of unsaturated fatty acids (UFAs), or a control condition. Following 3 months of treatment, individuals in the caloric restriction group exhibited increased verbal memory scores, and these improvements were correlated with decreased levels of fasting insulin and C-reactive protein. Notably, these results were strongest among subjects with the best adherence. Serum levels of brain-derived neurotrophic factor (BDNF), a growth factor thought to mediate the effects of aerobic fitness on brain function, were also assessed in this trial, but were not altered with treatment and were not associated with alterations in cognitive performance.

Martin et al. (2007) conducted a similar study among 48 overweight adults, aged 25–50 years. Participants were randomly assigned to one of four groups: caloric restriction, caloric restriction and exercise, a low-calorie diet condition, or to a control group (weight maintenance). At baseline, 3 months, and again at 6 months, cognitive tests were administered assessing verbal and visual memory, as well as concentration/attention. Overall, cognitive function changed very little across any group, and no consistent pattern of change emerged. In addition, changes in cognitive performance were not related to changes in caloric intake (indexed by daily energy deficit) or weight loss.

Several other randomized trials provide preliminary evidence that caloric restriction may confer cognitive and/or brain benefits in various patient populations. Horie et al. (2016) found that a 12-month nutritional counseling intervention among obese individuals with mild cognitive impairment was successful in improving cognitive performance across multiple subtests. Cognitive improvements were associated with changes in insulin resistance, CRP, leptin, and intake of energy, fat, and carbohydrates.

We previously examined this relationship in a sample of 120 middle-aged adults with hypertension and overweight or obesity (Smith et al., 2010). Participants were randomized for 4 months to a one of three groups: (a) a multicomponent weight loss intervention consisting of aerobic exercise and the DASH diet with caloric restriction, (b) the DASH diet without weight loss, and (c) a usual care control group. Results suggested that combined weight loss group showed improvements on several tests of executive function, learning, and memory, as well as psychomotor speed, with the DASH diet group alone showing more modest benefits on one measure of psychomotor speed alone compared with controls.

In one of the longest randomized trials to examined caloric restriction, Espeland et al. (2016) examined the potential persistent effects of the Action for Health in Diabetes clinical trial 10 years after randomization. The trial was designed to promote caloric restriction among adults with diabetes. In order to examine this relationship, the authors conducted a per protocol analysis, incorporating only individuals who exhibited at least modest weight loss. At the time of the 10-year follow-up, participants in the intervention group exhibited 28% lower white matter volume compared with control participants, who underwent a diabetes support and education program. In contrast, improvements in cognitive performance were relatively modest, only being observed on one subtest of processing speed.

In a relatively small trial, Prehn et al. (2017) examined changes in brain structure and function among 37 obese, postmenopausal women, randomized to an intensive 12-week low-calorie diet or a control group. In a *per protocol* analysis, the authors excluded individuals in the intervention group who did not lose at least 10% body weight, as well as participants in the control group who lost more than 5% of body weight. Participants in the intervention group exhibited improved memory performance paralleled by increased gray matter volume in the inferior frontal gyrus and hippocampus, as well as augmented hippocampal resting-state functional connectivity to parietal areas. The effects appeared to be specific to transient negative energy balance and were not detected after subsequent weight maintenance.

An overlapping but conceptually distinct question is whether weight loss is associated with improvements in neurocognitive performance. Although many studies achieve weight loss through a combination of exercise and dietary modification, more modest weight loss may be achieved through exercise alone. In addition, some studies have examined the impact of weight loss through bariatric surgery and its impact on cognitive change, although these studies are beyond the scope of the present review. In one of the few systematic reviews to examine intentional weight loss and cognitive function changes, Siervo et al. (2011) combined all randomized trials examining weight loss and cognitive function changes, including data from 12 studies, seven of which incorporated a control group in the study design. Of note, although the majority of studies included were behavioral weight loss interventions, gastric bypass studies were also included. The authors found that intentional weight loss was associated with small improvements in memory and attention/executive functioning across a heterogeneous and group of trials, both in terms of intervention, sample, and cognitive assessment. Despite these positive findings, several quasi-randomized (Bryan & Tiggemann, 2001) and randomized (Martin et al., 2007) trials have failed to find cognitive benefits with caloric restriction.

Whole Diet Interventions

While only a small number of studies has examined caloric restriction and cognitive function specifically, it should be noted that a growing body of evidence suggests that overall healthier dietary patterns, which often include modest caloric reductions, have shown preliminary evidence of mitigating cognitive decline (Martinez-Lapiscina, Clavero, Toledo, Estruch, et al., 2013; Smith et al., 2010). As noted above, our study examining the DASH diet, with and without caloric restriction and weight loss, was associated with modest improvements in cognitive performance, which were associated with weight loss and improved fitness (Smith et al., 2010). In addition, results from a single site among the larger multi-site PREMEDI study demonstrated that participants randomized to receive the MeDI diet exhibited better cognitive performance than controls (Martinez-Lapiscina, Clavero, Toledo, Estruch, et al., 2013) and these benefits were maintained among some participants, who showed a reduced risk of mild cognitive impairment during subsequent follow-ups (Martinez-Lapiscina, Clavero, Toledo, San Julián, et al., 2013). These studies have provided preliminary evidence that intentional modification of dietary intake may confer cognitive improvements (Smith & Blumenthal, 2010), a question that is now being examined in several ongoing randomized trials.

Mechanisms

There are several mechanisms linking caloric restriction to cognitive and brain health. Although the majority of existing evidence has been derived from animal models of neurodegenerative illnesses, a growing body of evidence in humans has extended these findings, providing preliminary evidence linking underlying changes in neuroinflammation, cerebrovascular health, and neural signaling processes to cognitive performance (Murphy, Dias, & Thuret, 2014).

Neuroinflammation

A growing body of evidence suggests that neuroinflammation and microglial activation in response to injury may play an important role in the development of late life cognitive dysfunction and AD (Grammas, 2011). Caloric restriction and exercise-induced weight loss appear to improve peripheral inflammatory markers, and animal models of caloric restriction suggest that reduced caloric intake may mitigate amyloid burden in mouse models of AD. Moreover, increasing evidence suggests that neuroinflammatory cytokines may be an important regulator of neuronal plasticity, synaptogenesis, and neurogenesis, suggesting that basal elevations of neuroinflammation may counteract neuronal proliferation associated with behavior modification.

Cerebrovascular Health

As noted earlier, obesity and associated vascular comorbidities are associated with substantially increased risk of stroke, cerebrovascular burden, and AD in later life. Not surprisingly, preliminary evidence suggests that subtle MRI evidence of microvascular dysfunction is evident even among younger obese samples (Guo, Bakshi, & Lin, 2015) and that weight loss may improve microvascular function (Haltia et al., 2007) particularly among diabetic patients (Espeland et al., 2016). Moreover, microvascular function has been shown to mediate the association between dietary intake and cognitive performance in some samples of older adults (Gu et al., 2016), underscoring its potential importance among individuals engaging in chronic caloric restriction.

Neurohumoral/Growth Factor Modulation

Although few studies have examined it directly, preliminary evidence suggests that caloric restriction may increase expression of growth factors known to be important for neural plasticity and neurogenesis, most notably BDNF. Animal models of caloric restriction have suggested an upregulation of BDNF following reduced caloric intake, and, although few human studies have examined BDNF changes following caloric restriction (Witte et al., 2009), emerging evidence from other behavioral interventions suggests that BDNF expression may play an important role in neurogenesis, particularly in perihippocampal areas that are seminal in AD progression. Indeed, animal models have demonstrated that BDNF expression following caloric restriction is associated with enhanced hippocampal neurogenesis. In one of the few human studies to examine this, Araya, Orellana, and Espinoza (2008) found that only 3 months of caloric restriction enhanced BDNF expression among insulin-resistant overweight and obese subjects, suggesting that BDNF may be possible with dietary modification.

A closely related neural mechanism is enhanced neurohumoral responsivity, particularly enhanced insulin sensitivity and insulin-like growth factor (IGF-1) expression, which have been implicated as important components of the neuropathological processes underlying dementia, with particularly detrimental effects to the hippocampus. Insulin and IGF-1 appear to act as neurotrophins by inhibiting apoptosis, and insulin resistance has been increasingly recognized as a risk factor for AD, with novel treatments currently being designed to enhance cerebral glucose utilization. In one of the longest randomized trials ever to examine this question, Colman et al. (2014) examined the long-term effects of caloric restriction vs. ad libitum eating patterns in a sample of 30 adult, male, rhesus monkeys. The monkeys were followed for 20 years, and detailed accounting of chronic disease development and causes of death were examined. In their study, not only did monkeys randomized to caloric restriction live longer, but also they exhibited better glucose homeostasis, lower incidence of cancer and diabetes, and exhibited more preserved brain volumes compared with the control monkeys, particularly gray matter volumes in the frontal lobes.

Oxidative Stress

One of the most enduring theories linking caloric restriction to successful aging is its presumed amelioration of oxidative stress, which remains a central mechanism of age-related decline. Indeed, genes facilitating oxidative stress responses and DNA repair are preferentially upregulated in the aging prefrontal cortex (Lu et al., 2004), implicating a central role in cognitive decline. Numerous animal studies have demonstrated that calorically limited mouse samples exhibit improved longevity and lower rates of oxidative damage, as evidenced by reduced accumulation of oxidatively damaged proteins, lipids, and DNA (Finkel & Holbrook, 2000). Although very few human studies have examined alterations in oxidative stress directly, Harvie et al. (2011) found that a 6-month randomized trial comparing caloric restriction with intermittent fasting yielded comparable improvements in markers of oxidative stress.

A related line of inquiry examines the impact of caloric restriction on sirtuins (Bishop, Lu, & Yankner, 2010), a family of proteins involved in cellular response to environmental and dietary stress. Specifically, these NAD-dependent deacetylases and monoadenosine diphosphate-ribosyl transferases influence the regulation of lipid and glucose metabolism, DNA repair, and insulin secretion and control cell survival. Although beyond the scope of the present review, sirtuins appear to be an important molecular mechanism linking caloric restriction to improved longevity (Mair & Dillin, 2008).

Future Directions

The existing body of evidence linking caloric restriction to cognitive function provides compelling preliminary data suggesting that limited energy intake may confer neuroprotective effects. Despite the available evidence, there are strikingly few large, well-controlled randomized controlled testing the benefits of caloric restriction among overweight or obese adults, and the vast majority of mechanistic data have been conducted in non-human samples, limiting the ability to draw conclusions regarding the putative neurobiological links between diet and brain function. Larger randomized trials examining caloric restriction among obese adults are needed to gain a more comprehensive understanding of the potential impact of dietary strategies to mitigate cognitive decline. Future studies could also benefit from delineating the unique effects of weight loss through caloric restriction with and without exercise, as many of the available studies utilized both treatment modalities to achieve larger treatment improvements in weight. A related, understudied aspect of caloric restriction is the potential benefit of intermittent fasting on cognitive and brain outcomes, which has been shown to produce comparable weight loss benefits when compared with traditional caloric restriction (Davis et al., 2016), reduces cardiovascular risk factors, is associated with reduced risk of age-related cognitive deficits, and may be easier for patients to adhere to. Finally, future randomized trials would benefit from careful assessment of mechanisms linking caloric restriction to cognitive function, including neuroimaging assessments of structural and functional outcomes, markers of neuroinflammation, neurotrophic expression, and oxidative stress.

Psychosocial: Substance Abuse—Street Drugs

Introduction

Drug use is a significant public health problem that impacts millions of individuals worldwide. In the United States, approximately 27 million individuals (12 years old and older) reported consumption of an illicit drug in the past 30 days—this translates to approximately 1 in 10 people in 2014. The percentage of individuals who have used an illicit drug in the past 30 days has increased each year since 2002 (Substance Abuse and Mental Health Services Administration [SAMHSA], 2015). Drugs of abuse impact neurotransmission, often influence neuropsychological performance, and confer risk of addiction. It has been well documented that substance use and abuse negatively impacts neuropsychological functioning. Since a review of every drug of abuse is beyond the scope of this chapter, we will focus on the most commonly used illegal psychoactive drugs. Whenever possible, this chapter will rely on findings from large-scale studies, review papers, and meta-analyses, as well as any pertinent novel, recent, and high impact research findings.

Before undertaking a review of the literature on neuropsychological consequences of substance use, there are several methodological challenges and limitations inherent in such work that are worth considering. One such pervasive challenge is heterogeneity of the participant samples. Participants within and across studies often have diverse patterns of substance use, vary on whether or not they meet criteria for a substance use disorder, often use multiple substances, and vary in prevalence of other comorbid conditions often common among substance users (e.g., psychiatric disorders, traumatic brain injury, HIV). Characteristics of substance users can vary on an array of domains that include length of abstinence, number and severity of polysubstance use, amount and frequency of use, and diagnosis and severity of

substance use disorders. For example, the neuropsychological effects of a particular drug may dissipate after a prolonged period of abstinence (e.g., cannabis; Schreiner & Dunn, 2012), or neuropsychological effects become more prominent after a prolonged period of abstinence (e.g., cocaine; Woicik et al., 2009). Perhaps one of the most intractable challenges to date is definitively determining whether neuropsychological impairments are a result of a substance use disorder or if these impairments precede a substance use disorder. Quasi-experimental designs are the only ethical research methods to use when studying the effects of chronic substance use on neuropsychological functioning in humans. As such, longitudinal designs and twin studies are some of the strongest research designs to assess whether neuropsychological deficits result from or predate substance use. With these issues in mind, we will focus on meta-analyses, longitudinal studies, twin studies, and recent novel studies whenever possible.

Benzodiazepines

Benzodiazepines (BZD) are one of the most widely used therapeutic drugs to treat anxiety and sleep disorders, with an estimated 3% of individuals endorsing prescribed lifetime use in 2014 (SAMHSA, 2015). Among high school seniors, use of Xanax (the most common nonmedically abused BZD) and perceived BZD availability have decreased over the past decade (SAMHSA, 2015).

Introduced during the 1960s, BZD became favored over prior sedatives and barbiturates because of their improved safety and low risk of lethality. BZD produces anxiolytic, anticonvulsant, sedative-hypnotic, and anesthetic effects, leading it to become synonymous with terms such as sedatives and tranquilizers. Created with the intention for only short-term use, BZD physiological and pharmacological dependence, withdrawal, and negative side effects are common even at low therapeutic doses. BZDs exert their effects on the central nervous system (CNS) by facilitating the rapid binding of GABA to its receptors with high concentrations in the amygdala, frontal cortex, insula, hippocampus, and cerebellum (Sieghart, 1994). Acute subjective effects of BZD administration include sedation, slowing, relaxation, and anterograde amnesia, which are directly associated with neuropsychological functioning (Buffett-Jerrott & Stewart, 2002).

Acutely, BZDs have been found to elicit deficits in many cognitive domains including processing speed, explicit and implicit memory, attention, and executive functions (Buffett-Jerrott & Stewart, 2002). However, differences in BZD chemical potency, bioavailability, and half-lives make it difficult to generalize results across individual studies.

To examine long-term BZD use effects, meta-analyses have provided greater insight on how cognitive functioning is influenced by prolonged use. Barker, Greenwood, Jackson, and Crowe (2004a, 2004b) evaluated cognitive performance in 12 neuropsychological domains and found moderate to large effects across all domains that included sensory processing, nonverbal memory, speed of processing, attention/concentration, general intelligence, working memory, psychomotor speed, visuospatial, problem solving, verbal memory, motor control/performance, and verbal reasoning in 13 studies.

Additionally, Barker and colleagues (2004a) conducted another meta-analysis to assess whether neuropsychological functioning in long-term users improves after BZD cessation. Results revealed small to moderate effect sizes in 5 of 11 domains, indicating an improvement in visuospatial, attention/concentration, general intelligence, psychomotor speed, and nonverbal memory performance. However, despite improvements, small to large negative effects were observed in verbal memory, psychomotor speed, speed of processing, motor control, visuospatial, general intelligence, attention/concentration, and nonverbal memory compared with controls, despite discontinued BZD use for 6 months.

Similarly, BZD half-life metabolism has been found to negatively influence cognition. In a single study conducted by Helmes and Ostbye (2015), BZD half-life classification (i.e., short, intermediate, and long acting) was associated with differences in neuropsychological performance. Specifically, intermediate BZDs were associated with poorer performance in judgment and language comprehension and long-acting BZDs with poorer language comprehension and verbal short-term memory. These results suggest that larger cognitive deficits are observed in BZDs with longer half-lives, but no deficits are observed in shorter-acting BZDs. Despite specific cognitive impairments associated with BZD use, risk of global cognitive decline and incident dementia is only slightly higher compared with nonusers (Gray et al., 2016). When comparing BZD users, a slight increase in individual risk was only associated with low BZD exposure and not with higher levels of exposure. These results further suggest that the risk for developing more severe neurocognitive disorders such as Alzheimer's or dementia is only slightly elevated for those using low-dose BZDs (Gray et al., 2016).

Overall, evidence supports that acute and prolonged BZD use affects neurocognitive performance persistently. Despite evidence suggesting discontinuation of BZD use improves cognitive performance, residual effects have been observed and need to be further explored.

Cannabis

Cannabis is the most commonly used illicit drug (per federal regulations) in the United States with over 45% of Americans reporting lifetime use in 2014 (SAMHSA, 2015). With growing efforts over the last decade to legalize cannabis for recreational and medicinal use, risk perception has steadily declined among users and nonusers (Volkow, Baler, Compton, & Weiss, 2014). Due to its widespread use among various ages, cannabis and its neuropsychological effects have been avidly researched and debated.

The genus Cannabis contains three subspecies, *Cannabis sativa*, *Cannabis indica*, and *Cannabis ruderalis*, all which contain over 400 compounds influencing its analgesic, sedative, and stimulatory properties. In 1964, delta-9-tetrahydrocannabinol (Δ^9-THC) was discovered to be the primary psychoactive constituent of cannabis, promoting interest in research and leading to the discovery of the endogenous cannabinoids. The discovery of the first cannabinoid receptor (CB1) in the mammalian brain in 1988 and the second (CB2) in the 1990s has led to a better understanding of how THC exerts its psychoactive effects by binding to CB1 receptors. CB1 receptors are located throughout the body with the densest concentrations located in the CNS. They are most abundant in the hippocampus, amygdala, basal ganglia, and cerebellum, structures known to influence learning, memory, reasoning, and emotional processing (Glass, Faull, & Dragunow, 1997), but can be found throughout cortex.

The psychoactive effects of cannabis on the CNS vary depending on route of administration and dose. The most common method of use, smoking, results in peak plasma concentrations within 3–10 min, and psychoactive effects lasting approximately 2–3 hr. Acute intoxication has been shown to affect neuropsychological functioning; however, results examining specific cognitive domains and age ranges provide varying results. In addition, many studies have provided evidence that regular and long-term cannabis use results in neurocognitive functioning deficits, even after the acute effects of the drug have subsided.

Due to heterogeneity in study design and limitations in methodology, single studies and research reviews provide a fragmented picture of cannabis' effects. To control for these limitations, the utilization of meta-analytic techniques has allowed for consensus among findings. Grant, Gonzalez, Carey, Natarajan, and Wolfson (2003) examined the non-acute (i.e., residual, long term, permanent) effects of cannabis use in 11 studies and were the first to highlight small observable effect sizes providing evidence for subtle overall cognitive differences in heavy cannabis users compared with nonusers. Schreiner and Dunn (2012) replicated these results and extended them with numerous additional studies published since the original meta-analysis. They found positive effects globally and in six cognitive domains including abstraction/executive, attention, forgetting/retrieval, learning, motor, and verbal language, indicating deficits after acute cannabis intoxication (i.e., minimum 25-day abstinence). Further examining prolonged cannabis abstinence effects, Schreiner and Dunn (2012) found no significant effects of cognitive impairment after 6 months of discontinued use, demonstrating impairments may only be limited to recent cessation influenced by THC metabolite presence.

However, there is ongoing debate on the various factors that may influence neuropsychological performance in cannabis users. Two that have received significant attention are sex and age of initial use. Sex differences observed in episodic memory and age of cannabis use initiation suggest that females may be at higher risk for developing neurocognitive vulnerabilities and maintaining use compared with males (Crane, Schuster, Mermelstein, & Gonzalez, 2015). Similarly, an earlier age of cannabis use onset has been postulated by others to result in worse neurocognitive functioning. Strong support for this idea emerged recently from the largest longitudinal study to date assessing the relationship between cannabis use and neurocognitive functioning (Meier et al., 2012). Importantly, baseline assessments of neurocognitive functioning were available for all participants prior to cannabis use onset. The authors found that neuropsychological decline was associated with persistent cannabis use, only when persistent cannabis use began before age 18. However, studies of monozygotic and dizygotic twin pairs have reported no neurocognitive differences between twin pairs discordant for history of cannabis use (Jackson et al., 2016).

Recently neuroimaging techniques including functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) have been used to further delineate the neurobiological effects of cannabis use. In a systematic review conducted by Martin-Santos et al. (2010), acute and chronic cannabis exposure was associated with decreased blood flow during resting global acquisition in prefrontal cortex (PFC) and anterior cingulate cortex (ACC) compared with nonusers. Similarly, in a review of 43 structural and fMRI studies, the authors concluded that THC exposure was associated with reduced hippocampal volume and lower prefrontal cortical, cerebellar, and striatal blood oxygen level-dependent (BOLD) signal compared with controls during cognitive tasks (Batalla et al., 2013). These findings indicate a possible inefficient neural network influenced by cannabis use, despite comparable task outcomes with nonusers. Finally, evidence from recent neuroimaging studies is suggesting altered reward processing and motivation among regular cannabis users (e.g, Volkow et al., 2014).

The preponderance of evidence demonstrates that acute cannabis use on neuropsychological functioning influences cognitive domains including learning and memory. Deficits are also observed among current heavy cannabis users when not intoxicated with less frequent users displaying minimal or no deficits, although there is ongoing debate on the extent of these deficits in this population. While current neuropsychological results have suggested cannabis use impairments may dissipate over time, future neuroimaging studies and further examining prolonged neural changes after cessation need to be explored to support prior evidence.

Cocaine

Cocaine is a psychoactive alkaloid that is found in the leaves of the coca bush, native to Southwest America. In 2013, cultivation of the coca bush was at its lowest in the last three decades, creating a decrease in the availability of cocaine. In 2014, approximately 4.3 million American adults reported using cocaine in the past year, and 1.5 million reported using cocaine in the past month (SAMHSA, 2015). Typically, cocaine is consumed in one of two forms, which are cocaine hydrochloride, a powered form of cocaine that is usually ingested intranasally, or crack cocaine, a free-base form of cocaine that is typically smoked. It is important to note that cocaine can cause ischemic and hemorrhagic cerebrovascular damage that can lead to neuropsychological deficits (Levine et al., 1990).

Similarly to other psychostimulants, acute effects of cocaine on neuropsychological functioning results in better attention (Johnson et al., 1998), speed of information processing (Higgins et al., 1990), and inhibitory control (Fillmore, Rush, & Hays, 2006). However, cocaine use can cause long-term neuronal and neuropsychological damage. Brain imaging studies suggest cocaine-dependent individuals have lower gray matter volumes in the premotor cortex, orbitofrontal cortex, temporal cortex, thalamus, and cerebellum compared with healthy controls. These deficits were associated with poorer performance on tasks of executive function and fine motor performance (Sim et al., 2007). Ersche, Williams, Robins, and Bullmore (2013) conducted a voxel-wise meta-analysis of MRI studies to determine structural brain abnormalities among individuals addicted to stimulants (i.e., cocaine, amphetamines, or methamphetamines). Although the meta-analysis included individuals addicted to cocaine, amphetamines, or methamphetamines, a majority of the studies (n = 10) included only participants who were addicted to cocaine. The meta-analysis contained 16 studies composed of 494 stimulant-dependent individuals compared with 428 healthy controls. Stimulant-addicted individuals had significant gray matter volume decreases in five specific regions: the insula, ventromedial PFC, inferior frontal gyrus, pregenual anterior cingulate gyrus, and anterior thalamus. The regions with gray matter volume decreases are primarily involved with executive function. These findings generally support research that suggests executive function deficits among cocaine-dependent individuals.

A qualitative review conducted by Jovanovski, Erb, and Zakzanis (2005) of the neuropsychological effects of cocaine use compared the effect sizes across studies to determine the most consistent neuropsychological deficits. Across 15 studies that included 481 cocaine users and 586 controls, the most consistent deficit observed among cocaine users was in attention and executive functioning. Attention deficits had the largest effect sizes followed by working memory, visual memory, and executive functioning. Small effect sizes were observed for deficits in language function (including verbal fluency and sensory-perceptual function). It must be noted that the cocaine-dependent individuals included in this meta-analysis have a wide range of number of days of abstinence (0–1,075).

One notable study conducted by Woicik and colleagues (2009) documented differences in neuropsychological performance among individuals with current cocaine use disorders and matched healthy controls in measures of attention, executive function, and verbal memory. However, these deficits were more pronounced in the individuals with cocaine use disorders who have a negative urine status for cocaine. These findings suggest that neuropsychological deficits for cocaine-dependent individuals may manifest after a longer period of abstinence, but more work is needed to understand the underlying cause for this observed effect.

Currently, the evidence generally suggests that the largest deficits associated with cocaine use are in the areas of attention and executive functioning, while small effects have been observed in memory and language functioning. These findings are supported by neuroimaging studies that have observed decreased gray matter volume primarily in the PFC. However, as documented by Woicik and colleagues (2009), these findings may be more pronounced after a longer period of abstinence from cocaine use. Future studies that evaluate the association of cocaine use and neuropsychological functioning may benefit from also examining cocaine-dependent individuals who have been abstinent from cocaine use for an extended period of time.

MDMA (Ecstasy)

3,4-Methylenedioxymethamphetamine (MDMA), or "ecstasy," has a similar chemical structure to both stimulants and hallucinogens and has been classified as an "entactogen." In the United States, 6.6% of Americans ages 12 and older have used ecstasy at least once in their lifetime (SAMHSA, 2015). A significant challenge to the study of the neuropsychological effects of MDMA is that ecstasy pills are expected to contain MDMA; however this is not always the case. Many ecstasy pills (also known as molly, candy, and rolling) contain other psychoactive substances or may not contain any MDMA at all. Specifically, out of 1,214 tablets sold as ecstasy, only 39% of the tablets contained pure MDMA, 46% did not contain any MDMA at all, and the remaining 15% contained both MDMA and other substances (e.g., caffeine, dextromethorphan, methylenedioxyamphetamine, methylenedioxyethylamphetamine, and methamphetamine; Tanner-Smith, 2006).

Attention performance has been measured during acute intoxication of MDMA and has yielded mixed results. Studies suggest no impairment in attention (Vollenweider, Gamma, Liechti, & Huber, 1998), though one study found that acute intoxication of MDMA can result in deficits in divided attention and tracking performance (Kuypers, Wingen, Samyn, Limbert, & Ramaekers, 2007). Impairments in memory performance have also been reported; however, these impairments appear to return to baseline levels after intoxication (Kuypers & Ramaekers, 2005). Kuypers, Wingen, Heinecke, Formisano, and Ramaekers (2011) designed a study to determine the neural substrates associated with memory impairment during acute intoxication of MDMA via MRI. Results suggest that impairments with memory encoding may be due to the influence of MDMA on middle frontal gyrus functioning.

Several meta-analyses have been conducted that address the neuropsychological sequelae of MDMA. Verbaten (2003) examined only studies with between-group designs between 1975 and 2002. This meta-analysis contained 14 studies, and the only inclusion criteria for the meta-analysis were that participants had to be abstinent from MDMA and other drugs for at least one week prior to the assessment. Results suggest that MDMA users performed significantly worse on measures of short-term memory, long-term memory, and attention. Kalechstein, De La Garza, Mahoney, Fantegrossi, and Newton (2007) conducted a similar meta-analysis of studies conducted until 2004, with lenient inclusion criteria (i.e., any studies that evaluated neuropsychological effects of MDMA with matched controls) resulting in 23 studies and strict inclusion criteria (i.e., matched controls on demographic and premorbid factors and MDMA users were abstinent at evaluation and not treatment seeking) resulting in 11 studies. MDMA users performed significantly worse in all domains in both conditions. Other meta-analyses have reached similar conclusions, with small to moderate effect sizes across all domains and a negative association between performance and length of MDMA use (Zakzanis, Campbell, & Jovanovski, 2007). Recently, a meta-analysis by Murphy et al. (2012) was conducted to determine the effects of MDMA on visuospatial memory. Liberal criteria for inclusion in the meta-analysis were applied (i.e., any study that used visuospatial memory tasks and participants who were abstinent during the evaluation), yielding 52 studies. Moderate effect sizes were observed for MDMA users performing significantly worse on recall or recognition of spatial distribution of stimulus elements, recognition of figures, and reproduction or production of figures.

Notable prospective studies have been recently conducted that included only MDMA-naive participants at baseline and followed the participants to determine the effects of MDMA after initiation of use. The study included 149 participants who had never used MDMA at baseline—109 participants were administered the 1-year follow-up. During the 1-year follow-up period, 43 subjects did not use any illicit substances, while 23 participants used MDMA more than 10 times. The remaining subjects, who used MDMA more than once but less than 10 times, were not included in the analysis. Change scores were compared between MDMA users and nonusers. MDMA users performed significantly worse on immediate and delayed recall of visual paired associations; however, there was no other area of cognitive decline (Wagner, Becker, Koester, Gouzoulis-Mayfrank, & Daumann, 2013). Using the same sample at a 2-year follow-up, immediate and delayed recall of visual paired associates declined significantly among MDMA users, and no significant decline was observed in other areas of neuropsychological functioning (Wagner et al., 2015).

Generally, the evidence supports that MDMA may cause decline in visual memory and learning impairment among users. Although notable, the small sample sizes among some studies limit the generalizability of these findings. A larger sample size may reveal small or moderate changes in cognitive domains other than visual memory and learning. Future studies in this area would therefore benefit from larger sample sizes. Additionally, meta-analyses suggest cognitive decline in several domains, though these findings are divergent among prospective studies.

Methamphetamine

Methamphetamine (e.g., ice, crank, crystal meth) is a potent and highly addictive stimulant of the CNS, the effects of which can last up to 12 hr. Methamphetamine can be consumed in a variety of ways, including snorting, smoking, and injection. Recent national estimates indicate that 1.3 million people (0.5% of the population) reported using methamphetamine in the past year and 569,000 (0.2%) reported using it in the past month, figures similar to those from previous years (SAMHSA, 2015).

Methamphetamine's lipophilicity allows it to cross the blood–brain barrier faster and thus penetrate the CNS to a greater extent than its parent compound amphetamine. Methamphetamine stimulates the release of dopamine while simultaneously blocking, to some extent, synaptic reuptake of dopamine, both of which result in increased levels of dopamine in reward regions of the brain.

The acute effects of methamphetamine may include autonomic arousal, tachycardia, suppression of appetite, euphoria, feelings of increased physical and mental capacity, elevated self-esteem, increased libido, insomnia, and irritability. Administration of moderate doses of methamphetamine can lead to enhanced attention and concentration (Johnson et al., 2005).

Long-term use induces neurotoxicity in several neurotransmitter systems, particularly the nigrostriatal dopaminergic pathways, thus altering the function of prefrontal–striatal circuits. A meta-analysis, which included 18 studies and a total of 487 participants with lifetime methamphetamine abuse/dependence and 464 healthy controls, revealed that chronic methamphetamine users showed impaired neuropsychological performance in the domains of learning, executive functions, memory, speed of information processing, and motor skills relative to healthy controls, which is likely related to the dysfunction in the neural circuits underlying these processes (Scott et al., 2007). These effect sizes were broadly in the medium range, such that methamphetamine users performed worse than controls in measures of attention/working memory, visuoconstruction, and language (Scott et al., 2007).

Neuroimaging studies have found a range of structural and metabolic abnormalities in the brains of chronic methamphetamine abusers. Structurally, methamphetamine abusers showed enlarged striatal volumes, suggesting an initial compensatory (inflammatory) response (Chang, Alicata, Ernst, & Volkow, 2007). However, a study found that greater usage ultimately led to a decrease in striatal volume, associated with greater cognitive impairment (Chang et al., 2005). Smaller hippocampal volumes have also been linked to poorer episodic memory performance among chronic users (Thompson et al., 2004). PET studies have found reduced dopamine transporter (DAT) density as well as reduced D_2 dopamine receptors in the striatum of methamphetamine users (Chang et al., 2007). Though changes in DAT density subside with prolonged abstinence, the psychomotor and learning impairments associated with them do not, which suggests either insufficient recovery or the involvement of other unidentified neural networks (Chang et al., 2007). Furthermore, H^1 magnetic resonance spectroscopy studies have revealed lower concentrations of the metabolite *N*-acetylaspartate (NAA), a marker for neuronal integrity and density, and creatine, which reflects cellular energy metabolism, in the basal ganglia of individuals who recently abstained from chronic methamphetamine use (Chang et al., 2007). The etiology and consequences of these abnormalities are not yet clear.

Studies have employed fMRI techniques to detect differences in the brain activity of methamphetamine abusers, which mostly involve hypoactivity of frontal areas. Notably, Salo, Fassbender, Buonocore, and Ursu (2013) found that methamphetamine abusers showed little to no activation in the dorsolateral PFC relative to controls during a variant of the Stroop task that measured trial-to-trial reaction time adjustments. PFC activity was negatively correlated with reaction time adjustments, such that less activity was related to longer reaction times and thus worse performance (Salo et al., 2013). These findings suggest a failure to adapt a behavioral response based on prior experience, which is a hallmark behavior of addiction (Salo et al., 2013). Hypoactivity of frontal and other areas in methamphetamine users has also been linked to deficits in socioemotional processing (Payer et al., 2008) and decision making (Paulus, Hozack, Frank, Brown, & Schuckit, 2003).

Together, these findings suggest that long-term methamphetamine abuse leads to learning and memory impairments, as well as executive dysfunction. Neuroimaging findings suggest that these deficits are linked to abnormalities in prefrontal–striatal circuits, most notably abnormalities in gray matter volumes of subcortical structures and hypoactivity of frontal areas. Further research is needed to determine whether these impairments will improve with prolonged abstinence.

Opiates

Opiate is extracted from the seeds of the opium poppy plant, with majority of the illegal opiates being grown in Afghanistan. Opioids are the synthetic form of opiates. Approximately 4.8 million Americans reported using heroin in their lifetime during 2014, a figure that has remained steady since 2013 (SAMHSA, 2015). Prescription opioid addiction, such as Vicodin and Oxycontin, has become a national crisis in the United States due to the increases in opioid abuse and overdose deaths. The number of deaths related to opioid abuse has almost tripled since 2010 (Hedegaard, Chen, & Warner, 2015).

Neuroimaging studies have documented detrimental effects of opiate use on brain structure and function. General cortical atrophy and enlargement of external and internal CSF spaces (Pezawas et al., 1998) have been shown among individuals addicted to opiates. Specifically, decreases in gray matter density have been observed in the prefrontal, anterior cingulate, insular, and temporal cortices among opiate abusers compared with healthy controls (Lyoo et al., 2006).

Gruber, Silveri, and Yurgelun-Todd (2007) reviewed the neuropsychological consequences of opiate use. Results suggest that neuropsychological deficits exist both acutely and residually in measures of attention, concentration, recall, visuospatial, and psychomotor speed. Executive function appears to suffer the greatest impact from opiate use. A recent meta-analysis on the neuropsychological effects of opiate use revealed that the most robust impairments were in measures of verbal working memory, risk-taking (i.e., delay discounting and decision making), and verbal fluency. This review analyzed 20 studies with 767 chronic opioid users and 15,196 healthy controls compared on 7 neuropsychological domains: short-term verbal working memory, short-term visuospatial working memory, long-term memory, attention, cognitive impulsivity, non-planning impulsivity, and cognitive flexibility (Baldacchino, Balfour, Passetti, Humphris, & Matthews, 2012).

Research on opioid addiction has focused on the neuropsychological impairments associated with methadone maintenance therapy (MMT), the most commonly used form of replacement therapy for opioid dependence. Neuropsychological deficits have been observed among patients on MMT including attention, working memory, memory, psychomotor speed, problem solving, and decision making (Darke, Sims, McDonald, & Wickes, 2000; Mintzer & Stitzer, 2002). When comparing patients on MMT to abstinent heroin abusers, patients on MMT had significantly poorer performance on measures of processing speed, visuospatial perception, cognitive flexibility, working memory, and logical reasoning (Verdejo, Toribio, Orozco, Puente, & Pérez-García, 2005).

These findings overwhelmingly suggest that there are neuropsychological impairments associated with opioid dependence. These cognitive impairments include verbal working memory, risk-taking, and verbal fluency. In addition, patients on MMT may experience cognitive impairments in processing speed, visuospatial perception, cognitive flexibility, working memory, and logical reasoning.

Discussion

Substance use is associated with numerous negative outcomes, including social, emotional, and economic consequences that make it a significant public health problem. The use of neuropsychological tools in the context of substance use disorders has helped us to gain a better understanding of how critical cognitive processes are affected by substances of abuse, acutely and in the longer term. This chapter presents a complex picture of consequences from use of various substances. The heterogeneity in findings is likely due to a variety of issues, including each drugs own unique pharmacological properties as well as the characteristics of participant samples. For example, did the study include individuals recently out of recovery, a community sample of users, individuals that used a certain amount of a drug, or individuals that met criteria for a substance use disorder? Regardless, as has been described in this chapter, adverse effects on neurocognitive functioning are common consequence of substance use. Indeed, our review suggests that substance abuse is generally associated with neuropsychological deficits. However, as noted, these deficits vary across substances, neurocognitive domains, pattern, severity, and duration. Collectively, in most cases, more severe, frequent, and symptomatic substance use (e.g., a diagnosable substance use disorder) is associated with poorer neurocognitive outcomes. Recovery of neurocognitive functioning with abstinence is a more complex issue. Whereas abstinence from some substances may result in normalization of neurocognitive functioning over time (e.g., memory functioning among cannabis users), other deficits seem to persist or progressively worsen despite abstinence with other substances (e.g., cocaine and BZD).

Another important issue to consider, which often looms in the background and has received progressively more attention in recent years, is whether any of the neurocognitive deficits observed among substance users may have predated use; rather than a consequence of use, they may serve as a risk factor for addiction. From a theoretical standpoint, measures of inhibitory control, decision making, and other aspects of executive functioning are plausible candidates for neurocognitive deficits that may predate heavy use. However, without prospective longitudinal studies that adequately assess neurocognitive functioning before and after initiation of substance use, this issue cannot be adequately resolved. Although such studies have been conducted by several research groups or among specific cohorts (e.g., the Dunedin cohort; CEDAR; Pittsburgh Youth Study), many of these were not specifically designed to examine changes in neurocognitive functioning over time. The newly launched Adolescent Brain Cognitive Development (ABCD) project aims to examine neurocognitive abilities and brain structure and function, alongside many other relevant factors, among a representative sample of 10,000 children starting at ages 9–10 and throughout adolescence and early adulthood. Substance use characteristics will also be carefully assessed in this project to provide a clearer picture of how the brain looks and functions prior to and after initiation of substance use and how it continues to change among those that use relative to those that do not. In the process, the results of this project will address many of these lingering issues.

Despite dramatic advances in the scientific study of the neuropsychology of substance use, there are plenty of areas in which future studies could help elucidate discrepant findings and further our understanding of substance use disorders. As noted, prospective longitudinal studies with large sample sizes will continue to move the field forward. Similarly, more sophisticated meta-analyses that carefully consider how heterogeneity of samples and specific substance use characteristics influence findings will be valuable to the scientific literature.

The Effects of Prenatal Stress on Offspring Development

Megan R. Gunnar and Colleen Doyle

Institute of Child Development, College of Education and Human Development, University of Minnesota, Minneapolis, MN, USA

Introduction

In recent decades, research from a wide range of disciplines has shown prenatal development provides a foundation for learning and health throughout the lifespan. A growing body of work suggests that variation in the prenatal environment can produce individual differences and program regulatory systems that subsequently influence developmental organization and outcomes in infancy, childhood, and adulthood. This research provides evidence of long-term educational, behavioral, and psychological sequelae of *prenatal stress* (PS). In this work, prenatal stress is often used as an umbrella term for maternal experiences that include physiological and psychological responses to perceived threat or challenge, as well as negative mood states (frustration, anxiety, depression). The central hypothesis guiding PS research is that maternal experiences influence the *in utero* environment, alter the fetus's developing central nervous system (CNS), and subsequently set probabilistic parameters for future brain and behavior development. Although epidemiological, correlational, and quasi-experimental research with human subjects supports this *fetal origins hypothesis*, confounding variables prevent these studies from providing definitive proof. Instead, strong causal evidence for PS effects comes primarily from animal experiments. This area of research underscores the importance of delineating the effects and mechanisms of stress during the prenatal period in order to provide the optimal foundation for child development.

The goals of this article are to (a) outline the essential features of normal prenatal brain development in humans, (b) review the primary methods for studying brain development, (c) summarize findings on the effects and mechanisms of PS, and (d) consider factors that might buffer against PS and promote resilience. Finally, conclusions are discussed in the context of implications for efforts to support the health of pregnant women and their children.

Prenatal Brain Development

Brain development unfolds through a series of complex and dynamic processes involving the interaction of genes and the environment (see Stiles, 2008). Human prenatal CNS development is organized into the *embryonic period* (conception—gestational week [GW] 8) and the *fetal period* (GW9—birth). The first step in embryonic brain development is the emergence of stem cells called *neural progenitor cells* at GW2. Through the process of *gastrulation,* neural progenitors become capable of producing all types of cells for the brain and CNS. Following their transformation, the region of neural progenitor cells is called the *neural plate.* During GW3, the first brain structure, the *neural tube,* begins to form. Through the process of *neurulation,* ridges rise along the sides of the neural plate, arch together, and fuse. Before closure of the tube, the anterior end expands to form three primary *brain vesicles* that are precursors of the forebrain, midbrain, and hindbrain. By GW8, these subdivide to form five secondary brain vesicles that are the precursors of the medulla, pons, midbrain, diencephalon, and telencephalon. From GW4–8 the embryo grows in size tenfold. During this time of rapid development, *neurogenesis,* or neuron production, begins. Between GW6 and GW20, the brain produces about 250,000 cells per minute.

At the start of the fetal period, neuron production begins to drive dramatic changes in the brain's gross morphology. The smooth structure of the immature brain is transformed as gyral and sulcal folding emerge. Between GW8 and GW22, the longitudinal fissure that separates the right and left hemispheres develops. Additional primary sulci form between GW14 and GW26, secondary sulci emerge between GW30 and GW35, and the development of tertiary sulci extends from GW36 into the postnatal period. These foldings allow the fetal brain to dramatically increase cortical surface area. By GW20, most of the billions of neurons in the human brain have been produced. *Neural migration* ensues in two main waves, with peaks at GW8–10 and GW12. Through migration, neurons radially form the six-layered *neocortex* in an "inside out" fashion, so that deeper layers are populated and mature first, and more superficial layers are populated and mature last. *Cajal–Retzius cells* control the positioning of neurons by producing a molecule, *reelin,* that signals neurons to stop migrating. Around GW16 neurons reach their final position and begin extending axons and dendrites, which allow them to communicate with other neurons via *synapses.* Few synapses are formed until GW28, when the pace accelerates to approximately 40,000 synapses per minute. Through synaptic communication neurons establish functional neural circuits that mediate sensory and motor processing and underlie behavior. Around GW32–34, *myelination* begins. This involves the production of the fatty sheath that insulates nerve fibers and allows for cells to transmit information faster.

Along with cell proliferation, naturally occurring cell death plays an essential role in CNS development. N*ecrotic cell death* eliminates cells that are damaged due to injury, and *apoptosis* eliminates cells that initiate an intrinsic suicide program. Since neurons that form connections with other neurons are more likely to survive, apoptosis is hypothesized to regulate the establishment of neural circuits. Apoptosis also eliminates cells like neural progenitor cells once their transitory functions are complete. During prenatal development normative cell death eliminates 50% or more of neurons.

Brain maturation begins a new phase at birth characterized by exuberant connectivity and refinement of neural circuitry. Between birth and the third year of life, gray matter increases from 50% of adult brain volume to 90%, and white matter myelination progresses to an adult-like pattern. Finally, *synaptic pruning* begins refining neural connectivity via plasticity processes that are influenced by the child's experience and environment (Greenough, Black, & Wallace, 1987).

Methods of Studying Fetal Brain Development

Animal models

Because experimental studies of typical and atypical fetal brain development are neither easy nor ethical with human subjects, animal models provide an essential tool for understanding PS effects. Animal experiments allow researchers to systematically manipulate the type, timing, and intensity of the stressor and test for differential effects on offspring development at the behavioral, anatomical, and cellular level of the brain. Stimuli used to stress the mothers include random light or noise, restraint, or removal from the home cage. Additionally, animal models provide an opportunity to tease apart pre- and postnatal influences on offspring development through cross-fostering designs. Although animal studies have used many mammals, the majority have been conducted on rodents. As a result, researchers often grapple with issues of translation when interpreting findings (Gottlieb & Lickliter, 2004).

Fetal physiological monitoring

For over seven decades researchers have studied indices of fetal physiological functioning, including fetal heart rate (FHR), fetal heart rate variability (FHRV), fetal movement (FM), and "coupling," or the association between FHRV and FM (see DiPietro, Costigan, & Voegtline, 2015). Over the course of pregnancy, these indices change in a predictable way that is reflective of brain maturation. This is because the heart is innervated by fibers from both branches of the autonomic nervous system, which interact to regulate FHR and FHRV; sympathetic innervation increases FHR, while parasympathetic innervation reduces FHR. Early in gestation, FHR is predominately under the control of the sympathetic nervous system. As the CNS develops, the maturation of the parasympathetic branch allows progressive activity of the vagus nerve to slow the heart down and modulate FHR in coordination with motor functioning. As a result, over the course of pregnancy, FHR decreases and FHRV and cardiac-motor coupling increases. Researchers often use fetal physiological monitoring to characterize the adaptation and individual developmental trajectory of the CNS in the fetus. Typically, 30–50 min of fetal monitoring using electrodes applied to the mother's stomach is required to detect within-individual stability and measure variations that emerge during fetal rest-activity cycles. There is evidence of rank-order stability of FHRV over gestation, suggesting continuity in individual differences in brain development is detectable during pregnancy. Additionally, by comparing typically progressing pregnancies with pregnancies characterized by intrauterine growth restriction and other conditions, researchers have identified deviations in fetal indices that reflect these conditions. Similarly, researchers have used fetal indices to examine possible deviations in fetal CNS development that are associated with PS effects. Finally, differences in fetal indices, independent of maternal factors, have been used to predict offspring behavioral and psychological development.

Fetal MRI

Since the development of magnetic resonance imaging (MRI) in the 1980s, researchers have used this technology to study fetal brain development (see Prayer et al., 2006). MRI uses a powerful magnetic field (MF) and radiofrequency (FF) pulse to align magnetically active nuclei (i.e., protons) and then knock the nuclei out of alignment. As the nuclei recover their alignment, they emit a radio signal that is converted into an image. Although MRI can generate detailed images depicting fetal brain anatomy, until recently it was not widely used due to safety concerns. Unlike other imaging methods, MRI does not involve radiation, which can directly kill cells or cause genetic mutations. Pregnant women cannot be scanned if they have metal devices or implants. However, primary safety concerns for the fetus include risk due to exposure to MF or RF pulse or to increased heat or noise caused by the MRI. In addition to animal studies examining these concerns, several follow-up studies of children studied with fetal MRI have been carried out. Although no significant adverse effects have been discovered, researchers typically do not use MRI to study normal brain development until after GW18, when the major steps of organ production and development have been completed.

Currently, the most significant challenge to using MRI to study brain development is fetal motion, which can cause ghosting or blurring of the acquired MRI image. In life-threatening situations, the use of a sedative can reduce fetal motion; however, this is not a practical approach for general use. Instead, the ongoing development of faster imaging and motion correction techniques are essential to advancing fetal MRI methodology. Currently, research using this approach is in the nascent stage. Because of the rapid pace of fetal brain maturation, changes that can be detected with fetal MRI occur on the order of weeks or even days. As a result, it is difficult to study fetal brain development at a precise developmental stage. Therefore, in order to fully leverage fetal MRI to study how PS may alter brain development, an increased understanding of temporal and regional variability of events in normal brain maturation is needed.

Effects of Prenatal Stress on Offspring Brain and Behavior Development

The delineation of PS effects depends on the definition of stress itself (see Gunnar & Davis, 2013). *Stress* is conceptualized as a state of disharmony or threatened homeostasis that sets in motion physiological and behavioral responses to reestablish homeostasis. *Distress* is a negative psychological response to the perception of threatening, difficult, or stressful experiences that can include a variety of cognitive and affective states, such as uncertainty, frustration, anxiety, and depression. Thus PS is equated with negative emotional states. This is problematic for several reasons. First, PS can involve physical challenges that do not involve negative emotions, such as the pregnant woman doing physically demanding work that activates stress hormones. Second, not all emotionally negative states activate stress biology (Hennessy & Levine, 1979), suggesting that associations between mood dysregulation and fetal outcomes may involve biology beyond activation of stress-mediating systems. Third, because it is the interpretation of the event that mediates the impact of objective conditions on stress biology, when PS is defined by the event (i.e., exposure to a natural disaster), there can be a wide variety of individual responses.

Notably, several researchers have shown PS is neither specific to pregnancy nor stress. Correlations among self-report measures of stress and symptoms of depression and anxiety are high during pregnancy and remain stable through the first 2 years after delivery. These results suggest that measures of PS may gauge factors like personality traits, coping skills, and social support. Additionally, many environmental stressors, such as low socioeconomic status, marital/family conflict, and paternal death or incarceration, are likely to persist after pregnancy. Since these factors can influence maternal caregiving, investigators must measure and control for postnatal levels of stress in order to differentiate pre- and postnatal influences on child development.

To test for PS effects on offspring brain and behavior development, investigators have looked for converging evidence from animal and human studies. Here we summarize results in both domains of research.

Animal studies

Results from animal models show offspring exposed to PS exhibit heightened anxiety and fear of novelty, diminished exploration and social interaction, deficits in attention, learning and memory, delays in motor development, and disturbances in motor behavior (stereotyped, non-directed motor behavior). These findings have been widely replicated in rats and rhesus monkeys using different stress paradigms. Also, PS alterations to offspring behavior have been associated with changes in brain development, including alterations to the hippocampus and amygdala, two areas of the brain that support learning, memory, and emotion regulation. These alterations include reduced neurogenesis, synaptic density, and dendritic length and complexity. Additionally, research shows PS alters the neurodevelopmental trajectory of the amygdala, such that animals exposed to PS exhibit initially reduced and subsequently increased amygdala volume. Offspring exposed to stress at the end of gestation also shows hypermyelination. Finally, animal experiments show that PS induces alterations to hypothalamic–pituitary–adrenocortical (HPA) axis functioning including elevated basal corticosterone levels, heightened HPA axis reactivity to acute stress, and decreased negative feedback of the HPA axis. These physiological alterations are associated with decreased binding capacity of both mineralocorticoid and glucocorticoid receptors in the brain.

Additionally, animal models suggest some sex-specific effects of PS. While males exposed to PS show deficits on tasks involving learning and spatial working memory, there are conflicting reports of learning deficits and learning enhancements for females. Male offspring with learning deficits show decreased neurogenesis in the dentate gyrus of the hippocampus, while female offspring with increased anxiety show decreased neurogenesis in the ventral hippocampus.

Most research on stress posits that mild forms of stress can have a positive effect on development and the organism's ability to respond to stress in the future. Similarly, animal models show differential effects of PS depending on exposure level. Although daily maternal restraint of 1 hr will reduce dendritic length and complexity in the brains of adult male rat offspring, restraint of only 30 min will increase dendritic length and complexity. There are no known equivalent studies with adult female rats. Other studies have shown enhanced learning ability of both male and female offspring following mild PS. Additionally, animal models show that fetuses are affected differently when subjected to a random versus predictable stress protocol. In response to a random stressor, glucocorticoid levels increased in maternal and fetal blood after each stress exposure. In contrast, levels no longer increased by the third day of a predictable stress protocol. These results suggest researchers should assess whether animals (and correspondingly, humans) adapt to certain types of PS experiences.

Animal designs that cross-foster pups from a stressed mother onto a control mother (and vice versa) have shown independent effects of pre- and postnatal influences on offspring development. Results from these studies suggest that chronic, unpredictable stress at the end of pregnancy can increase anxious behavior of mothers until after pups are weaned. During this time, persisting PS effects can decrease maternal caretaking behavior and increase glucocorticoids passed to offspring through milk. After cross-fostering, PS pups reared by control mothers showed reduced anxiety, and control pups reared by stressed mothers showed increased anxiety. Additionally, male PS rats reared by control mothers showed normalized HPA axis functioning. However, rearing by a control mother did not ameliorate learning deficits in PS male offspring. These results suggest that PS effects on learning may be prenatally mediated.

Quasi-experimental human studies

Prospective studies involving pregnant women who experienced natural or man-made disasters have found persisting effects on child outcomes attributed to PS. Notable programs of research have followed children whose mothers experienced an ice storm, hurricane and tropical storms, major floods and earthquakes, or an act of terrorism or war. These studies have attempted to disentangle the effects of objective stressors (i.e., days without power), subjective reactions (e.g., distress, perceived stress), and physiological stress reactivity (e.g., cortisol over 24 hr). Additionally, retrospective studies have examined PS effects in children whose mothers experienced disasters like the Dutch Hunger Winter of 1944–1945.

Results from these quasi-experimental studies have linked PS to increased prevalence rates of neurodevelopmental disorders (attention-deficit hyperactivity disorder, autism, schizophrenia), psychiatric disorders (depression, anxiety), difficult temperament, increased behavior problems, and deficits in attention, language, and motor development. Elevated subjective distress (and not objective stress) was associated with increased *internalizing problems* (anxiety, depression, social withdrawal) that remained stable from ages 4–11 years old. High subjective distress was also associated with increased *externalizing problems* (aggression, hyperactivity) that diminished over development relative to published norms. Although exposure to severe stress during an ice storm was associated with IQ, memory, and language deficits at 2, 5, 8, and 11 years old, moderate levels of stress were associated with enhanced cognitive abilities. Recent findings have shown brain differences might be associated with PS and/or behavioral alterations in these cohorts. Objective but not subjective PS predicted smaller right hippocampus volumes in males at age 11; no effects of PS were detected for females. In comparison to age-matched unexposed controls, PS exposure related to the Dutch Hunger Winter was associated with smaller brain volume in males but not females at age 68. Altogether, findings from quasi-experimental studies echo results of animal models showing PS effects may depend on stressor type, timing, and intensity, as well as offspring sex.

Correlational human studies

Early correlational research on PS effects focused on offspring *birth outcomes* (gestational age at delivery, birth weight, Apgar scores) that are thought to reflect adverse *in utero* exposures and fetal development. This work led to a widely replicated finding linking PS to shorter gestation and low birth weight. Although the broader interest of this research was the possible developmental sequelae of birth outcomes, initially very few longitudinal, prospective datasets were available to assess behavioral and psychological functioning beyond the neonatal period. Today, several datasets allow researchers to examine long-term outcomes. Although mounting correlational evidence suggests that PS is associated with persisting educational, behavioral, and psychological problems, caution is required in assuming causation.

Results of correlational human research on PS effects are varied. However, major findings that have been replicated by several different investigators may be organized and interpreted within the developmental psychopathology principles of equifinality and multifinality (Cicchetti & Rogosch, 1996). *Equifinality* suggests that a single developmental outcome (i.e., ADHD) may be influenced by many different factors. Accordingly, findings have linked a single type of offspring outcome (inattention/hyperactivity) to multiple types of PS (elevated levels of maternal stress, depression, anxiety, trait anxiety, and pregnancy-specific anxiety). Other outcomes that have been independently linked to these five types of PS include difficult temperament, increased negative behavioral reactivity, and increased anxiety. Also, lower verbal IQ has been independently associated with both elevated maternal anxiety and depression. In contrast, the principle of *multifinality* suggests that one developmental factor can lead to many different outcomes. Accordingly, high maternal anxiety has been associated with different offspring outcomes, including different types of internalizing and externalizing problems, and poor performance on executive function and decision-making tasks.

Correlational research findings also suggest that offspring sex and intensity and timing of PS exposure may induce different effects on development, some of which may be positive. Overall, PS findings suggest males may be more vulnerable to adverse *in utero* effects, with female outcomes being more variable. However, some reports contradict this. Although elevated maternal anxiety and cortisol early in pregnancy have been associated with deficits in infant cognition, moderate and high levels of PS late in pregnancy have been associated with enhanced infant cognitive maturation and abilities. Additionally, the timing of PS exposure has been related to alterations in offspring brain structure and connectivity development. Studies assessing PS effects in middle childhood have linked reductions in offspring gray matter volume to high levels of PS in the second (but not first or third) trimesters, including maternal anxiety and depression. Also, high levels of maternal stressful life events in the second trimester have been associated with precocious white matter tract development in the *uncinate fasciculus*, an area of the brain linked to behavioral disorders, including antisocial behavior and autistic spectrum conditions. Some investigators have interpreted this neurodevelopmental profile of reduced gray matter and precocious white matter as indicative of aberrant accelerated brain maturation induced by PS. Finally, correlational research has shown an association between PS and altered offspring amygdala development. Increased maternal prenatal cortisol levels have been associated with increased offspring amygdala volume at age 10. Also, elevated maternal depressive symptoms have been associated with atypical amygdala functional connectivity in 6-month olds that is consistent with patterns observed in adolescents and adults with major depressive disorder.

Correlational studies that have measured PS in the pre- and postnatal periods show that although many effects of PS are attenuated after controlling for postpartum measures, PS is independently associated with adverse child outcomes. Fetal studies provide additional, proximal evidence supporting putative effects of PS on offspring CNS development. Human and animal research has shown rapid fetal response to experimental manipulations designed to change maternal psychological state (both for induced stress and induced relaxation). Further, within the context of expectable prenatal CNS development (decreased FHR, increased FHRV, and cardiac-motor coupling), maternal distress (anxiety, depression, and negative mood) has been associated with variations in fetal indices and their rate of change over the course of gestation. Several studies suggest that PS is associated with an accelerated pace of fetal CNS maturation and more mature neural integration at birth.

It is possible that maternal self-report of PS and offspring outcomes in the pre- and postnatal period reflect a shared genetic contribution, instead of a causal influence of the prenatal environment. Comparisons between children conceived via *in vitro* fertilization using embryos from the mother and those conceived with donor embryos have been used to tease apart genetic and putative PS effects on *in utero* development (Rice et al., 2010). Results suggest that offspring inattention/hyperactivity may be due to a shared inheritance of characteristics, rather than PS effects on the *in utero* environment. In contrast, lower birth weight, shortened gestation, and offspring antisocial behavior were linked to PS in related and unrelated dyads, suggesting an *in utero* environment effect. PS was also linked to offspring anxiety; however this association was not significant after accounting for postnatal measures of maternal anxiety and depression. These findings underscore the importance of considering confounding genetic and postnatal factors in PS research.

Mechanisms of PS Effects

Despite strong evidence of PS effects from animal models, and compelling results from human studies, our understanding of the biological mediators of PS is incomplete. Research examining possible mechanisms of PS has focused on the endocrine, immune, and vascular systems, which play a major role in the response and adaptation to stress.

Maternal endocrine system

The maternal HPA axis has been the most widely investigated mediator of PS effects. PS is hypothesized to produce alterations in offspring brain and behavior development through the action of glucocorticoids. In human studies, however, few data show the HPA axis is the smoking gun behind PS effects. As previously reviewed, measures of maternal HPA axis functioning and PS or distress measures have independently been associated with offspring outcomes. However, with few exceptions researchers have failed to find an association between maternal stress hormones and measures of maternal distress in human studies (see Beijers, Buitelaar, & de Weerth, 2014).

Animal experiments, however, do show stress-induced maternal glucocorticoids mediate some offspring outcomes. By adrenalectomizing pregnant rats prior to the initiation of stress, and injecting them with either saline or maintenance levels of glucocorticoids, researchers were able to block glucocorticoid production in response to stress. Stress exposure in the absence of stress hormones prevented alterations typically observed in offspring, including increased anxiety, learning deficits, and HPA dysregulation. Moreover, when investigators administered additional glucocorticoids to adrenalectomized pregnant rats to simulate a stress response, they were able to restore increased anxiety and HPA dysregulation in offspring. However, this manipulation did not restore offspring learning deficits. These findings suggest that glucocorticoids mediate *some* PS effects seen in animal models and that other biological mechanisms likely play a role.

Accordingly, animal and human studies suggest that maternal thyroid hormone (TH) may partially mediate PS effects. TH is a biologically plausible mechanism for PS effects because TH deficiency is associated with mood disturbance, and maternal TH also helps to regulate multiple prenatal neurodevelopment processes, including neurogenesis, neuronal migration, axonal and dendritic growth, synaptogenesis, and myelination. Insufficient maternal TH levels, especially early in development when the fetus relies entirely on maternal TH production, are associated with alterations in offspring brain development and persisting behavioral deficits. Research has shown children of women with untreated TH deficiency at the beginning of the second trimester exhibit lower IQ and deficits in language, attention, and learning that echo PS effects seen in animal and human studies.

Maternal immune system

Recent research has highlighted a complex interplay between the maternal HPA axis and immune system and suggested that maternal inflammation during pregnancy is a likely mechanism of PS effects. Maternal inflammation may alter offspring development through small immune signaling proteins called *cytokines.* Animal models show that cytokines are released into the blood in response to infection, immune activation, and stress. Additionally, animal and human studies have shown that PS is positively correlated with higher circulating levels of proinflammatory cytokines and that cytokines in maternal circulation can cross the placenta and access the fetal brain. Research suggests cytokine signaling pathways may help regulate offspring neurodevelopmental events including neuronal differentiation and migration and axon and synapse formation. Animal and human studies have linked many types of infections and pathogens to offspring outcomes, prompting the hypothesis that maternal immune activation may be a common mechanism underlying these effects. Additionally, rodent models that use agonists of innate immune system receptors to stimulate a proinflammatory cascade of cytokines in the maternal immune system (in the absence of an actual pathogen) have provided evidence that maternal immune activation and not direct fetal infection alters offspring development. Recent research suggests the balance of maternal pro- and anti-inflammatory cytokine production may influence offspring outcomes; manipulating the maternal immune system to overexpress IL-10, an anti-inflammatory cytokine prevented behavioral abnormalities in offspring.

Maternal vascular system

Although there is no direct vascular connection between mother and offspring, maternal autonomic responses (heart rate, blood pressure) and hemodynamics (circulation of blood) influence the offspring via the placenta. Animal research has shown that PS releases adrenaline and noradrenaline into circulation, which can reduce placental blood flow and fetal oxygenation. Through prolonged *hypoxia*, or oxygen deficiency, PS can alter offspring brain and behavior development. Human studies suggest that due to the vasculature of the developing brain, the areas most vulnerable to hypoxic injury are subcortical structures, including the amygdala, hippocampus, thalamus, and hypothalamus. Furthermore, research shows these tissues may be most vulnerable to hypoxia prior to GW24. Hypoxia has been associated with offspring outcomes linked to measures of PS and distress, such as learning and behavioral problems, as well as peripheral nerve damage, hearing deficits, and seizures. Altogether, these findings suggest that maternal vascular mechanisms may be most likely to mediate PS effects on development in the first and second trimester of pregnancy.

The placenta

As previously indicated, the "maternal–placental–fetal unit" is a complex, dynamic system that facilitates the exchange of hormones, cytokines, oxygen, and nutrients between mother and offspring. As a result, the placenta is a likely mediator of PS effects. The placenta is the first fetal organ to develop, and for the majority of pregnancy, it is approximately one cell thick. During a normally progressing pregnancy, only a small amount of maternal stress hormones reach the fetal brain. Approximately 90% of circulating corticosteroids are sequestered by a corticosteroid-binding globulin (CBG) before they access the fetus, and most of the remaining 10% is converted to inactive metabolites by the placental enzyme 11β-hydroxy steroid de-hydrogenase-2 (11β-HSD-2). However, these dynamics shift at the end of gestation, allowing a surge in fetal cortisol levels to drive maturation of the fetal lungs and possibly help initiate labor. Research suggests that chronic PS reduces the level of CBG in rodents and downregulates the activity of 11β-HSD-2 in rodents and humans. Thus, altered placental functioning as a result of PS may play a role in offspring outcomes by allowing elevated levels of glucocorticoids to cross the placental barrier.

Additionally, the placenta plays a fundamental role in organizing the development of the fetal CNS through the production of placental corticotrophin-releasing hormone (pCRH). pCRH has been shown to regulate the maturation of the fetal HPA axis and other systems and modify the timing of labor onset and delivery. Maternal cortisol stimulates pCRH production, which in turn stimulates cortisol production. This positive feedback loop can progressively amplify pCRH and cortisol production during pregnancy. Thus, research suggests pCRH trajectory (i.e., rate of production acceleration), rather than absolute concentration of pCRH, may be an important indicator of PS alterations to fetal development. Notably, because the placenta produces pCRH in primates, but not other mammals, researchers are unable to study this mechanism in rodent models.

An emerging body of work has suggested that placental factors may mediate sex-specific PS-related offspring outcomes. As a result of sex-specific differences in the structure and function of the placenta, research suggests that female fetuses may make multiple adaptations in response to an adverse *in utero* environment, while males may show fewer signs of *in utero* adaptation (see Clifton, 2010). These findings align with results from animal and human literature showing that males may be more vulnerable to adverse PS-related outcomes, while females show a more varied response.

Offspring regulatory systems

Animal and human studies suggest that PS disrupts normal development of homeostatic regulatory systems in the offspring, leading to persisting dysregulation of the offspring's own endocrine, autonomic, and immune systems. This dysregulation is hypothesized to subsequently play a role in inducing adverse behavioral outcomes. Findings from animal work support this hypothesis. Mechanistically, PS has been shown to alter the number of glucocorticoid receptors in the offspring hippocampus, an area important in terminating the stress response. Rodent and nonhuman primates exposed to PS show a heightened, prolonged elevation of corticosterone in response to stress, and several investigators have replicated this finding in humans. Similar "programming" effects have been reported for the immune system. Injections of IL-6 into pregnant mice induced chronically elevated levels of IL-6 in adult offspring. Additionally, high levels of objective PS during an ice storm were associated with an immune profile biased toward a proinflammatory response in 13-year-old children.

Toward Resilience and Intervention

Not all women and children who experience high stress during pregnancy show biological evidence of this stress. Multiple factors may influence maternal and offspring susceptibility to stress effects, including genetic predispositions, individual differences in personality and temperament, and lifestyle factors. Research suggests that variation in the interpretation of a stimulus as stressful depends on the characteristics of the individual experiencing the stimulus. Accordingly, researchers interested in PS effects are beginning to assess maternal personality traits, as well as individual differences in maternal threat perception and reaction. Additionally, research suggests that environment and lifestyle factors also contribute to maternal resilience. Social support has been shown to "buffer" or reduce levels of self-reported stress during pregnancy. Lifestyle factors like exercise have been shown to promote resilience and healthy outcomes for pregnant women and their children. Notably, research also shows that postnatal caregiving experiences can play an important role in reducing or reversing PS effects. As reviewed here, fostering prenatally stressed (PS) pups onto control mothers after birth has been shown to prevent adverse offspring outcomes.

Conclusions

For many generations, the human brain was considered to be a *tabula rasa,* or blank slate, at birth. However, a growing body of research suggests brain and behavior development are already underway by delivery. Undoubtedly, animal models and other recently developed methods have been crucial to opening a new window into early brain growth that previously has been inaccessible. Our growing understanding of both typical and atypical fetal brain development has provided an important foundation for research investigating the "fetal origins" hypothesis that maternal health, emotions, and stress levels have long-term effects on offspring outcomes. Research shows that PS interferes with normal CNS development and induces brain perturbations that result in persisting effects on offspring functioning. Affected regions of the brain identified in this literature include the amygdala, hippocampus, and uncinate fasciculus. Additionally, PS is associated with reduced gray matter volume and hypermyelination. Central findings on offspring behavioral outcomes have associated PS with increased offspring anxiety, fear, and inhibition in the face of novelty, as well as deficits in attention, learning, memory, and motor maturation. Importantly, moderate PS has been associated with enhanced cognitive and motor maturation and ability level. Besides PS intensity, research shows that PS effects may depend on stress type, timing of exposure, and offspring sex. Although results are varied, findings suggest that PS exposure in early or mid-gestation is associated with increased risk for adverse offspring outcomes. It is possible the offspring is more vulnerable during early gestation when disruption to the rapidly developing architecture of the brain may have cascading effects. Currently, there is no unifying definition of PS, and many investigators confound PS with distress. This may help explain why human studies have had difficulty detecting a biological mediator of PS effects. However, research suggests that major regulatory systems that play a role in the adaptation and response to stress, including the maternal endocrine, immune, and vascular system, are likely mechanisms of PS effects.

Maternal experiences during the pregnancy have profound effects on development, which are not yet well understood by researchers, clinicians, and policy makers. The growing PS literature may identify new opportunities to support the health and resilience of women and their children. However, scientists have the duty to deliver findings to women in a clear way that does not promote scaremongering. Importantly, correlational research may be suggestive but is *not* strong evidence of a causal relationship. Based on currently available evidence, advisory panels such as the March of Dimes recommend that stress during pregnancy should be reduced, if possible. This might be accomplished by helping pregnant women build a strong support network, form a plan to cope with anticipated challenges, practice stress reduction techniques (mediation, yoga), and maintain healthy habits (sleep, exercise, nutrition). As PS research shows, supporting the health of women during pregnancy can help promote the optimal development of their children over the lifespan.

Psychophysiology of Traumatic Stress and Posttraumatic Stress Disorder

Diagnostic criteria for posttraumatic stress disorder (PTSD) were introduced in third edition of Diagnostic and Statistical Manual for Mental Disorders (DSM-III) (American Psychiatric Association [APA], 1980). Of course, scientific studies of trauma reactions extend back to Janet's work at the turn of the last century and Kardiner's (1941) description of "physioneurosis" among veterans of World War I. Seminal studies targeting psychophysiological biomarkers of traumatic stress reactions served a key role in mitigating initial skepticism from clinicians, scientists, and the community that questioned the validity of PTSD as a distinct diagnostic entity (Yehuda & McFarlane, 1995).

The DSM-III diagnostic criteria included three symptom clusters composed of reexperiencing, avoidance, and hyperarousal symptoms. Most of the biological research into the disorder was focused on the hyperarousal symptoms, such as exaggerated startle and hyperreactivity to trauma cues. Historically, the DSM diagnostic system has defined physiological reactivity in PTSD in broad terms, such as "heightened startle reactivity" and "increased physiological reactivity to trauma-related cues or reminders of the traumatic event."

The current conceptualization of PTSD as detailed in the DSM-5 (APA, 2013) includes four clusters: (a) intrusion or reexperiencing symptoms, such as intrusive thoughts or memories, nightmares, or flashbacks to the traumatic experience; (b) avoidance symptoms, which include avoidance of thoughts, feelings, people, or situations connected to the trauma; (c) negative mood and cognitions arising from the traumatic experience, including negative self-appraisal, self-blame, shame, detachment from others, and a loss of interest in previously enjoyable activities; and (d) hyperarousal symptoms, such as hypervigilance to trauma cues, exaggerated startle response, irritability and anger, and difficulties with sleep.

The current conceptualization of PTSD is highly informed by results from structured, empirical investigations of psychophysiological alterations that follow a traumatic event (Pole, 2007). However, a disproportionate number of these studies only included male combat veterans, the results of which do not readily generalize to females or other trauma populations. This trend is beginning to shift, with new studies aiming to establish explanatory models of PTSD from cardiac activity (heart rate [HR], heart rate variability [HRV]), sweat gland activity (skin conductance [SC]), and facial electromyogram (EMG) activity of facial muscles as indices of negative emotional states (e.g., frontalis or corrugator) or startle response (orbicularis oculi).

Broadly, the early psychophysiological studies of PTSD utilized one or more of the following paradigms: (a) resting physiological state, (b) responses to standard trauma cues (e.g., sound of bombs exploding, gunfire, or video of car crashes) or personalized trauma cues (e.g., scripts of the individual's traumatic event), or (c) startle reactivity to sudden loud auditory stimuli (typically pure tones).

The large collection of early work by Pitman, Orr, and colleagues contributed significantly to the knowledge base of psychophysiological trauma reactions in all three domains. Of special note was their work on the reactions to personalized trauma cues that was derived from Lang's bio-information theory of emotion networks (Lang, 1979). Specifically, this led to the development of an auditory script-driven imagery paradigm of trauma and neutral cues that were recorded and played back in the psychophysiological laboratory while measurement of autonomic nervous system reactivity was recorded (e.g., Pitman, Orr, Forgue, de Jong, & Claiborn, 1987).

An important meta-analysis of the early psychophysiological research (Pole, 2007) reported significantly larger effect sizes for higher physiological reactivity when comparing individuals with PTSD to trauma-exposed participants without PTSD. Additionally, a psychophysiological signature emerged, characterized by the absence of SC habituation to startling tones and a facial EMG pattern of negative emotional state in response to idiographic trauma cues. Notably, HR reactivity was the most consistent indicator of PTSD hyperreactivity, consistent with observations that elevated HR immediately following a traumatic event predicts the risk of PTSD (e.g., Bryant, Creamer, O'Donnell, Silove, & McFarlane, 2011).

Recent Developments in the Psychophysiology of Traumatic Stress and PTSD

Recent studies have focused on the role of the parasympathetic nervous system in PTSD. The vast majority of prior studies focused on the sympathetic nervous system, with little attention directed at the parasympathetic system, largely due to the insensitivity of measures (e.g., SC and HR) to parasympathetic tone and drive. However, it is now possible to quantify parasympathetic nervous system activity through measures such as HRV (Task Force of the European Society of Cardiology and the North American Society for Pacing and Electrophysiology, 1996). Innovative work by Porges (2011) provides a theoretic framework (i.e., polyvagal theory) for this line of inquiry. A second area of current interest is fear processing and the elucidation of brain fear circuits that drive PTSD symptoms. These research directions emphasize brain mechanisms that align with the National Institute of Mental Health initiative "Research Domain Criteria (RDoC)" to delineate linkages between biological factors, neural circuits, and clinical phenotypes (Insel et al., 2010).

The Polyvagal Theory and Traumatic Stress

Based on phylogenetic development of the nervous system, the polyvagal theory suggests that an individual's reaction to a challenge or life threat depends on activation of the underlying system. Two separate vagal systems have been identified: the unmyelinated vagus that is phylogenetically older and originates in the dorsal motor nucleus and the myelinated vagus that originates in the nucleus ambiguus (NA). According to this theory, the sympathetic nervous system activates the "fight-or-flight" response. The older vagal system is associated with immobilization or freezing behavior, while the newer pathway is linked to social aspects of survival and control of HR. Output from this system follows a respiratory rhythm that allows for noninvasive monitoring of respiratory sinus arrhythmia (RSA) as a measure of HRV secondary to breathing dynamics.

The polyvagal theory suggests that the activation of these systems follows the Jacksonian principle of dissolution, such that when an organism is faced with a challenge, the phylogenetically newest system is engaged first, followed by the older system if needed to secure safety. Neuroception, the unconscious detection of threat through temporal brain regions, determines which system is to be engaged. Consistent with this theory, trauma may induce a deficit in neuroception, which leads to incorrectly interpreting a safe situation as dangerous. Trauma survivors may then rely on the sympathetic nervous system more readily or have a lowered threshold for engagement of the sympathetic nervous system. Future RSA-targeted studies will help inform the role of neuroception in PTSD.

The polyvagal theory describes a harmonized synchrony between the sympathetic and parasympathetic systems. Specifically, the myelinated vagus serves as a "vagal break" on HR via the SA node. The myelinated vagus maintains HR at levels that are optimal for restoration and regrowth. When faced with a challenge, the vagal brake is released allowing for increased HR and mobilization of needed resources. Prolonged threat activates the sympathetic nervous system via the adrenal system. Persistence of the threat leads to freezing, fainting, or dissociative behaviors governed by the unmyelinated vagal system (Porges, 2011).

Faulty neuroception may lead to chronic activation of sympathetic drive and maladaptive social behavior. Preliminary evidence suggests engagement of the myelinated vagal system via music therapy leads to better regulation of the viscera and an increase spontaneous social behavior (Porges, 2011).

Specific findings examining alterations in the parasympathetic nervous system show that individuals with PTSD exhibit decreased HRV during trauma recall (Keary, Hughes, & Palmieri, 2009) at baseline, and during affective induction (Hauschildt, Peters, Moritz, & Jelinek, 2011). Further, there is evidence for higher basal HR with PTSD that may be driven by a reduction in parasympathetic input (Hopper, Spinazzola, Simpson, & van der Kolk, 2006). While promising, additional studies of the polyvagal theory and the role of altered vagal/parasympathetic responses are needed.

Traumatic Stress and the Psychophysiology of Fear Processing

Theoretical models of fear processing and PTSD emphasize the role of the amygdala (Norrholm & Jovanoovic, 2018). A traumatic event represents an unconditioned stimulus that elicits an unconditioned fear response, driven by activation of the sympathetic nervous system. While some traumatic events are repetitive, a single event is sufficient to elicit a conditioned physiological and emotional fear response even in the context of overt safety. For example, a combat trauma survivor may have an extreme physiological reaction to fireworks, despite the absence of an imminent threat or danger.

Psychophysiology and neuroimaging research demonstrate heightened amygdala activation in response to trauma cues in PTSD (Shin, Rauch, & Pitman, 2006). In addition, hyporeactivity in the medial prefrontal cortex (mPFC) inhibits amygdala activation in participants with PTSD, along with smaller volume and decreased functionality of the hippocampus (Shin et al., 2006). Without inhibition from the mPFC, hyperactivity in the amygdala creates the fear and anxiety symptoms in PTSD (Davis, 1992).

The "learning" conceptualization of PTSD proposes that the conditioned response is reinforced by avoidance of trauma cues, preventing extinction through operant conditioning. There is little empirical research to support avoidance as a mechanism inhibiting extinction in PTSD (Lissek & van Meurs, 2015). However, extinction learning in PTSD is not retained, as measured using physiological reactivity on the day following extinction learning. This deficit in retention corresponds to reactivity in the mPFC (Lissek & van Meurs, 2015).

Non-associative learning theories have also been suggested as a means to explain hyperarousal symptoms in PTSD. Individuals with PTSD exhibit poor habituation to repeated stimuli such as loud tones (Pole, 2007). There is also evidence of sensitization in PTSD with enhanced responses following repeated activation, for example, with greater HR responses to repeated loud tones and greater amygdala activation while viewing fearful or neutral faces (Lissek & van Meurs, 2015).

Future Directions

Two developing areas for psychophysiological investigation in PTSD are (a) reorientation toward mechanisms of physiological recovery (allostasis) (Ottaviani, 2018) and away from an exclusive focus on reactivity. Recently, Goodman and Griffin (2018) used HR recovery to significantly improve the ability to predict the risk for developing PTSD in a longitudinal design and (b) the use of psychophysiological indices as biomarkers of fear extinction in treatment studies. Clinical trials using a virtual reality environment (Diemer, Muhlberger, Pauli, & Zwanzger, 2014) and startle measurement demonstrate the high sensitivity of psychophysiological measures to treatment response (Griffin, Resick, & Galovski, 2012; Robinson-Andrew et al., 2014). Pretreatment psychophysiological reactivity also predicts posttreatment outcome (Norrholm et al., 2016). Finally, measurement and biofeedback using HRV is an effective treatment option for PTSD (Tan, Dao, Farmer, Sutherland, & Gevirtz, 2011; Zucker, Samuelson, Muench, Greenberg, & Gevirtz, 2009).

Similarly, targeted training to manage visceral activity elicited by a visual threat allows for the creation of new associations and realignment of fear network response (Norrholm & Jovanoovic, 2018). Application of these strategic interventions represents a potentially transformative focus of new clinical research studies.

Cognitive Reserve

Introduction

The relationship between neuropathology and clinical presentation is imperfect. An often-cited postmortem study of older individuals reported substantial Alzheimer's pathology in the brain tissue of individuals who did not have a corresponding degree of cognitive impairment prior to death (Katzman et al., 1988). The concept of cognitive reserve (CR) was introduced as an important explanation for this disconnect in pre- and postmortem disease phenotypes. The following chapter reviews the theoretical basis of CR and putative neural mechanisms underlying the construct. Potential pathways to enhance CR throughout the lifespan are discussed.

Brain Reserve Versus Cognitive Reserve

Katzman et al. (1988) reported greater brain weight and neuronal cell counts in cognitively normal individuals with neuropathological evidence of Alzheimer's disease (AD) compared with cognitively impaired individuals with a similar degree of neuropathology. This observation became the basis for the "passive" model of reserve, otherwise known as brain reserve (Satz, 1993). The brain reserve model highlights the importance of premorbid brain structure integrity, which naturally varies across individuals. Those with higher reserve (more robust neuronal integrity) prior to an injury or onset of disease are less likely to express symptoms compared with individuals with lower reserve. The brain reserve model is often referenced as a quantitative model because biological measures of brain integrity are summed to calculate a quantitative index. For example, neuronal/synapse count (Wilson et al., 2013), head circumference (Perneczky et al., 2010), and brain/intracranial volume (ICV) (Sumowski et al., 2013) have been utilized as markers of brain reserve. Not all studies report significant associations

between these markers and clinical outcomes (Jenkins, Fox, Rossor, Harvey, & Rossor, 2000; Tate et al., 2011), raising concern that additional factors contribute to individual outcomes despite similar levels of neuropathology.

CR was proposed as an alternative model to brain reserve. CR is described as an "active" model that emphasizes brain function (versus brain structure) and dynamic versus static mechanisms (Stern, 2002). Similar to brain reserve, a person with high CR would be expected to perform better on testing or have a better clinical outcome compared with an individual with lower CR at any given level of neuropathology. Importantly, when compared with those with low CR, individuals with higher CR experience a much faster disease progression after the expression of initial symptoms. These results suggest that a critical threshold governs disease manifestation, such that clinical evidence of severe cognitive dysfunction or dementia is delayed until the threshold of pathology has been met (Hall et al., 2009).

CR is quantified using proxy measures including education (Stern et al., 1994), occupational attainment (Stern et al., 1994), premorbid IQ (Armstrong et al., 2012), literacy (Manly, Schupf, Tang, & Stern, 2005), leisure activities (Scarmeas, Levy, Tang, & Stern, 2001), social networks (Bennett, Schneider, Tang, Arnold, & Wilson, 2006), and bilingualism (Gollan, Salmon, Montoya, & Galasko, 2011). Nucci, Mapelli, and Mondini (2012) demonstrated additional gain using an aggregate measure of multiple CR proxies, referred to as the Cognitive Reserve Index.

Evidence for CR

Stern et al. (1994) conducted one of the first studies of CR and risk of AD in a large group of older adults. Results from this study indicated that individuals with low CR (<8 years of education) had a 2.2 times higher risk for developing dementia over a 4-year period compared with those with high CR (≥8 years of education). Additionally, individuals with lower occupational attainment (e.g., skilled trade, office worker) were more than twice as likely to develop AD over the same four-year period compared with those with higher occupational attainment (e.g., manager, technical professional). A follow-up study reported that individuals who participated in more frequent leisure activities (high CR) had a 38% lower risk of developing dementia compared with those engaged in fewer leisure activities (Scarmeas et al., 2001). Perhaps most importantly, late life modifications to CR lower the risk of subsequent dementia, suggesting neuronal plasticity across the older adult age range (Valenzuela & Sachdev, 2006).

Higher CR is associated with better cognitive health in normal aging (Baker et al., 2017), AD (Scarmeas et al., 2003) and numerous neurological conditions including cerebrovascular disease (Brickman et al., 2009; Lane, Paul, Moser, Fletcher, & Cohen, 2011), human immunodeficiency virus (HIV) (Foley et al., 2012), and Parkinson's disease (Hindle, Martyr, & Clare, 2014). Other studies report the beneficial effects of higher CR on cognitive outcomes in traumatic brain injury (Kesler, Adams, Blasey, & Bigler, 2003), multiple sclerosis (Nunnari et al., 2016), Lewy body disease (Perneczky et al., 2008), hepatitis C (Bieliauskas et al., 2007), and frontotemporal lobar degeneration (Placek et al., 2016).

Neural Mechanisms of CR

The literature has utilized two broad terms (neural reserve and neural compensation) to describe the underlying neural mechanisms of CR (Stern, 2017). *Neural reserve* refers to the interindividual variability in brain regions or networks that contribute to cognitive performance and the resistance of these networks to neuropathology. *Neural compensation* refers to the recruitment of additional/alternative brain regions or networks to perform a cognitive task among individuals with brain degeneration.

Neural reserve encompasses the efficiency of a brain region or network needed to successfully perform a given task. Capacity refers to the maximum degree to which a brain network can be activated to perform a cognitive task, particularly as tasks become increasingly more challenging. Accordingly, a person with higher capacity is more likely to perform a difficult, resource-demanding cognitive task than someone with lower capacity. Neuroimaging studies of neural reserve, CR, and cognitive performance suggest that these concepts apply most readily to young adults with intact brain networks and limited neuropathology (for reviews see Anthony & Lin, 2018; Steffener & Stern, 2012; Stern, 2017).

Neural compensation is typically studied within the context of age-related changes in brain networks as well as pathological (e.g., AD) changes in the brain. Under the neural compensation model, once a primary network reaches capacity or loses function, an alternate (or "compensatory") network is activated to facilitate task completion. Accuracy, however, is not guaranteed. For example, the older adults who engage compensatory networks to perform a task are more likely to exhibit worse overall performance compared with older adults who did not require engagement of brain regions beyond the primary network (Zarahn, Rakitin, Abela, Flynn, & Stern, 2007). Both neural reserve and neural compensation are associated with CR (Habeck et al., 2003).

In terms of anatomical substrates, Stern et al. (2008) identified the superior frontal gyrus as key to CR-related benefits. Neural correlates of CR also include the medial temporal lobe regions (e.g., medial temporal gyrus, parahippocampal gyrus), which correspond with higher CR in a manner suggesting neural reserve in younger individuals, while the neural correlates of neural compensation in aging (independent of AD) include frontal regions (e.g., superior frontal gyrus, inferior frontal gyrus) (Anthony & Lin, 2018). Additionally, resting-state functional MRI reveals that activity in the default mode network and dorsal attention network correlates with CR in older adults (Arenaza-Urquijo et al., 2013; Bastin et al., 2012).

Cognitive Reserve Interventions

Life experiences have a greater impact on CR compared with brain reserve. For example, Richards and Sacker (2003) reported strong associations between CR and adult occupational attainment. Other studies suggest that participation in mentally stimulating social or leisure activities (e.g., knitting, gardening) relates to lower risks of dementia in older adults (Scarmeas et al., 2001). One study estimated a decline by 0.18 years for every day of self-reported participation in cognitively stimulating leisure activities in community-dwelling older adults (Hall et al., 2009). These results suggest that mental stimulation increases CR and provides protection against cognitive decline, even when implemented in late adulthood. Preliminary evidence indicates these effects may even extend to individuals with mild to moderate AD (Mondini et al., 2016).

Conclusions

CR is a protective mechanism against brain injury. Individuals with higher CR are more likely to exhibit better cognitive performance and lower risk of expressing clinically relevant symptoms of brain dysfunction. Additionally, the neuroimaging literature supports a neural basis for CR with the identification of specific regions and networks that associate with proxies of CR, such as education and occupational attainment. Future research is needed to examine the long-term outcomes of interventions designed to bolster CR throughout the lifespan.

APOE as a Risk Factor for Age-Related Cognitive Impairment: Neuropsychological and Neuroimaging Findings

Alzheimer's disease (AD) is the sixth leading cause of death in the United States, with an estimated 5.3 million living with the disease (Alzheimer's Association, 2015). The ε4 allele of the apolipoprotein E (*APOE*) gene (located on chromosome 19q13.2) is the best-established genetic risk factor for AD. Two single nucleotide polymorphisms (SNPs), rs7412 and rs429358, define the three major alleles: ε2, ε3, and ε4. The ε3 allele is most common, found in 79% of the population. Approximately 14% of individuals carry at least one copy of the ε4 allele, while 7% are ε2 carriers (Bertram, McQueen, Mullin, Blacker, & Tanzi, 2007).

In Caucasian samples, presence of the ε4 allele increases AD risk in a dose-dependent manner. For example, ε3/ε4 carriers have 3.68 times greater risk than ε3 homozygotes, while ε4/ε4 carriers have a sevenfold greater risk of developing AD (Bertram et al., 2007). The ε2 allele is considered protective; it is associated with longevity and 38% lower risk of AD (Bertram et al., 2007). Although the same relative pattern is observed in African American and Hispanic samples (risk among ε4 carriers > ε3 > ε2), the magnitude of the association between the ε4 allele and AD risk is weaker in these groups compared with Caucasians, suggesting that other genetic or environmental factors may be contributory (Farrer et al., 1997).

APOE encodes a lipid transporter that is expressed throughout the brain and the liver. The ApoE protein binds to low-density lipoprotein (LDL) receptors. The E4 isoform of ApoE has lower stability than E3 and E2, making it more likely to form destabilized protein conformations (Hatters, Peters-Libeu, & Weisgraber, 2006). This destabilized conformation contributes to altered lipid binding, protein misfolding, and protein aggregation, suggesting potential mechanisms for neurodegenerative processes (Hatters et al., 2006).

AD is associated with profound disturbance in cognition, with a clinical diagnosis of probable AD requiring deficits in two or more cognitive domains. Cognition progressively declines over the course of the disease, resulting in significant functional impairments. Elucidating how *APOE* modulates cognition and brain integrity can inform our understanding of the pathological progression of AD. Furthermore, identifying neuropsychological and neuroimaging phenotypes in relation to *APOE* status may help identify novel targets for prevention and treatment efforts. It is particularly important to study the effects of *APOE* across the lifespan, as the magnitude and direction of its effects on cognition and brain integrity differ from young adulthood through older age. Thus, we aim to provide a comprehensive overview of the relationship between *APOE*, cognition, and neuroimaging findings across the human lifespan.

APOE Genotype and Cognition

Given the profound impact of AD on episodic memory, studies of *APOE* and cognitive abilities have naturally focused on this aspect of cognitive performance. However, accumulating evidence suggests that *APOE* may also impact executive functions, processing speed, and general intellectual abilities (Wisdom, Callahan, & Hawkins, 2011).

Young Adulthood

Although *APOE* ε4 is associated with higher risk of AD, it may actually be associated with better cognitive performance earlier in the lifespan. Fetuses carrying the ε4 allele are less likely to be stillborn (Becher, Keeling, McIntosh, Wyatt, & Bell, 2006), while *APOE* ε2 has been associated with higher risk of perinatal death. Infant *APOE* ε4 carriers also have higher scores on an index of mental development at 24 months compared with ε2 and ε3 carriers (Wright et al., 2003). These findings suggest that the ApoE E4 isoform may exert a beneficial effect very early in brain development.

During younger adulthood, commonly defined as ages 18–39 years, ε4 carriers outperform noncarriers across a range of cognitive tests. For example, young adult ε4 carriers (aged 22.8 ± 4) have better episodic memory for a word list than ε3 or ε2 carriers (Mondadori et al., 2007). Among younger individuals (aged 24.7 ± 5.4) recovering from traumatic brain injury, *APOE* ε4 carriers score higher on standardized neuropsychological tests of attention, executive functioning, and episodic memory encoding (Han et al., 2007). Young ε4 carriers also have higher IQs (Yu, Lin, Chen, Hong, & Tsai, 2000), better verbal fluency (Alexander et al., 2007), and greater educational achievement (Hubacek et al., 2001) than noncarriers.

Although not all studies of young adults find differences between *APOE* ε4 carriers and noncarriers, collectively, the literature suggests that the ε4 allele may be advantageous during young adulthood. Han and Bondi have proposed that the effects of *APOE* may be an example of antagonistic pleiotropy (Han et al., 2007). Antagonistic pleiotropy is an evolutionary biology term referring to alleles that have differential effects on fitness at different points in the lifespan. Thus, *APOE* may confer a benefit during young adulthood but may be deleterious during older adulthood. It remains unclear when *APOE* ε4 carriers begin to show cognitive impairment relative to noncarriers. Studying middle-aged individuals can shed light on the transition of the effects of *APOE* from young adulthood to older age.

Middle Adulthood

Studies investigating the effects of *APOE* on cognition in middle age have yielded mixed results. This variability may be partially attributed to differing demographic characteristics and definitions of middle age. For instance, a baseline assessment of 452 middle-aged participants in the Wisconsin Registry for Alzheimer's Prevention (WRAP)—all of whom have at least one parent with AD—found no association between *APOE* and neuropsychological performance (Sager, Hermann, & La Rue, 2005). Similarly, the PATH Through Life project cohort of middle-aged adults (N = 6,560) reported no effect of *APOE* on cognition despite age-related declines in episodic memory, working memory, and processing speed in the same cohort (Jorm et al., 2007).

In contrast to these null findings, some evidence suggests that middle-aged ε4 carriers may show subtle differences in cognitive performance. No clear pattern of affected cognitive domains has emerged. Middle-aged ε4 carriers score more poorly on learning and memory tasks, verbal delayed recall, sustained attention, and working memory (Caselli et al., 2001; Flory, Manuck, Ferrell, Ryan, & Muldoon, 2000). Whether there is a dose-dependent relationship of the ε4 and cognition during middle age is an area of ongoing research.

The age at which *APOE* ε4 may transition from benefitting cognition to being detrimental remains an area of active research. Large-scale, longitudinal studies are needed to assess the trajectories of cognitive change in *APOE* ε4 carriers and noncarriers. In one such study, ε4 homozygotes began declining on verbal memory measures in their 50s, while noncarriers maintained their memory abilities until their 70s (Caselli et al., 2011). Another longitudinal study found that for *APOE* ε4 carriers younger than 57 years, verbal memory actually increased over the 4-year follow-up interval. In contrast, ε4 carriers older than 57 experienced a significant decline in immediate recall abilities (Jochemsen, Muller, van der Graaf, & Geerlings, 2012). Together, these studies suggest that *APOE* ε4 may begin to have a detectable adverse effect on cognition in the 50s. The changes in underlying neurobiological processes may begin even earlier, making a research into early biomarkers for AD a fertile area for future research.

Older Adulthood

The deleterious effects of *APOE* ε4 on cognition in older adulthood are robust. The APOE ε4 allele negatively affects several cognitive domains in a dose-dependent manner. The most recent meta-analysis to answer this question included 77 studies of 40,972 cognitively healthy adults (Wisdom et al., 2011). It assessed the effects of *APOE* on global cognitive ability and seven separate cognitive domains: attention, episodic memory, executive functioning, perceptual speed, primary memory, verbal ability, and visuospatial skill. *APOE* ε4 carriers performed significantly worse on measures of global cognitive ability, episodic memory, executive functioning, and perceptual speed compared with non-ε4 carriers but did not differ on attention or visuospatial functioning. The largest effect sizes were observed for episodic memory. Furthermore, these effects were moderated by age, with older ε4 carriers having larger deficits in episodic memory and global cognitive ability compared with noncarriers. These findings indicate that the adverse relationship between *APOE* ε4 and cognition may be magnified during the aging process.

Mild Cognitive Impairment and Alzheimer's Disease

Presence of the *APOE* ε4 allele is known to increase risk of developing AD, but it may also affect progression of the disease. Mild cognitive impairment (MCI) is a clinical diagnosis given to individuals who have significant cognitive impairment in one or more domains but are able to maintain independence in their activities of daily living. People with MCI may have impairments in memory (amnestic MCI) or another cognitive domain (non-amnestic MCI). The factors that increase the risk of conversion from MCI to dementia are as yet uncertain, although they may include cardiovascular risk factors, depressed mood, type 2 diabetes, and traumatic brain injury (Cooper, Sommerlad, Lyketsos, & Livingston, 2015).

A 2011 meta-analysis of prospective cohort studies of individuals with MCI found that carriers of a single *APOE* ε4 allele were 2.29 times more likely to convert, while ε4 homozygotes were 3.94 times to convert to AD-type dementia compared with noncarriers (Elias-Sonnenschein, Viechtbauer, Ramakers, Verhey, & Visser, 2011). Compared with noncarriers, ε4 carriers progressed more quickly and at an earlier age than noncarriers.

Summary of Neuropsychological Findings

Taken together, the available evidence supports the idea that the *APOE* ε4 allele is associated with better cognition in young adulthood but poorer cognition later in life. Not only does *APOE* ε4 increase a risk for dementia, but also it is associated with faster progression of age-related cognitive impairment. Longitudinal studies indicate that cognition may begin to decline during middle age in ε4 carriers, maintaining a steeper trajectory of decline into older adulthood. Thus, efforts to prevent or delay the progression of AD pathology likely need to target middle-aged individuals, before gross decline in cognitive ability manifests. Additionally, understanding the interaction of *APOE* with protective factors such as cognitive reserve (e.g., cognitive resilience in the face of neuropathological damage) will be an important avenue for future research.

Neuroimaging: Relationships Between APOE and Brain Integrity

There has been a surge of imaging genetics studies over the past two decades, including studies employing structural magnetic resonance imaging (MRI), functional MRI (fMRI), diffusion tensor imaging (DTI), MRI arterial spin labeling (ASL), and positron emission tomography (PET). These neuroimaging modalities shed light on gross brain morphology, activity of the brain during memory tasks or while at rest, WM microstructural properties, patterns of regional blood flow, and presence of AD neuropathology, respectively. Neuroimaging represents a powerful noninvasive method of detecting subtle differences associated with *APOE* genotype that may precede detectable cognitive impairment.

Magnetic Resonance Imaging

Regional brain volumes

Development of AD is associated with significant regional brain atrophy, with the most pronounced volume loss in the medial temporal lobes (MTL). The majority of studies investigating how *APOE* genotype impacts brain volume have thus focused on the hippocampus and other MTL structures. Homozygous ε4 AD patients have smaller volumes of the right hippocampus, amygdala, and entorhinal cortex compared with patients who are ε3/ε4 and ε3/ε3 (Lehtovirta et al., 1995) and may show greater atrophy over time.

In healthy older adults, longitudinal studies have consistently reported that the rate of hippocampal volume loss is greater in ε4 carriers than noncarriers. In at least two of these studies (Cohen, Small, Lalonde, Friz, & Sunderland, 2001; Crivello et al., 2010), however, the magnitude of the decline in hippocampal volume was not related to any cognitive changes over the same interval. In healthy, middle-aged individuals, findings are equivocal. One sample of 60–64-year-olds showed no volumetric differences associated with *APOE* genotype (Cherbuin et al., 2008). In contrast, another report demonstrated smaller hippocampal volumes in ε4 carriers younger than 65, with no differences in individuals older than 65 (Lind et al., 2006).

Collectively, literature suggests that *APOE* seems to moderate hippocampal volume loss during aging. *APOE* ε4-associated hippocampal atrophy may be related to neuronal cell death, loss of neuropil, or degeneration of fibers terminating in the hippocampus. Furthermore, it remains unclear whether hippocampal atrophy drives the higher AD risk among ε4 carriers or is a by-product of some other neurodegenerative process.

Task-based functional MRI (fMRI)

fMRI measures blood oxygenation level-dependent (BOLD) response in brain tissue. Higher BOLD response reflects increased neural activity in a given region. Comparing BOLD response while performing a cognitive task and during a control condition allows inference about *APOE*-related differences in regional brain activation during the specific tasks.

fMRI studies using episodic memory paradigms are equivocal. Some report higher (Bondi, Houston, Eyler, & Brown, 2005), while others report lower (Fleisher, Podraza, et al., 2009) BOLD signal in ε4 carriers. Differences in the memory tasks, participant age, and family history of AD, among other factors, may be contributing to the inconsistencies among the reports. Imaging studies focusing on healthy, young adult ε4 carriers typically report higher MTL activation during memory tasks (Filippini et al., 2009). Additionally, a lifespan study found overactivation in young ε4 carriers compared with noncarriers, while healthy older adults showed a pattern of task-based deactivation (Filippini et al., 2011). This evidence seems to suggest that younger *APOE* ε4 carriers depend on compensatory mechanisms to maintain performance, while early pathology in older ε4 carriers leads to lower recruitment of relevant brain areas.

Healthy, adult ε4 carriers also have higher activation compared with noncarriers on tasks requiring working memory (Wishart et al., 2006), verbal fluency (Smith et al., 2002), semantic categorization (Persson et al., 2008), and executive control (Trachtenberg et al., 2012). Thus, differential patterns of activation extend beyond the MTL to include frontal, parietal, and posterior cingulate regions. One interpretation of such findings is that ε4 carriers must recruit a broader network of brain regions to maintain performance. Longitudinal studies are needed to assess *APOE* ε4-related change in activation patterns over time.

Functional brain networks

In addition to probing task-related differences in BOLD activation, fMRI can be used to characterize patterns of activity when the brain is at rest. During resting-state fMRI, synchronous patterns of coactivity between discrete brain regions reliably emerge. These so-called resting-state networks overlap with functionally relevant regions known to be involved in visual processing, motor functioning, auditory processing, attention, and memory. Resting-state networks are neuronal in origin, and functional connectivity within these networks reflects underlying structural connectivity (Greicius, Supekar, Menon, & Dougherty, 2009).

MCI and AD involve loss of functional brain connectivity in several resting-state networks. The best-documented differences are in the default mode network (DMN), which includes the posterior cingulate, medial prefrontal, and inferior parietal cortices, and the hippocampus. DMN activity is anticorrelated with activity of brain regions recruited during cognitively demanding tasks. Integrity and activity of this network is thought to support episodic memory and self-referential thought. A limited number of studies have examined resting-state functional connectivity in *APOE* ε4 carriers. Two studies of healthy young and middle-aged adults have reported that ε4 carriers have higher DMN connectivity (Filippini et al., 2009; Fleisher, Sherzai, et al., 2009), but studies in healthy elderly and early AD show lower connectivity in ε4 carriers. This includes functional disconnection between the hippocampus and posterior cingulate cortex, precuneus, dorsal anterior cingulate cortex, and middle temporal cortex (Sheline et al., 2010). Disrupted functional connectivity is more pronounced in older individuals and is observed even in the absence of amyloid plaques (Sheline et al., 2010).

More research is needed to delineate the effects of *APOE* genotype on functional connectivity of the DMN and other resting-state networks. Characterizing longitudinal changes in network connectivity and dynamic interactions between networks will inform our understanding of connectivity loss with AD progression.

White matter integrity

Although early brain imaging studies focused on gray matter pathology in AD patients, the disease is also associated with profound changes in WM (Gunning-Dixon & Raz, 2000). DTI is a method of imaging the diffusion of water in brain tissue that provides information about the direction of WM tracts as well as their microstructural properties. Thus, DTI metrics may be more sensitive indices of WM disruption than WM hyperintensities. Compared with healthy older adults, AD patients show a more posterior profile of WM abnormalities, including alterations in the parahippocampal gyrus, temporal WM, splenium of the corpus callosum, and posterior cingulum (see Chua, Wen, Slavin, & Sachdev, 2008, for review).

WM microstructural alterations in *APOE* ε4 carriers appear to parallel the differences seen in AD patients. ε4 carriers have lower fractional anisotropy (FA) and higher mean diffusivity (MD), measures of microstructural disorganization, in the MTL and other regions (Honea, Vidoni, Harsha, & Burns, 2009). Preliminary evidence suggests that these microstructural differences are connected to cognitive abilities. For example, one study of 92 healthy older adults found that higher FA in the entorhinal cortex was associated with better memory performance in ε4 but not ε3 carriers (Westlye et al., 2012). Integrating DTI with other neuroimaging modalities will provide a more comprehensive description of brain network integrity and is an important area for future research.

Cerebral perfusion

ASL is a noninvasive method of quantifying cerebral blood flow with MRI. Deficits in cerebral perfusion increase with AD progression and serve as an index of cortical dysfunction (Alsop, Dai, Grossman, & Detre, 2010). Findings related to cerebral perfusion in *APOE* ε4 carriers have been mixed. For instance, a small study ($N = 24$) found that ε4 carriers have higher cerebral perfusion at rest but attenuated changes in MTL during memory encoding (Fleisher, Podraza, et al., 2009). Another study found a similar pattern of ε4-associated resting hyperperfusion in MCI patients, while ε4 carriers with AD had lower perfusion than ε3 carriers (Kim et al., 2013). This is consistent with an interpretation that ε4 carriers have greater metabolic demands at rest to compensate for their functional impairments early in the disease process, while this compensatory mechanism collapses in the face of more significant pathological burden in AD.

Positron Emission Tomography (PET)

AD neuropathology comprises two main processes: extracellular deposition of beta-amyloid (Aβ) plaques and intracellular accumulation of hyperphosphorylated tau protein in neurofibrillary tangles. Traditionally, these hallmarks of AD pathology were only detectable upon postmortem examination. The development of novel PET ligands has aided understanding of the progression of AD neuropathology *in vivo*. For example, Pittsburgh compound B (^{11}C-PiB) binds to Aβ in the cortex, permitting visualization of deposition of Aβ plaques. In healthy older adults and patients with MCI or AD, there is a gene–dose relationship between number of *APOE* ε4 alleles and higher ^{11}C-PiB retention in the frontal, temporal, and parietal cortices (Drzezga et al., 2009). Furthermore, longitudinal imaging studies report that older ε4 carriers have a greater rate of PiB retention compared with ε4 noncarriers over a 2–3 year follow-up interval (Villemagne et al., 2011). More recently, development of a novel tau ligand (^{18}F-THK523) has permitted *in vivo* imaging of neurofibrillary tangles. The effects of *APOE* genotype on ^{18}F-THK523 retention have not yet been explored, but this remains an exciting area for future research.

In addition to *in vivo* characterization of hallmarks of AD neuropathology, PET can be used to assess glucose metabolism using a fludeoxyglucose (^{18}F-FDG) tracer. Patients with AD have significantly lower regional cerebral glucose metabolism, and lower ^{18}F-FDG uptake may predict which patients with MCI will convert to AD (Chételat et al., 2003). Among AD patients, *APOE* ε4 carriers consistently show lower cerebral glucose metabolism compared with non-ε4 carriers, particularly within temporal, frontal, parietal, and posterior cingulate cortical regions (Lehmann et al., 2014). Differences in cerebral glucose metabolism are observed before the onset of cognitive symptoms, with healthy older ε4 carriers showing hypometabolism in the posterior cingulate, temporal, parietal, and prefrontal cortices (Langbaum et al., 2010).

In summary, *APOE* ε4 carriers show neuropathological signs characteristic of AD even before the onset of clinical symptoms, including higher deposition of Aβ plaques visualized via PET PiB imaging and cerebral hypometabolism in frontal, temporal, parietal, and posterior cingulate cortices.

Summary of Neuroimaging Findings

Collectively, neuroimaging literature suggests a role for *APOE* ε4 in brain integrity throughout the lifespan. Consistent with evidence that *APOE* ε4 is associated with better cognition early in life before becoming deleterious in older adulthood, younger ε4 carriers have higher task-based activation and resting-state functional connectivity in studied brain networks. Older ε4 carriers show the opposite patterns, including lower functional connectivity, smaller MTL volumes, disorganization of WM microstructure, cerebral hypometabolism, and greater deposition of Aβ plaques in the regions of interest. Ongoing longitudinal imaging studies will soon be able to answer important questions about the trajectory and magnitude of age-related changes that may serve as neuroimaging biomarkers of risk for AD.

Summary and Conclusions

Characterizing the effects of *APOE*, the best-established genetic risk factor for AD on neuropsychological functioning and brain health remains an area of active research. *APOE* appears to have a differential role on cognition and underlying brain integrity across the lifespan. Younger ε4 carriers, albeit exhibiting better cognitive performance, seem to require greater recruitment of functional brain resources. In older age, *APOE* ε4 becomes deleterious and is associated with cognitive decline as well as poorer brain integrity. It is possible that the ε4 allele was evolutionarily conserved because of its beneficial effects early in the lifespan; with humans today living decades longer than our ancestors, the adverse effects of *APOE* are now observed during aging. Alternatively, interactions between *APOE* and other AD risk factors (both genetic and environmental) may explain the conflicting patterns of findings across the lifespan. Given that older age is the biggest risk factor for AD, general age effects and inclusion of individuals in the early stages of age-related cognitive decline may confound the studies of older adults. Studying middle age as a possible transitional period will provide a rich source of information about the effects of *APOE* on cognition. By investigating the additive or synergistic effects of *APOE* with other genetic risk factors for AD, we may advance our understanding of the complex interplay between genes, brain integrity, and cognitive health. Furthermore, using multimodal imaging to create integrated descriptions of brain integrity will increase our ability to predict who is at greatest risk for MCI and AD. This is essential to identify those who may benefit most from early prevention and treatment efforts, reducing the global burden of AD.

Introduction

Diathesis–stress theories postulate that genetic vulnerability promotes the development of depression in the context of stress. The intuitive appeal of this theory was supported by twin research by Kendler and colleagues (Kendler et al., 1995) showing that risk for depression was substantially elevated among individuals whose co-twin had depression, but only if they themselves were recently exposed to a severe stressful life event. However, it was not until 2003 that molecular genetic variation was first associated with vulnerability to the depressogenic effects of stress (Caspi et al., 2003). Specifically, Caspi and colleagues reported evidence that the short allele of the serotonin transporter-linked polymorphic region (5-HTTLPR) polymorphism, which had been previously linked to reduced serotonin transporter expression as well as putative intermediate depressive phenotypes (Hariri et al., 2002; Heils et al., 1996; Lesch et al., 1996), confers vulnerability to stress-related depression. This initial report of a gene × environment (G × E) interaction spurred multiple subsequent replication and extension attempts that have collectively produced conflicting findings with even meta-analyses reaching opposing conclusions (Duncan & Keller, 2011; Karg, Burmeister, Shedden, & Sen, 2011; Munafo, Durrant, Lewis, & Flint, 2009; Risch et al., 2009; Sharpley, Palanisamy, Glyde, Dillingham, & Agnew, 2014; Taylor & Munafo, 2016; Table 1). These opposing results have led to great controversy within the literature, with divergent interpretations (Caspi, Hariri, Holmes, Uher, &

Moffitt, 2010; Duncan & Keller, 2011) highlighting the need for further study and collaborative meta-analyses (Moffitt & Caspi, 2014; Taylor & Munafo, 2016). Here, we briefly introduce the 5-HTTLPR polymorphism before summarizing the current literature on the 5-HTTLPR polymorphism and depression and exploring potential neural mechanisms through which these associations may emerge.

The 5-HTTLPR Polymorphism

The 5-HTTLPR polymorphism resides within the promoter region of the serotonin transporter gene (*SLC6A4*) (Lesch et al., 1996). The serotonin transporter (5-HTT) is a reuptake protein that regulates the duration and magnitude of synaptic serotonin. It is the target of common antidepressants and anxiolytics, such as serotonin-specific reuptake inhibitors (SSRIs), which block the transporter resulting in increased synaptic serotonin and signaling. The 5-HTTLPR polymorphism is a 43(initially reported as 44)-base pair imperfect repeat sequence in a GC-rich repetitive sequence that is located approximately 1 kb upstream of the 5-HTT gene transcription initiation site (Wendland, Martin, Kruse, Lesch, & Murphy, 2006). There are two commonly occurring alleles within this polymorphism, the short (s; 14 repeat) and long (l; 16 repeat) repeat, resulting in three genotype groups (s/s, s/l, l/l), although uncommon extra-long repeats have been reported in East Asian and some African samples (Goldman, Glei, Lin, & Weinstein, 2010; Nakamura, Ueno, Sano, & Tanabe, 2000). 5-HTTLPR allelic frequencies differ according to ancestral origin; relative to European samples, the frequency of the short allele is higher in Asian and lower in African populations with evidence that some phenotypic associations may be dependent upon ancestral origin (Murphy, Maile, & Vogt, 2013). Notably, a common orthologue of the 5-HTTLPR in rhesus macaques enables cross-species investigation (Caspi et al., 2010).

The 5-HTTLPR short allele has been associated with relatively less efficient transcription of the 5-HTT, resulting in less 5-HT uptake and elevated levels of synaptic 5-HT relative to the long allele (Heils et al., 1996; Lesch et al., 1996). In close proximity to the 5-HTTLPR polymorphism are two single nucleotide polymorphisms, rs25531 (G/A) and rs25532 (C/T), that moderate the influence of the 5-HTTLPR polymorphism on *SLC6A4* expression (Murphy et al., 2013). When the rs25531 G allele occurs alongside the 5-HTTLPR long allele, there is relatively less *SLC6A4* expression compared with when the rs25531 A allele is present (Hu et al., 2006). As a consequence, the presence of the G allele with the 5-HTTLPR long allele may render the long allele functionally similar to the short allele, leading many studies to recode alleles according to high and low expression with the 5-HTTLPR long and rs25531 G allele combination being grouped with the short allele as low expressing alleles. For rs25532, the T allele is associated with reduced *SLC6A4* expression, with a greater relative reduction when alongside the long relative to short allele (Wendland et al., 2008). While studies are more frequently including rs25531 in 5-HTTLPR investigations, the lack of consideration of rs25531 and rs25532 as well as other functional polymorphisms within *SLC6A4* may, at least in part, contribute to the mixed 5-HTTLPR psychiatric and neuroscience literature (Murphy et al., 2013).

5-HTTLPR Associations with Depression

The 5-HTTLPR polymorphism is among the most frequently studied genetic polymorphisms within psychiatry and neuroscience (Caspi et al., 2010). Notably, the vast majority of this research has been conducted in samples with European ancestral origins, leaving the generalizability of these findings across populations uncertain. Lesch and colleagues were the first to link this polymorphism to a psychiatric phenotype when they observed that the short allele was associated with elevated neuroticism (Lesch et al., 1996). This association has been replicated in some studies, with meta-analyses supporting evidence of a small but significant positive association between the short 5-HTTLPR allele and neuroticism, but not other anxiety-related measures (Munafo et al., 2009; Schinka, Busch, & Robichaux-Keene, 2004; Sen, Burmeister, & Ghosh, 2004). Further, similar associations with anxiety-like behavior have been observed with an orthologous variant in rhesus macaques (Caspi et al., 2010).

In a 2003 study that captured the attention of researchers and the general public alike, Caspi and colleagues reported evidence that the 5-HTTLPR polymorphism moderates the depressogenic effects of stress (Caspi et al., 2003). Specifically, these authors found that the short allele, which is associated with less 5-HTT expression and consequently less 5-HT reuptake and elevated synaptic 5-HT, was associated with greater rates of depression, but only among individuals who were exposed to adversity early in life or who experienced stressful life events as adults. The observation of a molecular GxE interaction predicting depression built upon existing twin studies (Kendler et al., 1995) and generated excitement that molecular G×E interaction studies may provide unique etiologic insight into psychopathology and resulted in a host of subsequent replication and extension studies. When these studies did not universally replicate the original report and subsequent meta-analyses reached opposing conclusions (Table 1), excitement was replaced by sober realizations that the effect was likely smaller than originally anticipated or potentially a false positive association that has been perpetuated by publication and citation biases (de Vries, Roest, Franzen, Munafo, & Bastiaansen, 2016; Duncan & Keller, 2011).

Differences in meta-analytic approaches such as study inclusion and analytic procedures may have resulted in divergent outcomes (Table 1; Taylor & Munafo, 2016). Meta-analyses that only included studies that closely approximated the methodology of the original report (Caspi et al., 2003) found null effects (Munafo, Durrant, et al., 2009; Risch et al., 2009), while later meta-analyses that adopted broader criteria allowing for more studies to be included have reported evidence of a 5-HTTLPR×stress interaction predicting depression or related phenotypes (Karg et al., 2011; Sharpley et al., 2014 but see also Taylor & Munafo, 2016). Meta-analyses focusing on specific medical populations have produced mixed results (Mak et al., 2013; Suppli et al., 2015).

Inconsistent results across meta-analyses may also result from how variability in study design among included studies is modeled. The two meta-analyses reporting evidence that the 5-HTTLPR×stress interaction does predict depression conducted further analyses stratified by stress assessment and type of stressor (Karg et al., 2011; Sharpley et al., 2014). These found that all methods of assessment (e.g., objective measure, interview, self-report) produced significant effects but that objective and interview-based assessments of stress produced the most robust results (Karg et al., 2011; Sharpley et al., 2014) and that self-report measures, which are often used in larger studies with less deep phenotyping, were not robust to individual study exclusion within the meta-analysis (Karg et al., 2011). The explanation of this difference could be attributable to more refined phenotyping leading to more accurate assessments of stress exposure that may enhance real associations (Moffitt & Caspi, 2014) but could also be attributable to the fact that such deep phenotyping is often present in studies of smaller samples, which are inherently more prone to produce false positive and negative results.

The type of and timing of stress exposure appears to moderate the magnitude of the 5-HTTLPR×stress interaction predicting depression. For example, Karg et al. (2011) found that the 5-HTTLPR×stress interaction was much larger when considering childhood maltreatment and that this effect was robust to the exclusion of any single study, which was not the case for stressful life events predominantly assessed during adulthood. The larger effect of childhood stress in the 5-HTTLPR×stress interaction may be attributable to the robust effects of early life stress on depression, potential neurodevelopmental vulnerability (Ansorge, Zhou, Lira, Hen, & Gingrich, 2004; Bogdan, Agrawal, Gaffrey, Tillman, & Luby, 2014), temporal plausibility (Moffitt & Caspi, 2014), and the reduced association between subsequent depressive episodes and stressful life event exposure (Kendler & Gardner, 2016). With regard to the last point, the empirically supported kindling theory of depression (Post, 1992) (Kendler & Gardner, 2016) suggests that initial episodes of depression are strongly predicted by the occurrence of stressful life events, while later episodes are predicted by prior episodes of depression but not major stressful life events. Implicit in this hypothesis is that depressive episodes result in biological and/or psychological scars that set the stage for future episodes (i.e., these individuals are kindled). Importantly, however, stress may not be entirely unpaired from subsequent episodes, but the extent of stress needed to evoke depression may be diminished. More specifically, evidence suggests that minor stressors, such as daily hassles, that would not be detected in many assessments of stressful life events may promote a depressed episode in a kindled individual (Monroe & Harkness, 2005). As such, it is plausible that kindling may also moderate the 5-HTTLPR×stress interaction predicting depression. This is supported by evidence that the 5-HTTLPR×stress interaction is most robust when considering early life stress (Bogdan et al., 2014; Karg et al., 2011) as well as evidence that low level stressors during adulthood are most predictive of depression in the context of the 5-HTTLPR genotype×stress interaction (Kendler, Kuhn, Vittum, Prescott, & Riley, 2005). However, the possibility that kindling may influence the 5-HTTLPR × stress interaction predicting depression remains speculative as kindling has not been formally tested in the context of a longitudinal design and 5-HTTLRP × stress interaction.

One aspect of the 5-HTTLPR, stress, and depression literature that is puzzling is the directionality of association in studies reporting positive results. The short allele, which is associated with stress-related depression in some studies, is associated with less *SLC6A4* expression. Because less 5-HTT availability is semi-analogous to the effects of common treatments for depression (e.g., SSRIs), the directionality of results may appear counterintuitive. However, converging work from nonhuman animal and human studies suggests that increases in 5-HT conferred by the short allele may result in latter depression due to elevated levels of serotonin experienced during early life and neurodevelopment. In a nonhuman animal model, rodents treated with SSRIs shortly after birth (equivalent to the third trimester of pregnancy in humans) behave normally as pups but display depressive- and anxiety-like behavior later as adults (Ansorge et al., 2004). In a human cohort study using data from the Finnish national registry found that prenatal exposure to SSRIs was associated with a three- to fourfold risk of depression during adolescence relative to offspring born of mothers with psychiatric disorders who discontinued SSRI use during pregnancy and mothers with psychiatric disorders who were not taking medication (Malm et al., 2016). Collectively, these data suggest that unlike the antidepressant effects of increasing synaptic serotonin by blocking the 5-HTT in adults, elevations of serotonin during prenatal development, and potentially into childhood, may increase risk for depression during adolescence and/or adulthood. Taken together, these findings suggest that the 5-HTTLPR short allele, which is associated with reduced 5-HTT efficiency and greater synaptic 5-HT levels, may increase risk for depression through exposure to elevated serotonin throughout development.

5-HTTLPR: Potential Neural Mechanisms Underlying Associations with Stress-Related Depression

Amygdala and Neuroticism

Imaging genetics is a research strategy that examines associations between both genetic and epigenetic variation and variability in brain structure, function, and connectivity, as well as risk for psychopathology (Bogdan et al., 2017). Imaging genetics provide a unique approach to mechanistically relate differences in 5-HTTLPR genotype to neural systems that mediate cognition, emotion, and behavior in health and disease (Hariri & Holmes, 2006). Most commonly, 5-HTTLPR imaging genetic studies have investigated amygdala responsivity to threatening information. Broadly, the amygdala and its connections are necessary for recognizing possible threat in the environment and then generating and regulating physiologic and behavioral reactions. Elevated amygdala response to threat is a hallmark of various forms of psychopathology and in particular stress-related disorder (Bogdan, Pagliaccio, Baranger, & Hariri, 2016). Amygdala function is regulated by serotonin (Holmes & Hariri, 2003), and Hariri and colleagues (Hariri et al., 2002) linked the short allele to elevated amygdala reactivity in one of the first imaging genetic studies. This finding has not been consistently replicated across studies, with meta-analyses concluding that a small effect may be present (Munafo, Brown, & Hariri, 2008; Murphy et al., 2013 but see also Bastiaansen et al., 2014). As such, heightened amygdala reactivity associated with the short allele remains a plausible mechanism, among many (e.g., hypothalamic–pituitary–adrenal axis function; Gotlib, Joormann, Minor, &

Hallmayer, 2008) through which the 5-HTTLPR polymorphism may confer vulnerability to the depressogenic effects of stress. Indeed, recent evidence that elevated amygdala reactivity prospectively predicts elevated depression symptoms following stressful life event exposure provides support for this speculation (Swartz, Knodt, Radtke, & Hariri, 2015). A related interpretation is that given the links between amygdala reactivity and neuroticism (Cunningham, Arbuckle, Jahn, Mowrer, & Abduljalil, 2010), it is plausible that elevated amygdala reactivity among short allele carriers contributes to neuroticism, which itself moderates the impact of stressful life events on the development of depression (Kendler, Kuhn, & Prescott, 2004). Future adequately powered prospective longitudinal studies employing structural equation models alongside convergent nonhuman animal models are needed to evaluate these putative mechanisms (Bogdan et al., 2016).

Neural Development

As alluded to earlier, 5-HTTLPR genotype may confer vulnerability to stress-related depression due to the neurodevelopmental consequences of reduced 5-HTT function. First, as mentioned above, pharmacologic blockade of the 5-HTT during early development in rodents (perinatal) and humans (prenatal) is associated with elevated anxiety and depression in adolescence and adulthood (Ansorge et al., 2004; Malm et al., 2016). Second, human neuroimaging studies suggest that the associations between 5-HTTLPR genotype and amygdala function is not related to current 5-HTT availability as measured with positron emission tomography, but by brain structure; this raises the possibility that differences conferred by 5-HTT genotype arise from indirect neurodevelopmental consequences on brain structure as opposed to its direct acute effects on serotonin transporter function (Kobiella et al., 2011). Lastly, there is the possibility that both 5-HTTLPR and early life stress may both result in downstream consequences associated with elevated 5-HT activity. For instance, both 5-HTTLPR genotype and early life stress are associated with diminished 5-HT1A receptor binding, suggesting a potential shared molecular pathway with additive influences (Spinelli et al., 2010). Further, this reduced 5-HT1A receptor binding is associated with differences in neurodevelopment and may confer vulnerability to depression and anxiety through disrupted prefrontal regulation of the amygdala and other subcortical structures (Pezawas et al., 2005).

Conclusions

The initial excitement generated by the Caspi et al. (2003) report that variation in the common 5-HTTLPR polymorphism moderates the depressogenic effects of stress have been tempered by replication studies and meta-analyses that have reached opposing conclusions. What is presently clear is that whether 5-HTTLPR genotype increases the risk for stress-related depression remains an empirical question that will be best informed by large longitudinal studies with deep phenotyping. In addition to conducting meta-analyses of existing studies that model between study variability, it is important for further research to evaluate possible reasons that may contribute to this mixed literature, such as the timing of stress exposure and whether kindling may reduce the 5-HTTLPR x stress interaction. Lastly, given accumulating evidence of epigenetic variation within *SLC6A4* associated with depression-related phenotypes (Nikolova et al., 2014; Swartz, Hariri, & Williamson, 2016), it will be important to not only consider genetic variation across the serotonergic system and related systems but also epigenetic signatures.

Author Biographies

Christina Di Iorio is a first-year clinical psychology graduate student and a research assistant in Dr. Bogdan's Behavioral Research and Imaging Neurogenetics (BRAIN) Lab at Washington University in St. Louis. She investigates the interaction of serotonin (5-HT) and NMDA with stress and reward processing and how these interactions impact brain structure and function as well as behavior.

Dr. Kimberly Johnson is an associate professor at the Brown School of Social Work at Washington University in St. Louis. Her research focuses on identifying genetic and environmental factors for cancer, with a particular emphasis on pediatric cancer in both the general and high-risk (neurofibromatosis type 1) populations. She also collaborates with investigators at the Washington University McDonnell Genome Institute on discovery of genomic risk factors for cancer in both adults and children.

Daniel Sheinbein is a medical student at the University of Missouri School of Medicine. His research focuses on behavioral correlates of treatments targeting obesity in children and adults.

Samantha Kahn is a research assistant at Dr. Bogdan's Behavioral Research and Imaging Neurogenetics (BRAIN) Lab. She joined the BRAIN Lab in December of 2014 and obtained her Bachelors in Psychological and Brain Sciences from Washington University in St. Louis in 2016.

Patrick England is a medical student at the Washington University School of Medicine and was previously a member of Dr. Ryan Bogdan's Behavioral Research and Imaging Neurogenetics (BRAIN) Lab in 2015 examining relationships between stress and other mental health outcomes.

Dr. Ryan Bogdan is an associate professor in psychological and brain sciences at Washington University in St. Louis. Dr. Bogdan's research is focused on mechanistic factors that drive variability in mood and behavior to gain insight into the etiology of psychopathology. He is particularly interested in how genetic variation and stress influence mood and behavior through neural mechanisms.

The Neuroscience of Well-Being: Part 1 (Conceptual Definitions)

Introduction

There is a growing recognition in mental health research for the need to understand the mechanisms of mental well-being over and above mental illness. The need for this research is driven by evidence suggesting that the absence of mental illness is not necessarily equivalent to optimal mental health or well-being. In fact, mental illness and mental well-being share only 25% in common variance (Keyes, 2005). This variance implies that the factors that contribute to mental illness are not necessarily the same factors that also contribute to mental well-being. Another need for the research is that optimal well-being transverses superior physical functioning and predicts increased longevity and healthy aging (Diener & Chan, 2011), resistance to infection (Steptoe, Dockray, & Wardle, 2009), and reduced risk for illness and mortality (Chida & Steptoe, 2008). Therefore, developing an understanding of the factors that mediate and promote mental well-being is vital for the future development of health promotion interventions. In particular, it would be important to understand the neurobiological mechanisms that mediate well-being and determine whether or not an individual is more or less likely to flourish. The purpose of this chapter is to provide a review of the conceptual definitions of well-being and the ways that it is currently being measured. A potential neural framework to help understand well-being is then presented, drawing from previous and current research. Suggestions for future research and clinical developments in this field are then discussed.

Conceptual Definitions of Well-Being and Their Measurement

Mental well-being is conceptualized and defined by one of three paradigms: (a) the hedonic perspective (subjective well-being), (b) the eudaimonic perspective (psychological well-being), and (c) the composite perspective (combination of both subjective and psychological well-being).

Hedonic Perspective, Subjective Well-Being (SWB)

The construct of hedonia or “subjective well-being” (SWB) is defined by measures of happiness and life satisfaction. Bradburn (Bradburn & Caplovitz, 1965) was the first to differentiate positive and negative affect in the context of social change, a factor structure later confirmed by Diener and colleagues (Diener, Smith, & Fujita, 1995). Andrews and Withey (Andrews & Withey, 1976) enhanced this model and added life satisfaction as a separate dimension to the two major types of affect. These three factors were shown to correlate substantially yet were clearly separable using multitrait-multimethod techniques (Lucas, Diener, & Suh, 1996). Wilson (Wilson, 1967) was the first to review the SWB literature of happiness, followed by a 30-year review by Diener (Diener, Suh, Lucas, & Smith, 1999). Diener summarized this work and defined SWB as three correlated yet separable components: *pleasant affect* such as joy, contentment, pride, affection, happiness, and elation; *unpleasant affect* including sadness, anxiety, stress, depression, guilt, and envy; and *life satisfaction* such as satisfaction with current, past, and future life and a desire to change. Other theorists have since expanded on specific elements of this model, specifically in terms of understanding pleasant affect and positivity. For example, Peterson and Seligman (Peterson & Seligman, 2004) attempted to identify and classify positive psychological traits in terms of what they refer to as the “six virtues”: wisdom and knowledge, courage, humanity, justice, temperance, and transcendence. Each virtue taps into 24 specific character strengths, which are thought to be measurable traits that transcend culture and history.

Commonly used self-report questionnaires of SWB include the 5-item Satisfaction with Life Scale (SWLS) (Diener, Emmons, Larsen, & Griffin, 1985) as a measure of overall life satisfaction and the 26-item WHO Quality of Life Scale (WHOQOL) (Murphy, Herrman, Hawthorne, Pinzone, & Evert, 2000) as a measure of quality of life for the domains of physical and psychological health, social relationships, and environment. Other more specific measures of SWB include measures of *happiness* using the 4-item Subjective Happiness Scale (SHS) (Lyubomirsky & Lepper, 1999), *flourishing* using the 8-item Flourishing Scale (Diener et al., 2010), and *positive/negative feelings* using the 12-item Scale of Positive and Negative Experience (SPANE) (Diener et al., 2010).

Eudaimonic Perspective, Psychological Well-Being (PWB)

Eudaimonia or “psychological well-being” (PWB) in contrast defines well-being in terms of the development of the human potential. This perspective was originally derived from Aristotle’s philosophy of happiness and what it means to live a good life as articulated in his *Nicomachean Ethics* (Broadie & Rowe, 2002). Ryff (Ryff, 1989) was a strong proponent for this perspective as she believed the previous literature on well-being was not strongly theoretically guided and that it neglected important aspects of positive psychological functioning. Some missing perspectives included Jung’s (Jung, 1933) formulation of individuation, Roger’s (Rogers, 1961) view of the fully functioning person, Allport’s (Allport, 1961) conception of maturity, and Maslow's (Maslow, 1968) view of self-actualization. Ryff (Ryff, 1989) also suggested that we need to consider how PWB may change and evolve over the lifespan to deal with ongoing life challenges as purported by Buhler's (Buhler, 1935) work on life fulfillment, Erikson's (Erikson, 1959) psychosocial stage model, and Jahoda's (Jahoda, 1958) definition of positive mental health over and above the absence of illness. To this end, Ryff (Ryff, 1989) proposed six essential dimensions of PWB: *self-acceptance,* the acceptance of self and one's past life*; positive relations with others,* the ability to feel empathy and affection for others and to be able to develop warm and intimate relationships*; autonomy,* the ability to be self-determined and independent and to possess an internal locus of control*; environmental mastery,* the ability to choose or create environments suitable to one's needs, to control complex environments, and to capitalize on environmental opportunities*; purpose in life,* to possess goals, intentions, and a sense of direction that provide a meaning to life; and *personal growth,* the ability to actualize and realize one's potential and to grow and expand as a person. Empirical evidence supports the six-factor structure of these dimensions with a higher-order common factor of PWB (Ryff, 1989).

Scientists have since studied specific elements of eudaimonic well-being to better understand its role in mental health. Goal theorists such as Scheier and Carver (Carver, Scheier, & Segerstrom, 2010) discuss how behavioral self-regulation and well-being can be maintained and emphasize the role of goal orientation, confidence, and optimism. In this sense, working toward particular goals is considered to make an impact on outcomes in future health and one's ability to deal with health scares. Confidence to achieve set goals is thought to lead to a more optimistic assessment of the expected outcome and therefore engages the necessary behaviors to see the goal through to fruition. This concept is akin to Ryff's (Ryff, 1989) dimension of *purpose in life* and how goals are central to achieve a meaningful life. Other theorists focus on a self-deterministic view of well-being whereby eudaimonia is characterized in terms of motivation, like pursuing intrinsic goals such as personal growth, intimacy, being mindful, and acting with a state of awareness (Ryan, Huta, & Deci, 2008). Mindfulness is an awareness of the present moment and facilitates meaningful decision making and enactment of intrinsic values. Intrinsic aspirations and mindfulness are contrasted to extrinsic aspirations such as wealth, fame, and image, which do not increase well-being because they do not satiate the basic psychological needs of autonomy, competence, and relatedness (Ryan et al., 2008).

The Ryff Scales of Psychological Well-Being (Ryff, 1989) are commonly used to measure specific components of PWB including autonomy, environmental mastery, personal growth, positive relations with others, purpose in life, and self-acceptance. Other more specific measures of PWB include measures of *gratitude* using the 6-item Gratitude Questionnaire (GC-6) (McCullough, Emmons, & Tsang, 2002) and *mindfulness* using the 15-item Mindful Attention Awareness Scale (MAAS) (Brown & Ryan, 2003).

Composite Perspective, SWB and PWB Combined

SWB and PWB are conceptually related but empirically distinct streams of positive psychological functioning. A number of studies have demonstrated this distinctiveness with factor analysis across measures of both SWB and PWB (Compton, Smith, Cornish, & Qualls, 1996). Findings from Keyes and Huta suggest that both SWB and PWB are important aspects of well-being and that they may have features that overlap such as mastery, self-acceptance or life satisfaction, and vitality (Huta & Ryan, 2010). Indeed, Keyes went on to develop one of the first composite indices of well-being called the Mental Health Continuum (long and short forms, MHC-LF and MHC-SF, respectively) (Keyes, 2002, 2007). The MHC index measures aspects of emotional, psychological, and social well-being with strong internal consistency (Keyes, 2005) and test–retest reliability over 4 weeks (Robitschek & Keyes, 2009) and 9 months (Lamers, Glas, Westerhof, & Bohlmeijer, 2012). Ryan further suggested that SWB and PWB are not distinct types of well-being but different endpoints for the same outcome. PWB specifies the conditions of optimal living and the effects of these conditions, which include not only hedonic aspects of pleasure seeking but also other elements of good health such as vitality, intimacy, and a sense of meaning. In contrast, SWB focuses on the experience of pleasure as a state that can be obtained through intrinsic goal-driven eudaimonic living or through extrinsic (albeit, less altruistic) means such as living a life of greed, materialism, or exploitation (Ryan et al., 2008).

More recently, Seligman integrated aspects of PWB and SWB into the PERMA theory of well-being, which includes the constructs of *engagement* (the loss of self-consciousness during an absorbing activity, also referred to as *flow* [Csikszentmihalyi, 1992]), *relationships* (the presence of positive and supportive relationships), *accomplishment* (the intrinsic goal of achievement and goal orientation), *positive emotion* (happiness and life satisfaction), and *meaning* (purpose in life) (Seligman, 2011). Consistent with this theory, Gatt and colleagues have developed a short 26-item composite scale of well-being called COMPAS-W (Gatt, Burton, Schofield, Bryant, & Williams, 2014), which includes some of the constructs proposed by Seligman. The COMPAS-W scale provides both an overall measure of total well-being and specific measures of subjective and PWB, including sub-measures of *composure* (competency and adaptability in stressful situations), *own-worth* (autonomy and independent self-worth), *mastery* (self-confidence and perceived control over one's environment), *positivity* (optimism and positive outlook), *achievement* (goal orientation and striving), and *satisfaction* (satisfaction with life, health, work, personal relationships, and emotions). This scale was tested in 1,669 healthy twins and showed strong internal reliability, test–retest reliability over 12 months, and construct validity with other physical and psychological health indicators. Individuals are scored along a continuous dimension of well-being or classified into three groups: flourishing, moderate, or languishing well-being. Univariate twin modeling of monozygotic and dizygotic twin pairs demonstrated a moderate impact of genetics toward overall well-being (heritability of 48%), plus an important role of unique environment at 52% (Gatt et al., 2014). Evidence from other twin studies has similarly suggested that common genetic factors contribute to overall well-being and its subjective and psychological subcomponents (Keyes, Myers, & Kendler, 2010). Moreover, in a later study, the COMPAS-W well-being scale was shown to share approximately 30% of variance in common with depression and anxiety symptoms in a large sample of healthy adult twins, of which 56% was due to genetic effects (Routledge et al., 2016). This finding is consistent with previous reports in healthy and clinical samples whereby mental health and mental illness have been shown to share about 25% in common variance (Keyes, 2005).

Together, this evidence suggests that both SWB and PWB contribute to overall mental well-being, thereby supporting the use of composite models and composite scales. Twin studies also suggest that both genetics and environment contribute to variance in well-being. The specific role of genetic factors may pertain to a protective effect toward positive well-being attributes, and/or they may modulate sensitivity to environmental influences, heightening responses, or biases toward positive life events and lifestyle factors (e.g., exercise, healthy diet) and against negative life events and factors (e.g., poor diet, alcohol and drug use). The moderate impact of environment also suggests that well-being is malleable to some degree and could be promoted further with enriched positive environments and/or intervention. If we can understand the neural mechanisms that mediate well-being, we can pinpoint which specific characteristics or patterns of behavior to target in interventions.

In the next chapter (Part 2), the core neural networks that are typically implicated in mental illness are summarized and discussed in relation to mental well-being. Current evidence will be reviewed and suggested future research developments will be discussed.

Introduction

Neurotrophins are structurally similar polypeptide growth factors that facilitate the growth and differentiation of the nervous system. Four types of neurotrophins have been identified in humans and animals, all with specialized functions. Nerve growth factor (NGF) was the first neurotrophin to be discovered in the early 1950s for its role in sensory and sympathetic neuron survival. Brain-derived neurotrophic factor (BDNF) was later identified in 1982 for its involvement in the development and maintenance of neurons through axonal and dendritic branching. Neurotrophin-3 (NT-3) and neurotrophin-4/5 (NT-4/5) are the most recent members of the mammalian neurotrophin family to be identified. Although less is known about their independent functions using *in vivo* methods, studies show that NT-3 and NT-4/5 demonstrate unique expression patterns that may be mechanistically important for certain growth pathways (Adachi, Numakawa, Richards, Nakajima, & Kunugi, 2014).

BDNF is the most widely studied neurotrophin in clinical research due to its known impact on human brain structure and behavior. BDNF signaling promotes long-term potentiation (LTP) and plasticity of the hippocampus, facilitates adaptive responses to brain injury, and is an important mediator of protein regulation in various biosynthetic pathways (Adachi et al., 2014; Egan et al., 2003). In this chapter we will review the diverse biological roles of BDNF and its interactions with sociodemographic variables and environmental stimuli to impact human health.

Genetic Structure and Biology of BDNF

Human BDNF is encoded by the *BDNF* gene on chromosome 11. The *BDNF* gene is structurally complex, with eight 5′ exons (exons I–VIII, plus the human-specific Vh and VIIIh exons) and functional promoters that are spliced onto one 3′ protein-coding exon (exon IX) (Adachi et al., 2014). Alternative splicing at each of the 5′ exons can produce different mRNA precursor transcripts (pre-pro BDNF isoforms), but only the 3′ region of exon IX contains the common coding sequence to synthesize the BDNF signaling peptide, pro-BDNF (~32 kDa). In humans, exons I, VII, and VIII of the *BDNF* gene contain the necessary ATG sequence to initiate translation, yielding pre-pro BDNF proteins with longer peptide sequences than untranslated exons with start codons in exon IX. Further, *BDNF* gene transcription terminates at two polyadenylation sites in exon IX, resulting in subpopulations of mRNA with short and long 3′ untranslated regions (UTR). Although all BDNF isoforms are converted to pro-BDNF with identical primary sequences, differences in signaling peptides and the length of the 3′UTR differentially influence physiological processes and tissue-specific expression, respectively (Adachi et al., 2014). Notably, the promoter elements in exon IV regulate activity-dependent BDNF expression.

Pro-BDNF consists of an N-terminal pro-domain of 129 amino acids and a C-terminal mature domain of 118 amino acids (Hempstead, 2015). Initially synthesized in the endoplasmic reticulum, the Golgi apparatus transports pro-BDNF to the trans-Golgi network (TGN) for packaging and secretion via constitutive or regulated pathways (Adachi et al., 2014). Secretory vesicles in the constitutive pathway transport pro-BDNF to the plasma membrane for continuous extracellular cleavage by plasminogen/plasmin and release of mature BDNF (mBDNF). In the regulated pathway, pro-BDNF vesicles accumulate at the plasma membrane via Ca^{2+}-dependent exocytosis and are eventually released by activity-dependent intracellular triggering signals. Here, pro-BDNF may be converted to mBDNF in the TGN by furin and other endoproteases, or in the immature secretory granules by proprotein convertases (Hempstead, 2015). Unlike other neurotrophins, BDNF is preferentially secreted by the regulated pathway to modulate synaptic activity and neural connectivity.

Mature BDNF mediates neuronal survival and differentiation by binding to the tropomyosin receptor kinase B (TrkB) on pre- and postsynaptic membranes. Conversely, pro-BDNF activates the p75 receptor, a member of the tumor necrosis factor family, which has shown to be proapoptotic when bound to a high-affinity ligand (e.g., sortilin). Indeed, animal studies show that conversion of pro-BDNF to mBDNF promotes late-phase LTP in the hippocampus, but that perfusion of pro-BDNF facilitates long-term depression (LTD). Similar studies show that secretions of pro-BDNF, rather than mBDNF, predominate following experimental conditions that induce LTD. These dichotomous functions of BDNF domains have been described as the "yin and yang of neurotrophic action" (Lu, Pang, & Woo, 2005).

Clues to the bioactive role of pro-BDNF came from investigations of a common single nucleotide polymorphism (SNP) at position 66 of the pro-domain in the *BDNF* gene/rs6265 (Egan et al., 2003). This SNP involves a valine (Val) to methionine (Met) substitution that influences the sorting of BDNF into the constitutive and regulated pathways. Specifically, the Met allele shows diminished capacity for sortilin binding (intracellular trafficking chaperone) and altered targeting of BDNF to secretary granules in the regulated pathway (Adachi et al., 2014). The net result is reduced activity-dependent release of BDNF. Interestingly, there is currently no evidence that the Val66Met marker influences the activity of mBDNF (Forde et al., 2014).

Of the 84 SNPs that have been identified in the *BDNF* gene, most research examining relationships between BDNF expression, brain, and behavior has focused on the Val66Met SNP. The Met variant of the Val66Met SNP is associated with abnormal sorting and secretion of BDNF (Hempstead, 2015), and this mutation is common among European and Asian ancestries. Other mutations within the *BDNF* gene have gained increased attention for their role in antidepressant efficacy and behavior (Colle et al., 2015), though much of this work remains preliminary. Given the large body of work dedicated to *BDNF* SNPs and brain–behavior phenotypes, this chapter will review the most salient gene × brain × behavior associations in the literature, with a primary focus on the Val66Met mutation.

BDNF Expression Patterns and Influential Variables of Bioactivity

Animal and human studies show that BDNF is widely expressed across the central nervous system (CNS), with high concentrations in the cerebral cortex, hippocampus, amygdala, hypothalamus, and cerebellum (Adachi et al., 2014). The ratio of pro-BDNF to mBDNF varies across the lifespan, with moderate concentrations of both peptide variants in adolescence, and a predominance of mBDNF in adulthood. However, plasma levels of BDNF decrease with age, as does signaling capacity in the brain. BDNF can also be synthesized and stored in peripheral tissues, yet the brain is the primary source of protein synthesis during development. Accordingly, early life stress has been associated with lower BDNF levels in the hippocampus, anterior cingulate cortex, and amygdala, and these reductions persist into adulthood (reviewed in van Velzen et al., 2016).

Hippocampal BDNF expression has been the focus of many investigations given the high level of BDNF expression in this brain region and its corresponding influence on neurogenesis in the dentate gyrus. Adult neurogenesis occurs through both environmental enrichment (exposure to various learning experiences, social interactions, and physical exercise) and genetic mechanisms, and the direction of these relationships is dependent on BDNF activity. Although the majority of literature regarding environmental enrichment and hippocampal neurogenesis comes from experimental studies in rodents, there is evidence to support a role for BDNF-dependent hippocampal neurogenesis in humans. Much of this evidence can be extrapolated from the neurobiological and behavioral similarities between rodents and humans, but additional support comes from studies showing exercise-induced increases in cerebral blood volume using magnetic resonance imaging (MRI), which has shown to correlate with hippocampal neurogenesis in mice (for review see Clemenson, Deng, & Gage, 2015). Perhaps the most salient evidence, however, comes from the well-known study of London taxi drivers, who exhibit larger hippocampal volume compared with controls and a positive correlation between hippocampal volume and spatial navigation expertise and visuospatial memory (Woolett & Maquire, 2011). Although BDNF concentrations and genotyping were not completed in these studies, the results reinforce a role for environmental enrichment in hippocampal neurogenesis, that is, likely partially BDNF dependent.

Genetic influence on hippocampal neurogenesis is believed to be a complex process that involves many gene × gene interactions that stimulate BDNF release. Interestingly, there is conflicting evidence whether the *BDNF* Val66Met SNP is a mediator of this process in humans. Below we review existing relationships between the Val66Met marker and hippocampal brain integrity, in addition to its relationship with other brain structures.

Relationships Between the *BDNF* Val66Met SNP and Brain Structure

Transgenic mouse models show that mice with the *BDNF* Met/Met genotype have smaller hippocampal volumes, reduced dendritic arborizations, and impaired synaptic plasticity compared with Val homozygotes and heterozygotes (Adachi et al., 2014). Smaller hippocampal volumes have been reported in a handful of human studies using structural MRI, though these outcomes have not been universally observed (reviewed in Harrisberger et al., 2015). Further, a recent joint meta-analysis of 31 published studies and one new sample ($n = 653$) did not reveal an association between the Val66Met SNP and hippocampal volumes in healthy adults (Harrisberger et al., 2015). The authors concluded that there is limited evidence for a direct relationship between the Val66Met SNP and hippocampal volume and that previous findings may be due to uniquely homogeneous samples and specific gene × gene interactions.

Apart from the hippocampus, other studies have identified a negative impact of the Met allele on gray matter of the dorsolateral prefrontal cortex, thalamus, amygdala, and fusiform gyrus and parahippocampal gyrus and total gray matter of the occipital and temporal lobes. Still, other studies employing similar analyses have not seen these effects (Forde et al., 2014). As with BDNF expression, it is possible that *BDNF* gene × brain relationships are dependent on moderating variables and that the direction of these relationships are region specific. For example, Van Velzen et al. (2016) revealed lower amygdala volume in maltreated children with at least one Met allele, whereas maltreated subjects with the Val/Val genotype demonstrated reduced cortical thickness.

Only a handful of studies have investigated the impact of the Val66Met SNP on white matter integrity, and there has been limited consistency in the observed outcomes. Perhaps the most interesting findings are from diffusion tensor imaging (DTI) studies showing increased fractional anisotropy (FA) (a marker of axonal integrity) in white matter tracts of healthy adult Met allele carriers. Higher FA is generally associated with more intact structure, suggesting an advantageous effect of the Met allele on white matter connectivity (Chiang et al., 2011). Although these studies group homozygous and heterozygous Met carriers together, met-carrying persons showed higher FA in the corpus callosum, fornix, inferior longitudinal fasciculus, superior longitudinal fasciculus, cingulum bundle, posterior thalamic radiation, posterior corona radiate, and internal capsule. In the largest of these studies, Chiang et al. (2011) examined white matter microstructure in 455 adult twins to determine the degree to which BDNF could account for genetic variance in tract-specific FA. Results revealed an FA deficit of 15% in major fiber bundles of Val allele carriers, and BDNF explained approximately 80% of the variance in FA (Forde et al., 2014).

More recent work suggests that the lack of a homozygous Met/Met group in previous studies has confounded earlier findings in both gray and white matter tissue. Forde et al. (2014) revealed associations between the heterozygous Val/Met genotype and cortical intrinsic curvature (a measure of surface morphology and cortical connectivity) that was distinct from either homozygous genotype. In addition, analysis of two common neuroimaging techniques, voxel-based morphometry and tract-based spatial statistics, revealed stronger associations between the Val66Met marker and gray matter (adjusted R^2 = 25–48%) versus white matter (adjusted R^2 = 14%).

Collectively these results suggest that the Val66Met marker influences BDNF brain functions other than neurogenesis. Forde et al. (2014) hypothesized that stronger relationships between Val/Met and gray matter indicate that the main effect of this SNP occurs primarily in gray matter synapses where it can modulate activity-dependent release of BDNF.

Relationships Between BDNF and Neuropsychiatric Function

There is substantial evidence that BDNF plays an important role in emotional health. Indeed, the ***neurotrophin hypothesis of depression*** originated from animal studies revealing inverse correlations between BDNF levels and stress-induced depressive behaviors, as well as increases in BDNF expression following chronic antidepressant administration (Russo-Neustadt, Beard, & Cotman, 1999). In humans, a recent large-scale study ($N = 1{,}751$) revealed that individuals with chronic and remitted depression demonstrate a sharper decline in serum BDNF over a 2-year period compared with those with incident depression and healthy controls. Further, the degree of BDNF decline was similar between the incident depression and control groups (Bus et al., 2015), and initiation or discontinuation of antidepressants did not significantly alter the trajectory of BDNF levels over the course of 2 years. Bus et al. (2015) concluded that depression contributes to lower levels of BDNF rather than low BDNF being causally linked to depression. The authors further speculated that a 2-year time period was too brief to observe meaningful changes in BDNF due changes in antidepressant treatment regimens.

With regard to the Val66Met SNP, there is inconclusive evidence that the Met allele increases risk for depression. However, a meta-analysis by Hosang, Shiles, Tansey, McGuffin, & Uher (2014) revealed a moderating effect of the Met allele between total life stress and depression. This interaction was stronger when life stress was stratified to stressful life events (broadly defined as negatively impactful events) rather than childhood adversity. Finally, additional work shows that sex interacts with *BDNF* SNPs to impact risk for major depressive disorder (MDD). A meta-analysis by Verhagen et al. (2010) showed that males carrying one or two Met alleles are at an increased risk for MDD—an effect that was not observed in females.

There are also conflicting findings regarding the relationship between anxiety disorders, peripheral BDNF levels, and the Val66Met marker. While meta-analyses of the Val66Met SNP fail to show elevated risk for anxiety disorders, a meta-analysis by Suliman, Hemmings, and Seedat (2013) revealed significantly lower plasma BDNF across a range of anxiety conditions. In this latter study, a stratified analysis examining peripheral BDNF in individuals with post-traumatic stress disorder (PTSD) and obsessive–compulsive disorder (OCD) showed lower BDNF in OCD patients, but not in those with PTSD. These incongruent effects of peripheral BDNF and the Val66Met SNP are common, though not well understood. For example, Hemmings et al. (2013) did not observe a direct link between the Val66Met SNP and OCD, but did report a dose-dependent effect of the Met allele as a moderator between childhood emotional abuse and OCD (Hemmings et al., 2013). Conversely, Moreira et al. (2015) *did* reveal a direct effect of the Met variant on increased risk for general anxiety disorder. This study implicates a generalized role for the Val66Met SNP on anxiety-related psychopathology and may explain the lack of relationship with distinct anxiety phenotypes. Alternatively, discrepancies between peripheral BDNF and the Val66Met marker may be a result of downstream interactions with other *BDNF* gene polymorphisms.

The Met allele has also been identified as a risk factor for substance use disorders, anthropometric characteristics, schizophrenia, and personality traits, though none of these findings have been consistently replicated. For many of these investigations, the Met allele served as a moderator of dysfunction between biobehavioral phenotypes and was not in itself a marker of disease risk. However, evidence for direct genetic effects can be observed from GWAS. To date, GWAS have identified the Met variant as a marker of antidepressant efficacy (Colle et al., 2015), introversion (Schlessinger et al., 2016), childhood obesity, and BMI (Mei et al., 2012). Interestingly, GWAS have identified several SNPs in the *BDNF* gene that are associated with BMI (rs4074134, rs4923461, rs925946, rs10501087, rs6265, rs10767664, and rs2030323), which may be a result of activity-dependent release in the hypothalamus or brain stem (for review see Waterhouse & Xu, 2013).

Relationships Between BDNF and Cognition

Several studies show that the Met allele is detrimental to a wide range of cognitive functions, including episodic memory, delayed recall, working memory, perceptual speed, visuospatial skills, and general cognitive ability (reviewed in Mandelman & Grigorenko, 2012). Interestingly, however, a recent study of 500 older adults reported associations between high BDNF expression and a slower rate of cognitive decline over a 6-year period, yet BDNF expression did not differ according to Met and Val gene variants, and the Val/Met marker was not associated with cognitive status (Buchman et al., 2016). Similarly, a meta-analysis of 23 studies ($N = 7{,}095$) did not reveal significant associations between the Val66Met SNP and cognitive phenotypes (Mandelman and Grigorenko, 2012). Mandelman and Grigorenko proposed a number of explanations for this finding. Most notably, the authors postulated that a lack of effect could be due to the functional diversity of BDNF isoforms across different brain regions, which may influence cognitions that share bioactive active pathways rather than behavioral similarities. This hypothesis is consistent with evidence that truncated BDNF (a pro-BDNF isoform, ~28 kDa) is a better predictor of cognitive performance and affective symptoms rather than total BDNF (exon IX) in serum of schizophrenic patients (Carlino et al., 2011). This is further supported with evidence that abnormal ratios of pro- and mature domains of pro-BDNF result in divergent pathological outcomes (Hempstead, 2015).

Interactions between exercise and BDNF have been shown to enhance various cognitive functions. Activity-dependent release of BDNF is the most common triggering mechanism in the regulated pathway, in which the majority of BDNF is transported to postsynaptic dendrites and spines. A 2015 meta-analysis shows that a single session of exercise can moderately increase BDNF levels, independent of assay type (serum vs. plasma) (Szuhany, Bugatti, & Otto, 2015). Further, interactions between exercise and BDNF on brain function have been consistently demonstrated in the literature, particularly with regard to their impact on learning and memory. It is well established that exercise enhances encoding and consolidation of new memories, and BDNF is a crucial mediator of this process. Recent work now shows that interactions between exercise and the Val66Met SNP significantly influence emotional memory consolidation. Keyan and Bryant (2016) demonstrated that brief aerobic exercise predicted an interaction between increased cortisol response and the Val homozygous genotype to enhance recall of positive, but not negative, memories. No interaction was observed among Met allele carriers, suggesting that Val homozygotes are more likely to exhibit memory benefits from exercise-induced cortisol secretion. The authors hypothesized that the lack of interaction in Met carriers may be due to reduced stress reactivity and blunted cortisol release compared with Val/Val genotypes, which has been demonstrated in earlier work (Keyan and Bryant, 2016).

Finally, the Met allele may play an important role in neurodegenerative disease. In a series of studies by Lim et al. (reviewed in Lim et al., 2016), Met allele carriers demonstrated a more severe preclinical presentation of Alzheimer's disease (AD) endophenotypes compared with highly penetrant mutations of the *APP*, *PSEN1*, and *PSEN2* genes. Lim et al. (2016) further revealed increased levels of tau and phosphorylated tau in cerebrospinal fluid of Met allele carriers, in addition to more pronounced deficits in hippocampal glucose metabolism and episodic memory. In patients with Parkinson's disease (PD), Met allele carriers exhibit greater cognitive impairments (Guerini et al., 2009) and early symptoms of dyskinesia (Foltynie et al.,

2009) compared with noncarriers. However, an association between the Met allele and risk for both AD and PD is not universally reported.

Conclusion

In sum, BDNF is an important neurohormone that supports brain health. Results from genetic studies collectively point to a role for the Val66Met polymorphism in phenotypic variation, yet the nature of this relationship remains highly elusive. The observed discrepancies across *BDNF* gene studies are likely due to a multitude of intervening variables, suggesting that genetic influence of BDNF expression is mechanistically specific. More conclusive evidence for gene × brain × behavior relationships may be observed via meta-analyses across more homogeneous population samples in order to capture the specificity of these interactions.

Introduction

The experience of trauma is common, and the majority of individuals will experience at least one traumatic event within their lifetime (Breslau, 2009; Kessler, Sonnega, Bromet, Hughes, & Nelson, 1995). Approximately 20% of women and 8% of men who experience a traumatic event develop posttraumatic stress disorder (PTSD) (Kessler et al., 1995). PTSD consists of persistent symptoms from four clusters, re-experiencing, effortful avoidance, negative alterations in mood and cognitions, and hyperarousal, after exposure to trauma (DSM-5; American Psychiatric Association [APA], 2013). Given that PTSD requires an etiological traumatic event, it is often thought of as a fear disorder in which an overgeneralized fear response interferes with the cognitive and emotional processing of the traumatic event leading to symptoms related to PTSD (Rauch, Shin, & Phelps, 2006). Others suggest that PTSD should be considered a disorder of affect dysregulation that involves a broader range of emotions beyond fear (Frewen & Lanius, 2006). Both of these models are reflected in research on the neural mechanisms that underlie PTSD and include the insula as a brain region that contributes significantly to the disorder.

This chapter will focus specifically on the insula in women with PTSD. First the importance of investigating the structure and function of brain regions specific to women will be discussed along with why it is thought there may be meaningful sex differences in the insula. Further background information regarding why gender differences in the insula may exist will be discussed. The chapter will then focus on research examining gender differences in the insula,

covering research on structural, functional, and connectivity findings. The information will be summarized, and future directions will be discussed.

Scientific Premise for Sex Differences in PTSD

Traditionally, neuroscience research has utilized male participants, although this has changed in human neuroimaging research over the past 20 years. Despite the increase in female participants, many neuroimaging studies present results that include men and women instead of examining gender-specific findings (Beery & Zucker, 2011). Investigation of gender-specific neural circuitry in PTSD imaging research is necessary given the fact that brain regions associated with PTSD, such as the insula, are sexually dimorphic (Ruigrok et al., 2014). It is possible that these sex differences impact neural function that affect the development, maintenance, and recovery of PTSD. Further, the higher prevalence rates of PTSD in women as compared with men highlight the importance of examining neural circuitry specific to women with PTSD. Although men have a higher occurrence of trauma exposure, the lifetime prevalence of PTSD is more than two times greater in women than men (Breslau, 2009; Kessler et al., 1995). This suggests that understanding mechanisms specifically associated with the development of PTSD in women may have a great impact.

There are social, environmental, and biological factors that likely contribute to differences in neural circuitry between men and women with PTSD. First, the type of traumatic events that men and women experience may impact gender differences in neural mechanisms. Although there are some discrepancies across the research, women are more likely than men to experience rape and sexual molestation (Breslau, 2009; Kessler et al., 1995; Koenen & Widom, 2009), while men are more likely than women to experience witnessing someone being injured or killed, having a life-threatening accident, physical attacks, and combat experience (Kessler et al., 1995). Some studies report a greater level of childhood trauma in women (Kessler et al., 1995), although other research has found that men have comparable with higher levels of childhood physical abuse and neglect than women (Koenen & Widom, 2009). Regardless, it appears that men and women are more likely to experience different types of traumatic events, and the differences in trauma types may differentially impact neurobiology.

Beyond the type of traumatic events experienced, women have a higher conditional risk of developing PTSD after they experience a traumatic event (Breslau, 2009; Kessler et al., 1995). It has been suggested that perhaps women are more likely to experience traumas that are associated with the development of PTSD such as rape. However, research has found that the type of traumatic event does not account for the full difference in conditional risk of PTSD (Breslau, 2009) and that women appear to have a greater sensitivity to assaultive trauma (Breslau & Anthony, 2007; Cromer & Smyth, 2010). Specifically, women as compared with men are more likely to develop PTSD following an assaultive traumatic event. Conversely, men and women have a similar conditional risk of PTSD after non-assaultive traumatic events. The mechanism through which women are more likely to develop PTSD after assaultive trauma is unknown; however, it has been suggested that “assault is a more normative experience for men than women, often occurring in the process of rough-and-tumble play that tends to be more common to boys” (Breslau and Anthony, 2007, p. 611). The higher conditional risk of PTSD for women may indicate that women process assaults differently than men and this may affect underlying neural mechanisms.

Biological sex differences in hormones may also be associated with differential neural circuitry in men and women. Specifically, it has been posited that low estrogen may be a risk factor for developing posttraumatic stress symptoms (Glover et al., 2012; Lebron-Milad, Graham, & Milad, 2012). The majority of research on estrogen and PTSD utilizes fear conditioning protocols to examine the impact of different estrogen levels on fear and safety learning (i.e., Glover et al., 2012; Merz et al., 2012). It is thought that PTSD is associated with deficits in processes related to fear extinction or inhibition (Jovanovic, Kazama, Bachevalier, & Davis, 2012; Jovanovic & Ressler, 2010). Glover and colleagues (2012) found that women with low estrogen levels as compared with women with high estrogen had significantly higher conditioned fear response during extinction training. Another study (Merz et al., 2012) comparing women on oral contraceptive with men and free-cycling women found unique contributions of cortisol on fear learning in each group. In men and free-cycling women, cortisol decreased fear learning. Conversely, fear learning was heightened when women on oral contraceptive were given cortisol. Although the role of hormones is not fully understood, current research suggests that estrogen may affect neural processes related to PTSD.

The Insula in PTSD

While brain regions such as the amygdala have been considered an integral component of the neurocircuitry model of PTSD since its inception (Rauch et al., 2000), the insula has only recently been implicated in the neural response to trauma. The insula, a small, bilateral cortical structure with anterior connections to the amygdala and posterior connections to the sensory cortex and thalamus, is thought to be responsible for several aspects of emotional processing and functioning, including the experience of core affect (Wager & Barrett, 2004). Recent attention directed at the role of the insula in the neurocircuitry of PTSD is plausible, given the wide range of possible affective responses an individual might experience after a trauma, and the well-known role of the insula in the experience of "disgust" (described more fully below). Inclusion of the insula within the neurocircuitry model of PTSD has coincided with alterations to the diagnostic criteria for PTSD in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) (APA, 2013). Among these changes was the incorporation of a new symptom cluster characterized by "negative alterations in cognitions and mood associated with the traumatic event(s)," which highlights the importance of understanding the multiple functions of the insula in PTSD.

Functions of the Insula

A number of neuroimaging studies have attempted to identify the functional responsibilities related to emotion of various subregions of the insula. In addition to the experience of core affect, the anterior insula is thought to be responsible for the conscious processing of subjective emotions (Craig, 2002, 2009). Lindquist, Wager, Kober, Bliss-Moreau, & Feldman Barrett (2012) specifically identify the left anterior insula as an important region related to the experience of anger and the right anterior insula as an important region related to the perception of disgust. These subregions may be implicated in a maladaptive response to an interpersonal trauma, as Lilly and Valdez (2012) highlight that interpersonal trauma is often associated with a complex emotional response inclusive of guilt, sadness, shame, disgust, and anger.

Another subregion purportedly important for the experience and processing of emotions is the posterior insula. Given that this cluster of neurons projects to the sensory cortex, the posterior insula is thought to be responsible for the transmission of homeostatic information such as pain, temperature, and physical touch (Rolls, Grabenhorst, & Parris, 2008). As such, the posterior insula is a reasonable anatomical substrate for physiological perceptions of and response to emotion. Activation of this subregion is believed to underlie abnormal hyperarousal symptoms experienced by trauma survivors.

A review conducted by Garfinkel and Liberzon (2009) also identifies relationships between the dorsal anterior insula and motivational states, cognitive control, and autobiographical memory. Within the context of the neurocircuitry of PTSD, overlap between the dorsal anterior insula and the formation, storage, and processing of autobiographical memories is intriguing, as the dysfunction among these processes is likely contributes to the occurrence of re-experiencing symptoms following a trauma. Given the multitude of functions for which various subregions of the insula are responsible, the identification of subregions and specific patterns of insula activation that are clinically relevant to PTSD remains a priority. Studies that have examined the insula in traumatized populations have preliminarily focused on the anterior insula as a key subregion in the neural dysfunction of PTSD (Hopper, Frewen, van der Kolk, & Lanius, 2007; Simmons et al., 2008), as this subregion is hypothesized to play an important role in salience processing (Koch et al., 2014).

PTSD and the Insula

Generally, individuals with PTSD exhibit hyperactivation within the insula as observed on neuroimaging (Etkin & Wager, 2007). Individuals with PTSD also demonstrate differential bilateral activation in the left and right insula in comparison with trauma-exposed and healthy control groups. A meta-analysis of the functional imaging literature by Patel, Spreng, Shin, and Girard (2012) found reliably increased activation in the right insula and left anterior insula in individuals with PTSD in comparison with healthy controls (Fonzo et al., 2010). They also reported that individuals with PTSD demonstrated increased activation in the left insula in comparison with a trauma-exposed control group in two studies: one of which utilized an implicit affective processing paradigm (Sakamoto et al., 2005) and the other that employed an associative learning paradigm (Werner et al., 2009).

However, decreased activation in the left insula in PTSD compared with a trauma-exposed individuals has been reported in Bremner et al. (2005) and Fonzo et al. (2010), often explained as a result of different activation patterns in the subregions of the insula, different paradigms across studies, and task conditions within studies. Some groups argue that decreased activity in the right anterior insula is related to the impaired ability of individuals with PTSD to anticipate and modify interoceptive changes (Simmons, Strigo, Matthews, Paulus, & Stein, 2009; Zhang et al., 2013). However, the relationships described above remain inconclusive, as the potential mediating factors, including gender and trauma type, have yet to be fully explored.

Mixed-trauma and mixed-gender imaging studies have reported relationships between BOLD signals in the insula and PTSD symptom presentations. For example, individuals diagnosed with dissociative PTSD demonstrated enhanced bilateral insula activation in response to the stimulus presentation of nonconscious fearful faces in comparison with individuals with non-dissociative PTSD (Felmingham et al., 2008). This study also reported that dissociation was positively correlated with bilateral insula activation in the conscious fear condition and positively correlated with left insula activation in the nonconscious fear condition. In a sample of victims of motor vehicle accidents (71% female), higher levels of self-reported alexithymia were associated with a greater BOLD signal in the right posterior insula, and lower levels of alexithymia were associated with a greater BOLD signal in the right anterior insula (Frewen et al., 2008). Earlier analyses of this sample yielded a significant positive correlation between right anterior insula activity and re-experiencing symptoms and a significant negative correlation between right anterior insula activity and dissociative symptoms during script-driven trauma imagery (Hopper et al., 2007). Lanius and colleagues (2007) reported greater activation in the left insula among individuals with PTSD compared with individuals with comorbid PTSD and major depression. This finding promotes further exploration of the left insula as a neural determinant of depressive symptoms following a traumatic event.

Another study found greater activation in the right insula in a sample of male and female victims of "civilian" trauma in comparison with healthy controls (Lindauer et al., 2008). Wei, Wang, Heppner, and Du (2012) reported decreased activation in the right insula in a sample of natural disaster survivors with mild to moderate posttraumatic stress symptoms in comparison with a healthy control group during a monetary donation task, providing further evidence for the role of the insula is in the reward/motivational pathway. A sample of fire disaster victims with PTSD (66% female) also exhibited reduced right insular cortex activation during word encoding and retrieval tasks than a healthy control group (Chen, Li, Xu, & Liu, 2009). Interestingly, the clinical sample activated the left insular cortex in a manner similar to the control group. A number of other mixed-trauma imaging studies have also identified significant insula hyperactivation (Whalley, Rugg, Smith, Dolan, & Brewin, 2009) and hypoactivation (Xiong et al., 2013; Zhang et al., 2013) in participants with PTSD.

Functional Imaging of the Insula in Female Interpersonal Trauma Survivors with PTSD

Conclusions regarding differential insula activation in females diagnosed with PTSD as related to interpersonal trauma can only be drawn by directly comparing results from studies on all-female and all-male samples. However, the conflation of trauma type likely remains problematic, as virtually all imaging studies that include only female participants focus on interpersonal trauma survivors. Similarly, those including only male participants often examine combat trauma. Nonetheless, findings from functional imaging studies in female victims of interpersonal trauma have generally been consistent with results from other traumatized samples, including male combat veterans (i.e., Simmons & Matthews, 2012). Aupperle and colleagues (2012) examined functional activation in a sample of 41 women diagnosed with PTSD related to intimate partner violence (IPV) (i.e., "physical and/or sexual abuse committed by a romantic partner … ."). Their results indicated that the anticipation of negative images, in comparison with that of positive images, was associated with greater activation in the bilateral anterior insula. In comparison with the control group, the PTSD group also demonstrated greater activation in the right middle/anterior insula. The authors suggested that the observed insula hyperactivation in the PTSD group reflects a discrepancy between "internally focused affective networks and externally focused cognitive control networks" (Aupperle et al., 2012). In our own research (Bruce et al., 2012), we found similar results in a sample of 32 women with PTSD as a result of interpersonal violence. Compared with 21 matched healthy controls, women with PTSD exhibited significantly higher levels of activation in the insula, particularly when attending to fearful stimuli. These findings suggest that consciously attending to emotional content further increases insular activity (Bruce et al., 2012).

In a related study, women with PTSD related to IPV demonstrated increased activation in the right anterior/middle insula as compared with a healthy control group during the anticipation of negative images (Simmons et al., 2008). A follow-up study on this sample revealed that women with PTSD related to IPV failed to activate the right anterior insula when anticipating an affective stimulus shift in comparison with the healthy control group, suggesting that these women were experiencing difficulty in modulating their interoceptive responses (Simmons et al., 2009). Frewen and colleagues (2008) observed increased activation in the left insula of women with PTSD from IPV during a relaxation condition and hypothesized that this region may be important for the awareness of autonomic arousal from pleasant affective states. They also noted a significant negative relationship between self-reported positive affect and activity within the right insula in this sample (Frewen et al., 2010).

Fonzo and colleagues (2010) reported similar findings in a group of women diagnosed with PTSD related to IPV. They observed increased activation in the left anterior insula in the PTSD group compared with healthy controls when subjects were tasked with matching fearful faces versus happy target faces. Increased activation of the right middle insula and left anterior insula was also observed in the clinical sample versus the control group when subjects were matching angry faces (Fonzo et al., 2010). A follow-up study on this sample found significant negative correlations between the severity of childhood maltreatment and activation in the left middle insula during the processing of angry faces and activation in the right anterior insula during the processing of fearful faces (Fonzo et al., 2012).

The insula may also play a role in the processing of emotional words in women with PTSD related to interpersonal violence. Bremner and colleagues (2003) observed increased activation in the right insula in response to the retrieval of emotional words from memory in their female sample of abuse survivors. Interestingly, this sample also performed an emotional Stroop task, and the trauma-exposed control group exhibited increased activation in the left insula in comparison with the women with PTSD (Bremner et al., 2004). The right middle and right anterior insula were also identified as subregions of interest in response to pain in women with PTSD related to IPV (Strigo et al., 2010). Participants demonstrated increased activation in the right middle insula during the initial painful stimulation and subsequent decreased activation in the right anterior insula that was significantly associated with avoidance symptoms of PTSD, suggesting deficits in interoceptive awareness in the clinical sample consistent with previous literature (Simmons et al., 2009, Zhang et al., 2013). However, Ludascher and colleagues (2010) reported a positive association between dissociative symptoms and activity in the left and right insula during the presentation of trauma-related script imagery in a small sample of women diagnosed with comorbid borderline personality disorder and PTSD related to interpersonal trauma.

Structural Imaging of the Insula in Female Interpersonal Trauma Survivors with PTSD

In comparison with functional imaging studies of the insula in women with PTSD related to interpersonal trauma, fewer structural studies have examined the insula as a region of interest within this population. Structural imaging studies of heterogeneous trauma samples (Corbo, Clement, Armony, Pruessner & Brunet, 2005; Chen et al., 2006, 2009; Dannlowski et al., 2011) and combat veteran samples (Chao, Weiner, & Neylan, 2013; Herringa, Phillips, Almeida, Insana, & Germain, 2012; Kasai et al., 2008) have generally identified reduced gray matter volumes in the insula in individuals with PTSD. Reduced white matter volume in tracks that innervates the insula has also been reported in a heterogeneous trauma sample of participants diagnosed with PTSD (Sun et al., 2013). Other studies (i.e., Eckart et al., 2012) have failed to find significant differences in insula volumes between heterogeneous trauma samples and controls. Fonzo and colleagues (2012) also reported no differences in insula volume between female interpersonal trauma survivors with PTSD and controls. However, a positive correlation was observed between gray matter volume in the left ventral mid-insula and the severity of childhood maltreatment. Given the positive findings across other traumatized samples, exploration of the relationship between PTSD related to interpersonal trauma and both white and gray matter volumes is warranted.

Functional Connectivity of the Insula in Female Interpersonal Trauma Survivors with PTSD

In a study of functional connectivity networks in a sample of female victims of physical or sexual assault, repeated exposure to a traumatic memory was associated with increased functional connectivity between the right amygdala and right anterior insular cortex (Cisler et al., 2014). The authors also reported increased functional connectivity between the left amygdala and right anterior insular cortex and between the medial prefrontal cortex and the right anterior insular cortex. More severe PTSD symptoms predicted increased functional connectivity between the right anterior insular cortex and related areas, suggesting enhanced network activation relates to PTSD. Cisler et al. (2014) concluded the right insular cortex is a particularly important neural mechanism underlying the fear extinction of traumatic memories.

Fonzo and colleagues (2010) found reduced functional connectivity between the left anterior insula and the dorsal anterior cingulate cortex (ACC), left amygdala, and dorsal left anterior insula seeds during a task requiring participants to match fearful versus target happy faces. Weaker associations were also found between the left and right mid-insula regions and the dorsal left anterior insula seed. Similar to results reported by Cisler and colleagues (2014), right posterior insula connectivity with the dorsal ACC was strengthened during this task (Fonzo et al., 2010). During a similar task of the processing of fearful and angry faces, a negative relationship was observed between childhood maltreatment severity and amygdala–insula connectivity in victims of IPV diagnosed with subsequent PTSD (Fonzo et al., 2012). Using a negative image anticipation paradigm, Simmons and colleagues (2008) reported significantly weaker connectivity between bilateral anterior and right anterior/middle insula and bilateral amygdala in females with PTSD related to IPV compared with controls. The authors suggest that the observed results indicate that amygdala–insula connectivity patterns in individuals with PTSD are task dependent.

More broadly, a recent study by Ross and colleagues (Ross, Lenow, Kilts, & Cisler 2018) suggests that PTSD (via the anterior insula network) is characterized by deficits in reinforcement learning for neutral/positive (i.e., nonfearful stimuli). In a sample of 15 women with PTSD as a result of assaultive violence, the investigators found weakened encoding of positive prediction errors (PE) during a general learning task compared with healthy controls. (Ross et al., 2018). They posited that impairments in PE encoding negatively impact multiple areas of functioning, including social learning and threat appraisal.

Mixed trauma of functional connectivity reveals similar results regarding the insula and related areas. For example, Sripada et al. (2012) found that male combat veterans with PTSD had higher connectivity between the right amygdala and right insula and between the left amygdala and right insula than a healthy combat-exposed control sample. Additionally, functional pathways including the insula have been implicated in relationships with dissociative symptoms (Lanius et al., 2005) and the recall of traumatic memories (Lanius et al., 2004).

Conclusions

The past decade has seen a significant increase in our understanding of the neurobiological mechanisms of PTSD. However, many gaps remain, including further elucidation of the etiology and neurobiology of PTSD within women. This is particularly important as women have a higher conditional risk of developing PTSD than men. Within the context of the neurocircuitry of PTSD, disruption of insula activity (higher or lower activation) is thought to be associated with several PTSD symptoms, including deficits in autobiographical memories and interoceptive cues. Moreover, recent findings of altered functional connectivity of insular subregions in women with PTSD suggest important neural mechanism impairments as well as possible pathways underlying the fear extinction of traumatic memories. Collectively, the findings provide a framework to guide the development of new targeted psychological or psychiatric interventions for this chronic and debilitating disorder.

Language and Literacy Development

Oral language development provides the foundation for later reading ability in grade school (Catts, 1993). The National Institute of Child Health and Human Development (NICHD) Early Child Care Research Network (2005) established that general language proficiency prior to kindergarten predicted reading skill in first grade. Additionally, this study found that first-grade vocabulary skills were positively related to reading in third grade (NICHD, 2005).

As Paul (2012) discusses, there is no longer a question of whether the quantity and quality of language input (nurture) or the biological capacity to learn and use language (nature) impacts language development. It is clear from the extant literature that both critically impact language development. Contemporary research is now focused on delineating the interdependence of biological and environmental factors that mediate language and literacy development, as well as key therapeutic targets to improve language and literacy skills, and ideally alter the developmental trajectories toward optimal performance.

Biological capacities for language and reading begin in the brain. Verbal and written language skills are supported by the perisylvian region of the language-dominant left cortex. However, brain regions responsible for decoding written form exist in both the left and right cerebral hemispheres, and these regions are located distal to areas that underlie core auditory language comprehension (Hickok, 2009). Decoding written words requires the transformation of visual linguistic input from an orthographic (the way a word looks) to a phonological (the way a word sounds) representation. This process is believed to occur bilaterally in the angular and supramarginal gyri in the posterior temporoparietal region. Hemisphere differences exist for orthographic decoding. The right hemisphere is more sensitive to the orthographic features of printed words and considers each grapheme individually, whereas the left hemisphere is able to process unified

whole words that are greater than the sum of their parts (Chiarello, 1988). Both hemispheres complement each other and work in parallel when decoding familiar and unfamiliar words, described by Coltheart, Curtis, Atkins, and Haller (1993) as a dual-route model. Another example of reading specificity in the brain is the visual word form area (VWFA) within the lateral occipitotemporal sulcus. Cohen, Dehaene, Naccache, and Leherily (2000) used functional magnetic resonance imaging (fMRI) along with event-related potentials (ERPs) to characterize the spatial and temporal organization of reading. The VWFA selectively responded to written words relative to line drawings (Cohen et al., 2000). Early controversy existed as to whether the VWFA was solely and uniquely involved in word comprehension because the emergence of written language was too recent and utilized by too few within the total human population to have affected the evolution of the human genome. However, the contemporary hypothesis suggests that reading acquisition engages brain regions that evolved for face and object recognition through a process of neuronal recycling (Dehaene & Cohen, 2007). Therefore, neuronal recycling requires experience, which some argue must occur at specific time periods.

Additionally, later language and reading abilities are influenced by the early development of the brain. During this dynamic time, there are critical periods in which the child's nervous system is particularly impacted by environmental input (Purves et al., 2001). For instance, neuroimaging studies have reported that early literacy experience has a significant influence on the pruning and strengthening of cells and connections within the brain (Castro-Caldas, Petersson, Reis, Stone-Elander, & Ingvar, 1998).

Alarmingly, less tangible factors can have detrimental effects on the developing brain. For example, language and reading disorders are associated with alterations in brain anatomy and genetic factors. Using magnetic resonance imaging (MRI), De Fosse et al. (2004) found that boys with autism spectrum disorder (a disorder often accompanied with language deficits) and boys with a specific language impairment (SLI) exhibited atypical patterns of asymmetry of the language cortex. In other words, the language dominant area of the brain was found to be in the right hemisphere of the boys rather than the left hemisphere. Additionally, differences in cortical mass in left hemisphere regions and anomalous gyral and sulcal folding patterns have been observed in individuals with developmental dyslexia (Brown et al., 2001). Functional neuroimaging studies of children and teenagers with dyslexia reveal decreased activity in the left occipitotemporal region and increased activity in right hemisphere homologues (Shaywitz et al., 2002).

Studies dating back almost two decades established a heritable component to reading difficulties (Stevenson, Graham, Fredman, & Mcloughlin, 1987). In this 1987 study, correlations among identical and fraternal twins were assessed, and genetics were found to contribute moderately to reading ability, after controlling for intelligence. A more recent study of identical and fraternal twin pairs found supporting evidence that genetics have an influence on reading deficits (Astrom, Wadsworth, Olson, Willcutt, & DeFries, 2012). Though research has discovered regions on chromosomes 1, 3, 6, 15, and 18 that possess multiple candidate genes implicated in individual reading differences, including reading disorders such as dyslexia (Schulte-Körne et al., 2007), the studies are complex with results that are not universally replicated. For instance, one of these candidate genes, KIAA0319 (chromosome 6), has been correlated with dyslexia susceptibility as well as multiple reading-related traits in some studies, but in another study, the association between KIAA0319 and dyslexia was not found (Dennis et al., 2009). While these findings suggest that there are genetic and biological factors associated with language and literacy abilities, more research must be completed before assuming causal relationships.

While these etiological studies highlight genetic and neurobiological factors in language and literacy development, except in the most extreme cases of intellectual disability, anyone can be taught to read. There are important reading components that have either genetic or environmental contributions to variance in reading ability, such as word recognition and oral language.

For instance, many people with reading disabilities have poor phonological processing ability, which is found to be highly heritable, while they may also struggle with the spelling of words, which is not significantly heritable (Olson, Wise, Conners, Rack, & Fulker, 1989). Based on research, interventions can be tailored to meet the needs of individuals with different learning abilities. The importance of social guidance in shaping children's development, as supported by Vygotsky's sociocultural theory (1978), is the focus of many investigations by researchers interested in language and overall cognitive development. According to Vygotsky (1978) adult–child interactions provide social and cultural guidance that supports the development of children's cognitive skills. Through parent–child interactions, children learn the behaviors and norms of their culture, including speech and language patterns, as well as any other symbolic knowledge necessary for reading.

Important Home Literacy Practices

Early reading attitudes, knowledge, and abilities, also known as emergent literacy skills (Teale & Sulzby, 1986), are vital for later language and reading competence (Senechal & LeFevre, 2002; Storch & Whitehurst, 2002). Teale and Sulzby (1986) established that the critical time for the development of language and emergent literacy skills occurs during the preschool years. Because children spend much of their time at home during their preschool years, several studies have found that there is a relationship between the home literacy environment and children's later language and literacy skills (Forget-Dubois et al., 2009; Senechal & LeFevre, 2002).

A number of different home literacy practices are capable of improving language and literacy skills. One of the most important factors in language and literacy outcomes is the quantity and quality of language input (Hart & Risley, 1995; Hoff, 2013). Hart and Risley (1995) studied the language input based on socioeconomic status (SES) and found that children living in poverty heard an estimated thirty million fewer words by age four than their higher-SES peers. Hoff (2013) found that higher-SES mothers provided longer, more complex utterances and asked more open-ended questions. The children who were exposed to more quality language had higher outcomes on language assessments.

Book reading is also strongly correlated with overall literacy (Dickinson & DeTemple, 1998; Frijters, Barron, & Brunello, 2000). The frequency of shared reading time at home corresponds to higher vocabularies and stronger literacy skills in preschool and primary school (Raikes et al., 2006). Importantly, the interactive style and quality of parental practices during shared reading time predicts literacy outcomes. For example, shared reading involving eliciting abstract language, adding information, and asking open-ended questions about material read predicts stronger language development (Whitehurst et al., 1994). Maternal sensitivity and responsiveness is also critical as supportive maternal behavior was the strongest single predictor of language and pre-academic skills when entering kindergarten (Landry, Smith, Swank, & Miller-Loncar, 2000).

Critical Components of Quality Reading Instruction

Not surprisingly, academic curriculum plays a significant role in language and literacy development. During the emergent literacy stage, it is essential that preschool literacy instruction includes phonological awareness, print concepts, alphabet knowledge, and literate language ability (Justice & Kaderavek, 2004). *Phonological awareness* refers to knowledge of syllables and rhyme, as well as the ability to blend and segment sounds within words. Knowledge of *print concepts* is the understanding of how to hold books, how to turn the pages, left-to-right reading progression, awareness of words and letters on the page, etc. *Alphabet knowledge* is knowing the names and sounds of letters and that the sounds make up words. *Literate language* is the understanding of abstract language and awareness of narrative language.

The critical components of literacy in elementary school include phonemic awareness, phonics, reading fluency, vocabulary, and comprehension (National Reading Panel, 2000). *Phonemic awareness* refers to the ability to manipulate phonemes in spoken syllables and words (i.e., what word would you have if you changed the /t/ in cat to a /p/?). *Phonics* is the ability to understand and apply letter-sound correspondence for the purposes of reading and spelling. These lower-level processes are represented in the dual-route processing model, which states that a reader can pronounce a word aloud by following letter-sound correspondence rules starting from left to right of the letter string (i.e., hit is /h/ /I/ /t/), or the individual recognizes the word and provides the correct pronunciation instantaneously (Coltheart et al., 1993). An individual is able to read more fluently with the latter route and with words that they encounter frequently. *Vocabulary* is word knowledge or the ability to understand the words that have been correctly decoded. *Fluency* is the ability to read orally with speed, accuracy, and proper expression. Lastly, *comprehension* is the capacity to synthesize and understand new information in relation to prior experiences. There are many additional factors that are important in regard to reading comprehension, such as working memory capacity, inferencing ability, comprehension monitoring, and executive function (Cutting, Materek, Cole, Levine, & Mahone, 2009). Quality literacy instruction includes teaching all five main components because each of these five skills are interconnected such that a weakness in any element affects reading ability as a whole.

Scarborough (2003) described this interdependence of individual factors as a "reading rope" in which skilled reading results from the integration of background knowledge, vocabulary, language structures, verbal reasoning, and literacy knowledge. When combined with phonological awareness, decoding, and sight recognition, the individual strands or skills result is skilled reading (Paul, 2012).

Conclusion

Overall, language and literacy development are deeply related in a bidirectional manner (Light & McNaughton, 2009). Due to decades of research, it is well understood that genetics plays a significant role in the variation of reading abilities among people and contributes to the risk of developing a reading disorder. Fortunately, genes are not the only contributors of language and literacy development. Children who receive more opportunities for quality language interactions and who receive comprehensive literacy instruction targeting phonemic awareness, phonics, fluency, vocabulary, and comprehension achieve the greatest language and literacy proficiency (National Reading Panel, 2000). Research will continue to investigate the influence gene expression, neurobiology, and environment has on language and literacy development so that interventionists can monitor and support the language and literacy skills of all children.

The Neuroscience of Well-Being: Part 2 (Potential Neural Networks)

Justine Megan Gatt

Neuroscience Research Australia, Sydney, NSW, Australia
School of Psychology, University of New South Wales, Sydney, NSW, Australia

Introduction

Part 1 of this chapter series summarized the various ways mental well-being has been conceptualized and measured to date, spanning the hedonic, eudaimonic, and composite well-being perspectives. As discussed, research to date has mostly focused on defining the best ways to measure well-being at the phenotypic level and its role in psychological health. In contrast, knowledge of the neuroscience mechanisms that underpin well-being is still relatively lacking. In the current chapter, the core neural networks of threat, reward, and executive control and their role in mental well-being will be discussed. Some evidence supporting these neural networks in mental well-being is reviewed, and future developments for this work are highlighted.

Potential Neural Networks of Mental Well-Being

Emotional and/or cognitive function are typically impaired in major mental disorders such as major depression and anxiety disorder (Williams, 2016a), and it is neural networks such as threat, reward, and executive control (both attention and cognitive control) that underscore some of the core processes of emotional and cognitive function (Williams, 2016b). These networks are therefore likely to be central to resilience to adversity (Berridge & Kringelbach, 2011; Feder, Nestler, & Charney, 2009), motivated goal-directed behavior (Ernst & Fudge, 2009), and mental well-being. Patterns of network activation are usually measured not only during the presentation of a specific task known to activate the regions of interest but also at rest in the absence of a task to measure "default mode" function (Greicius, Krasnow, Reiss, &

The Wiley Encyclopedia of Health Psychology: Volume 1: Biological Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editor: Robert H. Paul.

Menon, 2003). It is also sometimes used as an alternative indicator of neural activity because it minimizes the typical limits in methodology that are sometimes associated with task-activated paradigms (e.g., poor signal-to-noise ratio, practice effects, and habituation) (Greicius, 2008). Changes in these networks can be identified physiologically using tools such as functional magnetic resonance imaging (fMRI) and electroencephalography (EEG), each tapping into different spatial and temporal network properties, or behaviorally using neurocognitive performance tasks (Williams et al., 2008).

A breakdown in the structure and interactivity of one or more of these networks can lead to the onset of different psychiatric syndromes. For instance, patients with disorders like post-traumatic stress disorder and major depression have shown a cognitive bias toward stimuli that are negative and threatening over stimuli that are positive and rewarding (Williams, 2016a). Whereas patients with pleasure-seeking disorders such as dependent drug use and compulsive disorders have demonstrated a bias toward stimuli that are pleasurable, combined with a lack of inhibitory behavioral control (Berridge & Kringelbach, 2011; Feder et al., 2009). Changes in neural activation have also been found at rest in different psychiatric disorders including depression, anxiety disorders, and schizophrenia (Fox & Greicius, 2010; Williams, 2016a). It could therefore be hypothesized that individuals who are flourishing will demonstrate patterns of neural activation contrary to patients with mood or anxiety disorders. It could also be predicted that an optimal state of well-being would be associated with neural activity that is demonstrative of a bias in attention toward seeking reward over avoiding threat, in combination with superior executive control.

Threat

Humans and animals have an innate automatic survival instinct to detect threat in their environment. The experience of a potential threat triggers a cascade of neurophysiological changes commonly known as the "fight-or-flight" response. In the fight-or-flight state, the sensory cortex signals the amygdala (the emotional processing center), which then signals the hypothalamic–pituitary–adrenal (HPA) axis. These signals facilitate the response to stress. Following this feedforward response, reentrant feedback is then sent from the higher cortical areas, like the prefrontal cortex (PFC) and the hippocampus, to appraise the threat and then respond. The physiological response to the threat cue is determined by the interplay of the HPA with the autonomic nervous system (ANS) and its sympathetic and parasympathetic nervous system responses. The sympathetic nervous system triggers the fight-or-flight response, which includes the release of corticotropin-releasing hormone (CRH), adrenocorticotropic hormone (ACTH), and cortisol. The consequent circulation of epinephrine through the bloodstream then triggers other physiological effects like an increase in heart rate, blood pressure, and blood glucose for the production of energy. Once the perceived threat is removed, the parasympathetic system is engaged via the vagus nerve of the nucleus ambiguus (which modulates heart rate oscillations, as measured by heart rate variability), thereby easing the effects of sympathetic activity and returning the body to a calm homeostatic state (Thayer & Lane, 2000).

Stimuli of emotional expressions are frequently used in laboratories to measure a response to threat, particularly a fearful face relative to a neutral or happy face (Williams, Palmer, Liddell, Song, & Gordon, 2006). In stress-related disorders, fear triggers an accentuated neural circuit for threat that involves key projections of the amygdala to the medial prefrontal cortex (MPFC) (Morris et al., 1996). Patients with lesions or damage to the amygdala show specific impairments in recognizing fearful facial expressions (Broks et al., 1998). Studies in clinical cohorts of anxiety disorder patients also show that fear, more than any other emotion, activates the amygdala (Morris et al., 1996), particularly to masked (or nonconscious) rather than unmasked (or conscious) fear stimuli (P. J. Whalen et al., 1998) and also to other forms of stimuli like an unpleasant picture versus a neutral or pleasant one (Irwin et al., 1996). In animal lesion studies, the amygdala is only activated when new aversive learning is acquired but not in later stages of fear processing or behavioral expressions of anxiety (Kalin & Shelton, 2000).

Negative mood states also asymmetrically activate the PFC. Negative affect or anxiety, induced by film, increases activation in the right side of the prefrontal and anterior temporal regions (Davidson, Marshall, Tomarken, & Henriques, 2000), particularly in the right inferior PFC and right medial orbital prefrontal cortex (OFC) (Rauch, Savage, Alpert, Fischman, & Jenike, 1997). Positron emission tomography (PET) studies of glucose metabolism during evoked affective paradigms show right-sided increases in metabolic rate in anterior orbital, inferior frontal, middle, and superior frontal gyri during induced negative affect (Sutton et al., 1997). These patterns of asymmetry have been shown in clinical patients to phobic stimuli with increased activation in the right inferior PFC and right medial OFC (Rauch et al., 1997) and in patients with bilateral lesions of the ventromedial PFC (VMPFC) who found it difficult to anticipate future negative (or positive) consequences but not immediate punishment or reward (Bechara, Damasio, Damasio, & Anderson, 1994). Asymmetry may also assist an emotional response because individuals with greater left-sided prefrontal activity show greater recovery after the offset of a stimulus that is negative (Larson, Sutton, & Davidson, 1998).

Together, these findings highlight the role of the fight-or-flight response for basic survival and how it can be accentuated toward increased acute and/or chronic stress in patients with psychiatric disorders. Neuroimaging studies need to examine the same relationships in individuals who have varied levels of mental well-being. To better understand how the threat network functions in the flourishing well-being state, we need to investigate the changes in the structural regions of the brain, how those regions may function differently, and also how they may connect differently in interaction with each other. Future studies could also examine whether these differences are more focal to a specific region (e.g., sensory cortex alone) or whether it is the magnitude of activation to the stressor or threat response recovery time rather than overt activation that differentiates levels of well-being separate from levels of risk (Schuyler et al., 2014).

Reward

Reward, like food and social relationships, is also necessary for survival because it induces learning. Moreover, the prospect of reward also induces goal-directed behaviors to achieve the reward and experience subjective well-being and pleasure. The presence of reward encourages more frequent and intense behaviors, and the absence of reward can lead to behavioral extinction (Schultz, 2000). At the neural level, reward is processed by dopamine neurons of the ventral tegmental area (VTA) and the substantia nigra. The VTA projects to the nucleus accumbens (NAc) (of the basal ganglia) through to the amygdala and hippocampus. The VTA also projects to the dorsal and ventral PFC via the mesolimbic pathway, whereas the substantia nigra projects to the caudate and putamen via the nigrostriatal pathway (McClure, York, & Montague, 2004).

A number of neuroimaging studies have started to examine associations between well-being and the reward system. For instance, sustained engagement toward positive images in the striatum and right dorsolateral prefrontal cortex (DLPFC) is positively associated with mental well-being, whereas aggregate striatal activity over the scan session (how fMRI is normally coded) was not (Heller et al., 2013). Both psychological and subjective well-being independently predict sustained striatal activity, but when combined into the same model, only psychological well-being predicted sustained activity. Individuals with greater sustained striatal activity also had lower daily cortisol output. These same patterns were also found for the DLPFC. Together, sustained activity in the striatum and DLPFC has been shown to account for 29% of the variance in well-being. The striatum helps to anticipate and process learning associated with reward and reinforcement (Haber & Knutson, 2010).

Many studies have also observed that positive mood states asymmetrically activate the PFC. For instance, left-sided electrical brain activity in the prefrontal and anterior temporal regions is increased by reward or positive effect induced by film across EEG and fMRI methods (Davidson, Jackson, & Kalin, 2000; Tomarken, Davidson, Wheeler, & Kinney, 1992). Reward also activates the left dorsolateral prefrontal (DLPFC) and medial orbitofrontal (OFC) regions when examined in EEG studies using source-localization LORETA techniques—specifically within the alpha 2 sub-band (10.5–12 Hz) (Pizzagalli, Sherwood, Henriques, & Davidson, 2005). Some studies indicate that activity in the OFC reflects the amount of reward, whereas other studies indicate that activity in the DLPFC shows the amount of reward and the consequent response in behavior (Wallis & Miller, 2003). Neural connectivity between these regions may channel behavior because OFC activation has been found to peak at 80 ms prior to DLPFC activation (Pizzagalli et al., 2005). Moreover, during the inducement of positive affect, metabolic increases in left-sided pre- and postcentral gyri have been confirmed by PET studies of glucose metabolism evoked during affective paradigms (Sutton et al., 1997). These compelling patterns of asymmetry have also been confirmed in association with self-report measures of psychological and subjective well-being in healthy older adults (Urry et al., 2004). It is predicted that these patterns of asymmetry reflect how the PFC is integral to the organization of emotional behavior (Levenson, 1994) and affective working memory (Watanabe, 1996). Even nonhuman primates with left-sided prefrontal activation show lower levels of cortisol and CRH levels over time, compared with animals with higher right-sided activation (Kalin, Shelton, & Davidson, 2000).

One possible mechanism for the effects on asymmetry is the inhibitory pathway of the MPFC to the amygdala, demonstrated in both rat extinction studies (Morgan, Romanski, & LeDoux, 1993) and human metabolic studies (Abercrombie et al., 1996). Subjects with increased left prefrontal activity may possess greater inhibitory control over the amygdala when exposed to different emotional stimuli (Davidson, Jackson, et al., 2000). However, some studies failed to produce these effects (Murphy, Nimmo-Smith, & Lawrence, 2003). It is possible however that the motivational context of the stimuli may impact the effects as positive stimuli with stronger emotive tendencies (e.g., pictures of desserts) show greater left frontal activation when compared with affective pictures, which did not always cause significant shifts in cortical activity (Harmon-Jones & Gable, 2009). Moreover, other studies suggest that the affective component is not central to determine activity in asymmetry but that it is how the subject is motivated that distinguishes this activity. "Approach motivation" (typically measured using stimuli that display or induce positive affect or anger) is associated with greater left frontal cortical activity, whereas "withdrawal motivation" (fear stimuli) is associated with greater right frontal activity (Harmon-Jones, Gable, & Peterson, 2010).

Within the limbic region, studies suggest associations between reward processing and activity within the amygdala and posterior cingulate cortex (PCC). In particular, the amygdala has been shown to respond to stimuli that are appetitive as well as stimuli that are threatening (Hamann, Ely, Hoffman, & Kilts, 2002). Asymmetrical patterns in the amygdala may affect responses to stimuli that are positive; increased activity in the right amygdala may be specific to stimuli that are unpleasant or to the removal of a reward (such as losing money), whereas increased activity in the left amygdala occurs with the attainment of reward (winning money) (Zalla et al., 2000). Studies using event-related potentials (ERPs) also highlight the role of the PCC in positive affect. When individuals were shown pleasant and unpleasant pictures of varied intensity, individuals with high extraversion (associated with optimism and high subjective well-being) reacted more to pleasant pictures regardless of emotional intensity and were more resilient to mildly unpleasant pictures compared with individuals with low extraversion (Yuan et al., 2012). Source modeling suggests that this enhanced brain sensitivity to pleasant events and resistance to the impact of unpleasant events are generated by the bilateral PCC (Yuan et al., 2012), which, together with their collected regions (including fusiform gyrus, amygdala, and basal ganglia), are critical to regulate positive emotion (Amin, Constable, & Canli, 2004).

Physiological responses are also fundamental to the reward network, like the acceleration of the heart through the ANS, which is normally heightened with affect intensity but is not necessarily emotion specific (Watson, Wiese, Vaidya, & Tellegen, 1999). For instance, in some studies, increases in positive affect were associated with reduced ambulatory heart rate over the day (Steptoe, Wardle, & Marmot, 2005). In contrast, other studies reported increased cardiovascular function (higher heart rate and blood pressure) with increased positive affect (Schwartz, Warren, & Pickering, 1994), but this may be due to physical activation caused by interpersonal interactions or a greater engagement with challenge (Maier, Waldstein, & Synowski, 2003). Other studies have suggested an "undoing hypothesis": that positive emotions may speed the recovery from cardiovascular reactivity caused by negative emotions, thereby returning the body to a normal level of activation (Fredrickson, Mancuso, Braniqan, & Tugade, 2000). In these experimental studies, Fredrickson showed that participants who viewed clips of positive emotion following a clip of fear had the fastest cardiovascular recovery compared with those who were showed neutral or sad clips (Fredrickson & Levenson, 1998). Fredrickson and her colleagues interpreted this effect according to their ***broaden-and-build theory***, which states that positive emotions broaden one's "thought–action repertoire." A thought–action repertoire describes acts that are triggered by specific thoughts or emotions. For example, joy creates the urge to play, whereas fear creates the urge to escape (Fredrickson, 2004). Therefore, positive emotions may help to move one from a thought–action repertoire that is narrow and triggered by emotions that are negative, quick, and direct and encourage escape, attack, or expel toward a thought–action repertoire that is broader and expands the scope of one's tendencies to act. These broader thought–action repertoires could be used to explore, engage in novel experiences, promote self-growth, and expand mechanisms that can help one to cope with stress. Therefore, positive mindsets are thought to possess long-term benefits because they can develop personal resources that are adaptive and resilient (Fredrickson, 2004).

In summary, these findings highlight the importance of reward to survival because it encourages learning and induces behaviors that are goal directed to attain (or maintain) higher levels of well-being and pleasure. Evidence from neuroimaging and EEG studies has started to support the role of reward in well-being. This evidence is in stark contrast to the lack of studies that examine the relationship between well-being and threat. Evidence suggests several key regions in the reward network may be associated with increased flourishing. These include increases in striatal and DLPFC activity in response to reward, as well as asymmetric activation of the left PFC (in particular the DLPFC and OFC), both of which are associated with increased well-being. The relationship between well-being and patterns in asymmetric left PFC activation may reflect an increased inhibitory control over the amygdala when subjected to different emotions. If this is true, we may predict that individuals with elevated well-being would also possess similar levels of inhibitory control over the amygdala when exposed to threat. The autonomic evidence similarly suggests that the impact of positive emotions on cardiovascular recovery times is modulated following threat exposure. Future neuroscience studies should explore associations between mental well-being and both reward and threat networks to assess their differences and how they may interact.

Executive Control

Executive control is a broad term used to outline the core functions of working memory, response inhibition, and set shifting (Friedman et al., 2008). Executive control, also called the central executive network (CEN), coordinates mental activity to achieve goals and to focus attention on tasks. In contrast, when the brain is at rest and not focused on a task (e.g., when relaxing on a beach), the mind-wandering or "default mode" network (DMN) is activated (Raichle et al., 2001). The circuits central to executive control include activity in the ventral and lateral prefrontal cortex (VLPFC and DLPFC), the inferior parietal cortex to tasks that are inhibitory or require sustained attention (e.g., the go/no-go or n-back working memory tasks), and reduce activation of the motor cortex to enable motor response control (Kelly et al., 2004).

The executive control network also processes and regulates emotion and often involves the same regions with overlapping functions. For instance, the DLPFC is used for attention (Corbetta, Patel, & Shulman, 2008) and working memory (Owen, McMillan, Laird, & Bullmore, 2005) and for regulating emotion (Kalisch, 2009). Various regions of the ACC are thought to respond differently to cues that involve cognition versus emotion. For example, the dorsal ACC is activated more during cognitive processing and top-down/bottom-up connections to the PFC (measured with the classical Stroop), whereas the ventral ACC and amygdala–hypothalamic circuits are activated more during emotional cognitive tasks (i.e., the emotional Stroop) (P. Whalen et al., 1998). The hippocampus regulates context, in particular memory that is declarative and context dependent (Davidson, 2000). Loss in the hippocampus is frequently reported in patients with anxiety or depressive disorder (Bremner et al., 2000), and the impact of this hippocampal loss is thought to affect contextual learning and memory where otherwise "normal" emotional responses are activated in inappropriate contexts. Another key region involved in higher-order regulation is the insula. The insula has been observed in functions involving higher-level cognitive control and attention, including a regulatory role in emotional and empathic processes (Menon & Uddin, 2010). The insula's sensitivity to salient events (together with the ACC) suggests that these regions are a "neural switchboard" switching between the default and the executive control modes to access attention and memory and guide behavior (Menon & Uddin, 2010). In wellness studies, positive correlations have been reported between the right insula and purpose in life, positive relations, and personal growth in a cross-sectional cohort of healthy participants (Lewis, Kanai, Rees, & Bates, 2013). Other studies have also associated the right insula with self-awareness (Craig, 2009), regulation of bodily states (Singer, Critchley, & Preuschoff, 2009), and agentic control (Lee & Reeve, 2012). However, many of these studies are correlational. Therefore, to predict outcomes in well-being over time, future studies need to investigate how different regions activate and respond during tasks that involve emotional and executive control.

Studying how cognition interacts with emotion may also help us to understand the links between executive control, threat, and reward. Generally speaking, we may anticipate that people who are in a happy and relaxed mood would demonstrate better cognitive performance than someone who is angry or sad. Fredrickson's (Fredrickson, 2001) broaden-and-build theory suggests that positive emotions broaden an individual's thought–action repertoires and expand personal resources like cognitive functioning (e.g., executive control, knowledge) and psychological resources (e.g., resilience, creativity), which may lead to more enduring states of well-being. These newly expanded resources can then be drawn on later in times of coping or other cognitive challenges. The broaden hypothesis has been supported in studies that induce positive affect because positive emotions broaden the scope of attention and the size of the thought–action repertoire relative to a neutral state (Fredrickson & Branigan, 2005). Positive emotions are associated with cognitive processes that are more creative, flexible, and expansive (Murray, Sujan, Hirt, & Sujan, 1990) and increase the preference for varied behavioral responses (Kahn & Isen, 1993). Positive emotions also improve persuasive communication at different stages of memory processing: at encoding, participants in a positive mood simplify their message and are persuaded equally by both weak and strong arguments, and at retrieval, participants in a positive mood use more simplified processing strategies by drawing on global rather than detailed evaluations of the message to assess validity (Bless, Mackie, & Schwarz, 1992). Positive affect facilitates cognitive flexibility toward specific tasks such as word association (Isen, Johnson, Mertz, & Robinson, 1985), word fluency (Green & Noice, 1988), and specific problem solving (Ashby, Isen, & Turken, 1999). Usually, increased cognitive flexibility is only detected when the situation is neutral or positive in emotional content or is minimally engaging (Ashby et al., 1999). Furthermore, the presence of positive affect can help a person to cope with negative events because defensive behaviors are reduced (Aspinwall, 1998). Because these studies have used positive affect that is low in approach motivation, it is also important to consider the role of cues that trigger approach motivation such as reproduction, social attachment, and the ingestion of food and water. In contrast, breadth of attention is reduced in an individual with positive affect and high approach motivation because of their attempt to achieve the desired goal (Gable & Harmon-Jones, 2008).

Future Developments

In summary, this chapter has discussed how the three networks of threat, reward, and executive control may interact to influence well-being. Neuroimaging studies of well-being have started to emerge, most particularly for circuits of reward and for specific measures of subjective well-being. Few studies have considered the direct links between well-being and the circuits of threat or executive control. For threat, we predict that the response to stimuli that are negative would attenuate. Similarly for executive control, we predict that increased well-being would be associated with more superior executive control processes that include working memory, response inhibition, and set shifting. Furthermore, we predict that elevated executive control would also make an integrative impact on the processing of emotion for threat and reward. Future neuroscience studies need to examine both the structural morphology of different brain regions using different imaging techniques (e.g., MRI, DTI) and how well different regions of the brain and their connections function during both task-activated and resting paradigms. For a complete and composite view of both structure and function, a combination of functional imaging and electrophysiological techniques (i.e., fMRI and EEG) may also help to combine high spatial resolution with high temporal resolution.

In addition to more comprehensive neuroimaging assessments, future studies also need to incorporate phenotypic assessments of well-being that encompass both subjective and psychological aspects of well-being. The COMPAS-W well-being scale (Gatt, Burton, Schofield, Bryant, & Williams, 2014) is one such example that could be used in future studies as an all-inclusive index of well-being. This same measure could also be used in studies of *resilience* whereby the trajectory of well-being scores and mental health over time could be tracked in individuals exposed to a childhood or adult trauma or adversity (e.g., the experience of neglect, abuse, war, natural disasters, personal illness or injury, and other major life events). Resilience defines the process of adaptive recovery from adversity and the ability to maintain optimal levels of well-being in the face of dynamic challenges to psychological resources (APA, 2010). Therefore, while mental well-being defines a state of positive mental health, resilience defines the process of returning to that state following adversity or trauma exposure. In this sense, we could predict that some of the same neural and biological mechanisms that underpin well-being may also contribute to resilience. This does not however necessarily implicate that someone who is flourishing at any given point in time would also be resilient should they be exposed to serious adversity; to demonstrate resilience would necessitate the presence of additional factors that buffer against the trauma (e.g., genetic, environmental, or other socio-ecological factors). The characterization of such predictive factors of resilience is still yet to be determined (see Alexander and Gatt, In Press for further discussion).

Many of the well-being (or resilience) studies to date are cross-sectional and/or correlational, which limits interpretation in terms of cause and effect. Longitudinal and experimental studies are required to better understand these underlying networks. For instance, causality could be more easily established in studies that consider whether interventions that improve executive function or other functions (albeit, via behavioral or cognitive training or neurofeedback strategies) also promote increased well-being and resilience. The first step however is to understand the neural mechanisms of well-being in order to develop strategies that optimize these features. Should evidence support the elementary networks of threat, reward, and executive control in well-being, then it may be arguable that interventions would need to promote adaptive responses to threat and perceived stress, a positive outlook, autonomy, higher-order cognitive capacities to master the regulation of emotion and behavior, and the ability to set goals and strive. When viewed as a whole, these strengths contribute to an overall sense of subjective and psychological well-being (Gatt et al., 2014). This framework also complements Fredrickson's "broaden-and-build" theory that similarly suggests that "…positive emotions broaden individuals' thought-action repertoires, enabling them to draw flexibly on higher-level connections and wide-than-usual ranges of precepts, ideas, and action urges; broadened cognition in turn creates behavioral flexibility that over time builds personal resources, such as mindfulness, resilience, social closeness, and even physical health" (p. 3) (Garland et al., 2010). When mapping the trajectory of mental health outcomes in response to such health promotion strategies, or simply over time, it is important to keep in mind the modulating influence of basic demographic variables such as age and sex. The outcome of such studies can then help shape the types of interventions that will promote well-being and resilience and the specific individuals to target, particularly in more vulnerable cohorts such as children and adolescents.

Conclusion

Understanding mental well-being is paramount to psychological and psychiatric research and mental health promotion in the general population. Much work is needed to understand the neurobiological mechanisms of well-being so that these essential qualities can be promoted in mental health programs in children and adults alike. This chapter has provided an outline of possible neural networks involved in well-being and some evidence to date, as well as possible future developments to aid progress in mental health and mental illness research, policy, and treatment.

Early Life Stress

Introduction

Early life, defined here as postnatal life from birth through adolescence, is a developmental period during which individuals are especially sensitive to the biological effects of stress (Lupien, McEwen, Gunnar, & Heim, 2009; though prenatal stress also appears to exert profound influence on health outcomes in offspring, this topic is beyond the scope of this chapter). There is strong evidence that environmental input during early life can program physical, cognitive, and emotional traits to be optimally adaptive for survival and reproduction in that environment (Bock, Rether, Groger, Xie, & Braun, 2014; Nederhof & Schmidt, 2012). Severe early life stress, including famine or war, child abuse and/or neglect, poverty, or exposure to family conflict and violence, has been repeatedly associated with negative cognitive, emotional, and physical health outcomes (Brown, Susser, Lin, Neugebauer, & Gorman, 1995; Eriksson, Räikkönen, & Eriksson, 2014; Kaplan et al., 2001). These adverse experiences appear to lead to changes in the body and brain that can be adaptive in a harsh and traumatic environment. However, these adaptions can increase risk for developing a range of psychiatric disorders and social adjustment problems later in life (Heim & Nemeroff, 2001). The focus of this article is the mechanisms through which early life stress influences neural development and in turn behavioral and psychological outcomes.

Classifying Types of Early Life Stress

The term “stress” has been used to describe different concepts, including both environmental events and individuals’ physical and psychological responses to these events. Here, we define stress as activation of bodily and neural systems that respond to potential threats in the environment. We define a “stressor” as “any unpredictable or uncontrollable stimulus that could—potentially—pose a threat to the organism” (Levine & Ursin, 1991). In early childhood, many of the most salient stressors are those that disrupt the attachment bond between a child and

his/her caregiver(s). The establishment and maintenance of an emotional bond between an infant and its mother or parents is believed to "program" emotional and social development throughout the lifespan (Ainsworth, 1962; Bowlby & King, 2004). Adverse experiences that can disrupt this bond include separation from caregivers, neglect, parental psychopathology, and various forms of abuse.

Early life stress has traditionally been characterized in terms of allostatic load, the cost of repeated biological responses to chronic stress exposure (McEwen, 2012) or cumulative risk models, the combination of risks posed by aggregate exposure to multiple stressors (Evans, Li, & Whipple, 2013). These models consider an individual's global exposure to multiple stressors in predicting risk for negative physical or psychological health outcomes. For example, a child who was abused and had an incarcerated parent would be at higher risk than a child who was abused but was not exposed to additional stressors. More recently, some researchers have advocated that subtypes of early life stressors should be categorized in terms of the presence of harmful input, such as caregiver abuse or exposure to violence, and inadequate input, such as caregiver neglect, separation from caregivers, or scarcity of resources (Humphreys & Zeanah, 2015). Subtypes of early life stressors have similarly been characterized in terms of threat or deprivation (McLaughlin & Sheridan, 2016; Pollak, Cicchetti, Homung, & Reed, 2000). In these models, a neglected child has been exposed to qualitatively different types of stressors than a child who has been abused, and we would expect divergent outcomes between the two. However, exposure to multiple subtypes of early life stressors is common (Vachon, Krueger, Rogosch, & Cicchetti, 2015). Although there is some preliminary evidence that these subtypes of stressors may be associated with different neural and behavioral outcomes (Dennison et al., 2017), this is a relatively new idea, and consequently current scientific understanding of these differential pathways is limited.

In terms of human development, more is known about effects of deprivation-related stressors than threat-related stressors. Many of the seminal human studies on neurobehavioral effects of early life stress have stemmed from the Bucharest Early Intervention Project (Zeanah et al., 2003), a randomized controlled trial conducted between 2000 and 2005 that compared foster care as an alternative with institutional care for young Romanian children. In this project, half of a group of 136 children were randomly assigned to high-quality foster care and the other half to remain in institutional care. Children in the intervention group were adopted into foster care between 6 and 31 months of age, and all children were seen for follow-up assessments several times throughout childhood. Findings thus far indicate that early institutionalization leads to profound deficits in many domains of functioning, including cognitive and socioemotional development, brain structure and function, and an elevated incidence of psychological impairment. Children randomized to foster care showed reliably better outcomes in each of these areas than those who remained in institutional care (Nelson et al., 2007). In addition, children who remained in institutional care showed blunted physiological responses to psychosocial stressors compared with children randomized to foster care and to community controls (McLaughlin et al., 2015). As a whole, findings from this project have been interpreted to suggest that the deprivation of a consistent attachment figure in infancy and early childhood is a significant stressor that impairs the optimal development of systems that promote physical and psychological health.

Other forms of early life deprivation, such as caregiver neglect, poverty, and food insecurity, also appear to adversely influence development. Caregiver neglect, defined as a failure to meet children's basic physical needs with respect to clothing, hygiene, food, and/or safety (Leeb, Paulozzi, Melanson, Simon, & Arias, 2008), is one of the most common forms of child maltreatment; it is estimated that 20% of children worldwide experience neglect (World Health

Organization, 2002). Neglect can be similar to institutionalization, in that children who experience severe neglect lack a caregiver that reliably responds to their needs (Bruce, Gunnar, Pears, & Fisher, 2013). Often, these children are placed into foster care families. Also like children who were institutionalized, individuals with a documented history of neglect show dysregulated stress hormone levels (Fisher, Stoolmiller, Gunnar, & Burraston, 2007), as well as deficits in higher-level cognitive function. Poverty is another deprivation-related stressor that has been associated with adverse outcomes in terms of brain development (Brito & Noble, 2014), language development and higher-level cognition (Noble, McCandliss, & Farah, 2007), academic achievement (Hair, Hanson, Wolfe, & Pollak, 2015), and emotion regulation (Kim et al., 2013) by prospective longitudinal studies. While children who are neglected or institutionalized do not reliably have their emotional needs met from their caregiver, children exposed to poverty, especially poverty severe enough to result in food insecurity, may not reliably have their physical needs met. In sum, a child's exposure to uncontrollable, and potentially unpredictable, failure to receive necessary physical and/or emotional stimulation can be characterized as a significant stressor.

In contrast to these deprivation-related stressors, caregiver abuse represents a direct and acute threat to a child's well-being. Children in abusive families may experience physical harm and threat (Bick & Nelson, 2016; Pollak, 2015), which results in chronic stress. Children in these environments may also experience a nonnormative emotional learning environment. While children in abusive families may have their physical needs met, abusive caregivers are often inconsistent in their responses to a child's behavior—sometimes responding in normative ways to their children and other times becoming either extremely reactive or unresponsive to their children (Milner & Robertson, 1989). This type of inconsistency can make it challenging for children to learn environmental contingencies between their own behavior and their caregiver's reactions. In addition, abusive caregivers often provide ambiguous emotional signaling to their children, producing unclear facial and vocal expressions of emotion (Shackman et al., 2010). All these factors likely contribute to significant alterations in emotional, cognitive, and brain development that are well documented in abused individuals (Hanson et al., 2015; Harms, Shannon-Bowen, Hanson, & Pollak, 2017; Hart & Rubia, 2012), as well as their increased risk for developing psychiatric disorders (Heim & Nemeroff, 2001).

In addition to overt maltreatment, less severe and more common forms of early adversity such as disrupted parent–child relationships have also been linked to poorer mental and physical health in adulthood. For example, individuals who grow up in families characterized by high levels of conflict and aggression, relationships that are cold, unsupportive, or neglectful, and chaotic daily lives tend to show more behavioral problems in childhood and poorer health in adulthood (Carroll et al., 2013; Repetti, Robles, & Reynolds, 2011; Repetti, Taylor, & Seeman, 2002). Individuals exposed to these subtler forms of early life stress within the family show problems in emotion processing and social competence, disruptions in stress-responsive biological regulatory systems, and poor health behaviors such as substance abuse (Repetti et al., 2002). In sum, the term "early life stress" encompasses a range of stressors and levels of severity, which poses a challenge for research in this area.

Measurement of Early Life Stress

Another challenge for researchers in early life stress relates to measurement of early adversity. For ethical reasons, the Bucharest Early Intervention Project is the only study using random assignment involving humans that has been conducted to examine the effects of early life stress. In the majority of studies, children who are exposed to early adversity within the family environment also tend to experience high levels of stress in other domains, such as school-related stress and tension within the neighborhood and community. Thus, it is difficult to isolate how specific sources of early life stress impact children's health and development. However, a number of experimental studies involving rodents provide insight into the specific effects of disrupted caregiver behaviors on offspring.

Most animal studies of stress have either focused on the effects of stress during adulthood or on how early stress influences later neurobehavioral patterns in adults (Malter Cohen et al., 2013). For the most part, rodent models of childhood stress have tended to utilize periods of maternal separation. This approach tends to induce intermittent, rather than chronic stress (i.e., pups are separated from the mother and then reunified). Recently, however, a reliable model of chronic fragmented maternal care, including maltreatment, has been established for rodents. In this model, insufficient bedding and nesting materials in the home cage causes mothers to neglect or even abuse their pups and, in turn, induces early life psychosocial stress in offspring (Baram et al., 2012; Molet, Maras, Avishai-Eliner, & Baram, 2014). In parallel with human studies of maltreatment, this model of early family adversity has been shown to contribute to cognitive and emotional dysfunctions, as well as disrupted brain development (Brunson et al., 2005) and disrupted biological stress responses (Gunn et al., 2013) in offspring.

However, animal models have limitations in terms of generalizing results to humans. First, certain types of early life stress that may be unique to humans—such as emotional abuse—cannot be simulated. Rodent models such as the limited bedding/nesting paradigm tend to induce maternal behavior that most closely resembles neglect, but rarely results in physical abuse and obviously cannot approximate emotional abuse. In addition, the fact that rodents are born in litters makes rearing environments fundamentally different between rodents and humans. Several studies have examined early life stress in nonhuman primates, who exhibit similar mother–infant interactions as humans (Nelson & Winslow, 2009). A subset of nonhuman primate mothers do physically abuse their infants, though abuse differs from human families in that it tends to be short lived, confined to an infant's first month of life, and does not co-occur with neglect (Sanchez, 2006). Thus, the specific types of maltreatment environments that human children experience cannot be fully replicated in animal models. Second, rodent and even nonhuman primate models unable to reproduce the rich repertoire of cognitive and emotional behaviors that occur in human development. Third, brain regions mature at different rates and trajectories, which differ across species (Avishai-Eliner, Brunson, Sandman, & Baram, 2002). These differences pose a challenge for researchers who intend to directly compare the age of a developing animal with a specific human age in terms of overall brain development, especially in rodent studies. Due to these limitations, research examining the sequelae of early life stress in humans remains necessary.

Studies involving human subjects typically take either a retrospective or prospective approach to measuring early adversity. Retrospective reports of childhood experiences can be obtained from adults and are therefore a convenient measure in many situations. Some commonly used retrospective measures are questionnaires such as the Childhood Trauma Questionnaire (CTQ) (Bernstein, Fink, Handelsman, & Foote, 1994) and the Adverse Childhood Events Scale (ACES) (Felitti et al., 1998), which ask participants if they experienced maltreatment or negative life events in childhood. Other studies use interview methods, such as the UCLA Life Stress Interview (Hammen, Marks, Mayol, & de Mayo, 1985), which assesses current chronic stress in addition to a retrospective report of childhood stress.

The validity of retrospective reporting of early life stress is debated. A potential confound with this approach is that adults' current levels of stress and/or mood may affect their subjective feelings regarding their childhood (Colman et al., 2016): for example, current life difficulties may cause them to have a negative bias of their lives as children. In addition, retrospective reports are subject to omission errors (Widom & Morris, 1997), and studies report weak correlations between retrospective reports and prospective measures. For example, in a large longitudinal birth cohort study (Reuben et al., 2016), a prospective measure of adverse experiences that were documented during childhood was only moderately correlated with retrospective reports by adult participants. The accuracy of retrospective reporting may also depend on the types of events that are queried. For example, in this study, higher agreement between prospective and retrospective measurement was reported for objectively adverse events, such as the loss of a parent, than for events involving subjective interpretation, such as emotional abuse. Furthermore, personality traits (neuroticism and agreeableness) were associated with the extent to which retrospective and prospective measurements were congruent. Another important difference between prospective and retrospective measurement is that prospective measures are often objective (e.g., measured through Child Protective Services Records or other informant reports), while retrospective reports are inherently subjective. Indeed, Reuben et al. (2016) found that prospectively measured early life stress best predicted objectively measured health outcomes, while retrospective reports best predicted subjective health outcomes. These associations suggest the possibility for common method bias—i.e., individuals who feel worse about their health also have more negative views regarding their early life experiences. For all these reasons, it is recommended that researchers use prospective measures whenever possible.

Behavioral Sequelae of Early Life Stress

Despite measurement issues, findings from studies using different methods, or involving humans versus animals, show substantial overlap in terms of the neurobehavioral effects of early adversity, including impaired cognitive and emotional development (Lupien et al., 2009). For example, studies involving both rodents (Ivy et al., 2010) and humans (Hanson et al., 2017; Harms, Shannon-Bowen, et al., 2017) have found deficits in learning and memory, along with abnormal development of associated brain regions, following early life stress (Teicher, Tomodo, & Andersen, 2006). Examining emotional development, Malter Cohen et al. (2013) tested parallel models of early life stress in both rodents (limited nesting material) and humans (early institutionalization), reporting evidence that early adversity inhibited the ability to suppress attention toward potentially threatening information in favor of goal-directed action, indicating deficits in fear regulation in both species. These findings have been replicated by many other studies that examined humans or rodents separately (Heim & Nemeroff, 2001; Tottenham & Sheridan, 2010).

Early stress appears to alter threat perception, which can lead to increases in both anxiety and aggressive behavior. In Shackman, Shackman, and Pollak (2007), abused children showed increased attention to visual and auditory anger cues, as indexed by event-related potentials (ERPs) relative to non-abused controls. In addition, the amount of attention children allocated to these threatening emotional stimuli mediated the relationship between physical abuse and child-reported anxiety. In a later study (Shackman & Pollak, 2014), the same researchers showed that a history of maltreatment was also associated with higher levels of negative affect expression and aggression (measured by negative feedback directed toward a putative peer) during a laboratory task. Attention to threat (angry faces) again mediated the relationships between maltreatment and both negative affect and aggression. Thus, over-attending to threat appears to be a key mechanism through which early stress becomes associated with emotional and behavioral problems.

Behavioral and neuroimaging studies also suggest abnormal reward processing, which integrates emotional and cognitive systems, in individuals exposed to early stress (Birn, Roeber, & Pollak, 2017; Dillon et al., 2009; Goff et al., 2013; Hanson, Hariri, & Williamson, 2015; Mehta et al., 2010; Pechtel & Pizzagalli, 2011; Weller & Fisher, 2013). For example, in an incentive-based learning task, abused children and adolescents did not respond to differences in reward probability, failing to increase their response speed as the chance of winning increased (Guyer et al., 2006). This finding suggests that the abused children were unable to acquire or effectively use information about differing reward probabilities. In addition, studies of risk-taking found reduced exploration behavior, which could have yielded larger rewards, in neglected (Loman et al., 2014) and abused adolescents (Sujan, Humphreys, Ray, & Lee, 2014) relative to control groups. Finally, Harms, Shannon-Bowen, et al. (2017) found deficits in both acquisition and reversal of stimulus–reward associations among adolescents who had been physically abused. Although this is a relatively new area of research, and requires replication in experimental animal research, this emerging evidence suggests that early life stress has profound impacts on reward processing.

Abnormal development in threat sensitivity, emotion regulation, and reward processing may contribute to the association between early adversity and increased risk for a range of psychiatric disorders and behavioral problems (Jaffee, 2017). Early life stress, particularly maltreatment, has been linked to elevated risk for developing major depression (Scott, Smith, & Elis, 2010) and anxiety disorders (Cohen et al., 2006), including PTSD (Breslau et al., 2014), as well as increased levels of suicidal thoughts (Thornberry, Henry, Ireland, & Smith, 2010) and self-injurious behavior (Yates, Tracy, & Luthar, 2008). In addition to higher internalizing symptomatology, victims of maltreatment show increased externalizing problems in adulthood, including higher incidence of antisocial behavior (Johnson & Leff, 1999), and more frequent criminal activity and arrests (Maxfield & Widom, 1996; Thornberry, Henry, Ireland, & Smith, 2010).

Neurobiological Sequelae of Early Life Stress

Early life stress influences an individual's development at multiple levels, including behavior, neurobiology, and the epigenome. To appreciate these influences, it is necessary to understand how organisms respond biologically to stressors in the environment.

The Stress Response

In humans and animals, sophisticated biological systems have evolved to respond to potential threats in the environment. Here, we provide a brief overview of this stress response. An acute stressor activates the hypothalamic–pituitary–adrenal (HPA) axis, which induces the release of corticotropin-releasing hormone (CRH) and vasopressin (AVP) from the hypothalamus and adrenocorticotropic hormone (ACTH) from the pituitary into the blood. This stimulates the release of glucocorticoid (cortisol in humans and corticosterone in rodents) from the adrenal cortex. The HPA axis follows a basal circadian activity rhythm and is regulated by a negative feedback mechanism moderated by corticosteroids that constrain the response of the axis after its activation. This negative feedback mechanism is complex, but briefly, corticosteroids bind to glucocorticoid receptors (GRs) and mineralocorticoid receptors (MRs) that are expressed in most bodily tissues and act as transcription factors (Larsson et al., 2012; Sanchez, Arnt, Hyttel, & Moltzen, 1993). GR activation causes a negative feedback loop at several levels of the HPA axis that ends the stress response and the release of cortisol once a threat has been removed (for more information, see Provencal & Binder, 2015).

Through this negative feedback mechanism, the HPA system responds very effectively to acute, short-term environmental threats, which were typical throughout most of human evolution. However, the HPA axis is less well equipped to deal with chronic stress. In this context, the negative feedback mechanisms that regulate the stress response can break down, resulting in either hypersensitive or blunted HPA system reactivity. In animal models, early life stress resulting from maternal separation, or from the limited nesting model, tends to lead to hyperreactivity of the HPA axis in adulthood, including increased CRH signaling in response to a stressor and impaired GR-mediated negative feedback (van Bodegom, Homberg, & Henckens, 2017). However, in another model of early life stress, early social deprivation, rodent pups are temporarily separated from their mother and littermates and housed in a novel environment. This more severe stress can decrease stress-induced corticosterone levels in these animals are either blunted or unaffected relative to non-stressed controls (Sandi & Haller, 2015), suggesting reduced HPA sensitivity relative to non-stressed controls. Human findings similarly show variation in the effects of early adversity on HPA axis function. For example, exposure to interparental aggression, corporal punishment, or frequent emotional maternal withdrawal was found to increase baseline (i.e., non-stressed) cortisol levels (Davies, Sturge-Apple, Cicchetti, Manning, & Zale, 2009) and cortisol stress responses (Bugental et al., 2003). In contrast, there is also evidence institutionalization or maltreatment can result in HPA axis hyporeactivity. For example, a recent study showed that childhood maltreatment was associated with decreases in cortisol response during psychosocial stress in adulthood (Grimm et al., 2014). Similarly, studies involving human children exposed to severe neglect, abuse, orphanage/institutional care, or involvement with child protective services report lower basal levels of corticosteroids (Bernard, Zwerling, & Dozier, 2015; Bruce, Fisher, Pears, & Levine, 2009; Gunnar and Donzella, 2002). In general, the literature suggests that more severe early stress is more likely to lead to hypo- versus hypercortisolism.

Inconsistent findings of either increased or decreased stress responsiveness after early adversity might be explained by a trajectory of initial hyperactivation of the HPA axis that progresses to a state of sustained stress hyporeactivity when the stressors are severe and/or chronic (Fries, Hesse, Hellhammer, & Hellhammer, 2005; Pryce, Bettschen, Nanz-Bahr, & Feldon, 2003). HPA hyporeactivity may serve as a compensatory adaptation that protects the organism from deleterious effects of chronic high levels of stress hormones. Initial evidence for this trajectory of HPA axis responsivity resulting from chronic stress has been demonstrated in animal models (Saltzman et al., 2006; Sterlemann et al., 2008). However, more research is needed to investigate mediating and moderating factors that influence how stress affects development of the HPA system.

Early Life Stress and Epigenetics of the Stress Response

Epigenetic mechanisms—changes in gene expression that do not involve changes in the DNA sequence—appear to be important factors that mediate the extent to which early life stress leads to blunting or hypersensitivity of the HPA axis (Conradt, 2017). Although the specific epigenetic modifications that may contribute to differential HPA system trajectories following early stress are not fully understood, the field has made rapid progress in recent years in elucidating how some of these mechanisms operate. For example, we now know that decreases in

GR expression and activation tend to be associated with an increase in the stress response, and this can be explained by epigenetic mechanisms (Provencal & Binder, 2015). DNA methylation, which can function to switch genes between “on” or “off” positions, is one epigenetic mechanism used by cells to regulate gene expression. Stress that occurs during certain developmental sensitive periods may lead to long-term changes in the methylation of genes that regulate the stress response (Zannas, Wiechmann, Gassen, & Binder, 2016). One such gene that has generated recent interest is the FK506 binding protein 5 (FKBP5) gene, which regulates glucocorticoid sensitivity. Childhood maltreatment has been associated with long-term demethylation of this gene (Klengel et al., 2013), which contributes to increased expression of FKBP5 (Harms et al., 2017). Higher expression of FKBP5 appears disrupt the negative feedback mechanism that regulates the HPA axis, resulting in glucocorticoid resistance, higher cortisol levels, and prolonged recovery following exposure to stress (Tyrka, Ridout, & Parade, 2016; Zannas & Binder, 20143). Another important gene that regulates the HPA axis is the glucocorticoid receptor gene, *NR3C1*. This gene shows greater methylation in physically abused children relative to non-maltreated children (Romens, McDonald, Svaren, & Pollak, 2015). A recent study examined the entire human genome in girls exposed to varying levels of childhood stress, finding that girls with high levels of stress exposure showed differential methylation in 122 genes, as well as changes in expression in 12 genes (Papale, Seltzer, Madrid, Pollak, & Alisch, 2018). Several of these genes are known to be involved in the stress response systems, but others serve different regulatory functions throughout the body, suggesting system-wide changes in biological functioning as a result of stress. Thus, early stress in the form of maltreatment appears to induce multiple epigenetic changes in stress response system and beyond that have implications for individuals’ biological reactivity to subsequent stress.

Influences of Early Life Stress on Neural Circuitry

In addition to alterations in the stress response, epigenetic changes induced by early life stress appear to play a role in altering brain structure and function following early life stress (Labonte et al., 2012). According to the neurotoxicity hypothesis (Sapolsky, Krey, & McEwen, 1986), chronic glucocorticoid release (induced by extended stress exposure and potential epigenetic modifications that contribute to impaired GR negative feedback) facilitates neurodegenerative processes, resulting in structural changes in the volumes of various brain regions. The brain regions most consistently affected by early life stress include the hippocampus, amygdala, and prefrontal cortex. These regions coordinate learning and memory processes, emotional reactivity, and emotion regulation.

The limbic system, a set of brain regions immediately beneath the cerebral cortex, supports a variety of functions including emotion, motivation, and memory formation. Limbic regions, particularly the hippocampus (facilitating memory formation) and amygdala (facilitating emotional processing), are profoundly affected by early life stress. Studies of hippocampal development in stressed animals provided some of the earliest evidence for effects of chronic stress on the brain, showing decreased branching, reduced length, and atrophy of dendrites in hippocampal neurons among stressed relative to non-stressed rats (e.g., Cook & Wellman, 2004; McEwen, 1999). The limited bedding/nesting model has also been associated with a reduction of synapses and dendritic spines, as well as dendritic atrophy in the hippocampus (Brunson et al., 2005). In humans, structural findings regarding the effects of early life stress on limbic system development are more mixed and tend to involve both hippocampus and amygdala (or finding that early adversity is associated with changes in one region but not the other). For example, some studies show larger amygdala volumes relative to control groups among previously institutionalized children who were adopted (Mehta et al., 2009; Tottenham, 2010), or smaller hippocampal volumes, with later adopted children showing larger abnormalities (Hodel et al., 2015). However, several studies show no differences in hippocampal (Mehta et al., 2009; Sheridan, Fox, & Zeanah, 2012; Tottenham, Henry, Ireland, & Smith, 2010) or amygdala volumes (Hodel et al., 2015) between previously institutionalized children and controls. Another study that employed detailed hand tracing of amygdala and hippocampus volumes showed that various forms of early life stress (physical abuse, early neglect, or low socioeconomic status) were associated with smaller amygdala and hippocampal volumes (Hanson et al., 2015). Divergent findings in humans could be due to a number of factors, including developmental timing of stress exposure, nonlinear brain development, different effects based on type of stressor, and methodological factors. However, the preponderance of evidence suggests that early stress alters trajectories of limbic brain development, which has implications for memory and emotion processing.

In addition to the limbic system, the prefrontal cortex and its connectivity with the limbic system are affected by early life stress. In animals, maternal separation is associated with long-term changes in prefrontal microstructure (Braun, Lange, Metzger, & Poeggel, 2000; Ovtscharoff & Braun, 2001; Poeggel et al., 2003) in rodents and with decreased medial prefrontal cortex volume in nonhuman primates (Lyons, Parker, Katz, & Schatzberg, 2009; Spinelli et al., 2009). Similarly, in humans, early maltreatment is associated with reduced gray matter volumes in medial prefrontal cortex and anterior cingulate gyrus (Dannlowski et al., 2012; De Brito et al., 2013; Edmiston et al., 2011; Hanson et al., 2010) as well as decreased functional connectivity between medial prefrontal cortex and amygdala (Burghy et al., 2012). Furthermore, a higher number of self-reported adverse childhood experiences have been linked with a smaller volume in regions such as anterior cingulate cortex and caudate that interface with the limbic system and prefrontal cortex (Cohen et al., 2006).

Studies using diffusion tensor imaging (DTI) studies, a method for evaluating structural connectivity through white matter tracts, show that early life stress disrupts microstructural integrity in the brain. Previously institutionalized or neglected children and adolescents show reduced integrity of the uncinate fasciculus (Eluvathingal et al., 2006; Govindan, Behen, Helder, Makki, & Chugani, 2010; Hanson et al., 2013), a white matter tract connecting limbic and frontal lobe regions (Behen et al., 2009). Moreover, several studies have found reduced global white matter volume, disrupted prefrontal white matter organization, or reduced prefrontal cortical thickness (reflecting the width of the cortical gray matter and potential brain atrophy) in children exposed to early deprivation (Eluvathingal et al., 2006; Mehta et al., 2009; Sheridan et al., 2012; McLaughlin et al., 2014). A study that assessed exposure to adverse childhood experiences through self-report found reduced microstructural integrity of the corpus callosum, which connects the two brain hemispheres (Paul et al., 2008). In this study, all participants were free of psychiatric symptoms, suggesting that white matter structure can be impacted by stress even in the absence of psychopathology. Finally, there is evidence that early life stress disrupts the global organization of brain networks—young adults with a history of childhood maltreatment show decreased network centrality in a number of cortical areas relative to non-maltreated individuals (Harms et al., 2017) (Teicher, Anderson, Ohashi, & Polcari, 2014). Decreased network centrality is likely to impair high-level cognitive functions that rely on the integration of information from multiple regions. In sum, various forms of severe early stress appear to alter both fronto-limbic structure and connectivity. These consequences may impact high-level cognitive processes such as emotion regulation and goal-directed behavior.

Gene–environment interactions and neural circuitry

Effects of early stress on neural structure and function appear to vary based on genetic factors. Genes involved in regulating serotonin levels and brain-derived neurotrophic factor (BDNF), a moderator of synaptic plasticity, have been shown to moderate the effects of stress on neural circuitry. Some individuals in the population carry "risk alleles" of these genes that increase their neurobiological sensitivity to negative environmental events. In one study, early life stress combined with the HTR3A CC genotype group of the serotonin 3A receptor gene was associated with smaller gray matter volume in hippocampus and frontal cortex and higher negative affect, compared with the T carriers (Gatt, Williams, et al., 2010). In another study, carriers of both BDNF methionine and HTR3A CC risk alleles who were exposed to high levels of early life stress showed elevated emotion-elicited heart rate, as well as right frontal hyperactivation and right parietotemporal hypoactivation in EEG asymmetry, compared with non-risk allele carriers (Gatt, Nemeroff, et al., 2010). These findings reflect gene–environment interactions associated with early stress that may increase the likelihood of developing internalizing psychopathology among risk allele carriers.

Additional Considerations

Additional factors that appear to moderate the effects of early stress on physical and mental health outcomes include developmental timing of stress and sex differences. In addition, we outline promising research addressing prevention and intervention mechanisms that may promote resilience in the face of early adversity.

Developmental Timing of Stress

Evidence suggests that stressors exert different neurobehavioral effects depending on when they occur during an organism's development, and early life stress is generally associated with longer-lasting impacts than stress experienced during adulthood (Lupien et al., 2009). However, in rodents, whose offspring are born relatively immature in terms of neuroendocrine development, there is strong evidence for a stress hyporesponsive period (SHRP) during the first two weeks of postnatal life, in which the HPA axis does not respond, or reacts only minimally, to environmental stressors (Levine, 1994). This period may have evolved to protect the developing brain from the effects of elevated glucocorticoids. There is controversy as to whether such a period exists in humans, though there is evidence that caregivers (when not absent or abusive) provide a strong buffering effect against stress in early childhood (Gunnar & Cheatham, 2003). It should also be noted that, because rodent pups are born less mature but mature at a faster rate than human infants, perinatal stress will impact different stages of development depending on which species is studied (Lupien et al., 2009).

In terms of brain development, stress exposure at different developmental periods is likely to have different impacts because regions mature at different rates (Andersen, 2003). For example, one study found that childhood sexual abuse experienced between 3 and 5 years of age was associated with reduced hippocampal volume, while abuse experienced in adolescence was associated with reduced gray matter volume in the frontal cortex (Andersen & Teicher, 2008). These findings are congruent with the developmental trajectories of these regions, with the hippocampus maturing in early childhood and the prefrontal cortex continuing to develop throughout adolescence (Lupien et al., 2009). Another study found that stress reported in late childhood (ages 8 and up) was associated with smaller anterior cingulated and insula volumes, while stress reported in early childhood did not impact the volume of these regions (Baker et al., 2013). This finding may be due to changes in the emotional processing of stressful events across development.

Stress experienced during certain developmental periods can show incubation effects, where impacts do not become apparent until later ages: for example, having a mother with maternal depression has been associated with abnormal HPA activity and depressive symptoms in adolescence (Halligan, Hubert, Goodyer, & Murray, 2007). Indeed, a number of mental health problems associated with early life stress tend to surface for the first time in adolescence (Giedd, 2008). Studies show that adolescents are highly vulnerable to psychosocial stress, possibly due to a protracted glucocorticoid response to stress that persists into adulthood (Gunnar, Wewerka, Frenn, Long, & Griggs, 2009; McCormick & Matthews, 2007). For example, chronic variable stress in adolescent rats has been shown to induce long-term alterations in hippocampal structure, cognition, and HPA axis function (Isgor, Kabbaj, Akil, &Watson, 2004). However, most scientific knowledge regarding the impacts of adolescent-specific stress is derived from animals, and more research is needed to determine the long-term impacts of adolescent stress in humans.

Sex Differences

A number of studies suggest that males and females respond differently to developmental stressors, with most evidence indicating that females are more vulnerable to early life stress. Females who experienced trauma, who experienced physical abuse, or whose mothers were depressed during infancy show higher rates of depression, anxiety, and PTSD compared with males (Baker and Shalhoub-Kevorkian, 1999; Macmillan et al., 2001; Pitzer et al., 2011). Sex differences following early life stress are also found in HPA system reactivity. For example, exposure to early trauma has been shown to be positively associated with cortisol response to CRH challenge in men but not in women (DeSantis et al., 2011). This finding suggests that women are more prone to a blunting of the HPA axis as a result of early stress. A recent study involving youth also found that in girls relative to boys, cortisol responses to stress were more highly correlated with genetic risk factors in genes that regulate the HPA axis, suggesting higher susceptibility to “risky” alleles in girls (Pagliaccio et al., 2014). There is also evidence that white matter structure is affected by early stress to a greater extent in females than in males (Paul et al., 2008). Animal models suggest that sex hormones play a role in the diverging neurobiological and behavioral responses to stress that occurs during adolescence between males and females (McCormick & Matthews, 2007). However, more research that specifically examines mechanisms for sex differences in the neurobiological sequelae of early stress is called for. Such research is especially important given that the risk for depression, for which early stress is often a contributing factor, is much higher in females beginning in adolescence (Kessler et al., 2003).

Prevention and Intervention Research

There are promising areas of research addressing prevention and intervention mechanisms to ameliorate negative effects of early life stress on health. Given that stress first affects the HPA system, the most effective prevention and intervention mechanisms should moderate long-term alterations in this system as a result of early stress (Bruce et al., 2013), and two intervention programs so far have been shown to do so. Multidimensional Treatment Foster Care for Preschoolers (MTFC-P) is a preventive intervention that focuses on the use of consistent, contingent parenting strategies. MTFC-P has been shown to reduce placement disruptions, increase secure attachment-related behaviors (Fisher, Burraston, & Pears, 2005; Fisher & Kim, 2007), and prevent blunting of diurnal cortisol slopes in foster children (Fisher et al., 2007). These positive effects among children may be related to a reduction in caregiver stress resulting from the intervention (Fisher & Stoolmiller, 2008). Another intervention, the Incredible Years Series, was designed to reduce externalizing behaviors by enhancing parenting practices and child social competence among families with preschool-aged children who have siblings convicted for criminal activity. This preventive intervention has been shown to decrease child aggressive behavior (Brotman et al., 2008) and prevent blunted cortisol responses to social challenge (Brotman et al., 2007). Among families with low parental warmth, there is evidence that this intervention reduces child aggression via increased cortisol response, suggesting that HPA axis function mediates the positive impact of this intervention on child behavior (O'Neal et al., 2010).

Throughout infancy, childhood, and adolescence, the body and brain are undergoing dramatic changes and are profoundly shaped by environmental cues. As discussed earlier, many of the deleterious effects of early life stress are associated with a mismatch between the early life environment and later environments that an individual experiences. For example, the adaptations a child develops as a result of institutional care (blunted HPA reactivity, early puberty, preservation of emotional brain systems at the expense of higher-level cognitive systems) may increase their ability to survive long enough to reproduce in a very harsh, deprived environment. Similarly, increased vigilance to threat in the context of physical abuse increases a child's likelihood of avoiding harm in that particular family environment. However, these adaptations can hinder optimal functioning in an adoptive family and resource-rich environment, in school, or at a job later in life, resulting in a higher risk for physical and mental health problems. Stress-exposed individuals tend to exhibit reduced cognitive flexibility, meaning that once a stress-exposed individual learns a specific behavioral strategy during childhood, she/he may persevere with this strategy even if it becomes maladaptive when the environment changes (Harms, Shannon Bowen, et al., 2017). This dilemma presents another potential area for intervention: for children whose adverse environments cannot be fully replaced, perhaps early intermittent exposure to "mismatching" environments may facilitate cognitive and behavioral flexibility in novel situations (Bock et al., 2014). Programs such as Head Start and Boys and Girls Clubs might show positive impacts in part through exposing children from impoverished backgrounds to novel environments. Given the systemic effects of early life stress on physical and mental health outlined above, more research addressing prevention and intervention mechanisms is a profound societal need.

Conclusion

In sum, early life stress takes many forms, but all types of severe early adversity studied thus far have potentially negative impacts on long-term health and development. Early childhood stress influences lifetime physical and psychological health through alterations in the stress response system, the epigenome, and the development of brain circuitry that facilitates cognitive and emotional process. Priorities for future research on early life stress should include an emphasis on prospective measures of stress, longitudinal designs, attention to developmental timing (especially studies that examine adolescent-specific stress), and a focus on prevention and intervention work to mitigate the negative health effects of severe early stress.

Introduction

Problematic alcohol consumption is a major contributor to disability-adjusted life years worldwide (World Health Organization [WHO], 2014). Much of the burden is due to neuropsychiatric disorders, primarily alcohol use disorders, causing disability and mortality compared with other chronic diseases (WHO, 2014). It is well established that excessive alcohol consumption directly impacts brain structure and function (de la Monte & Krill, 2014; Geibprasert, Gallucci, & Krings, 2010; Keil, Greschus, Schneider, Hadizadeh, & Schild, 2015; Kim, Lee, Young, Shin, & Kim, 2014; Zahr, Kaufman, & Harper, 2011). The mechanisms are varied and include the direct neurotoxic effects of alcohol on neurons and secondary effects of hepatic dysfunction and/or nutritional deficiency. Collectively, the neuropathological, morphological, and biochemical changes are referred to as alcohol-related brain damage (ARBD) (Zahr et al., 2011). In this chapter, we describe the clinical characteristics, neuropathological features, and neuroimaging signatures of ARBD.

Alcohol Consumption and Brain Dysfunction

The long-term effects of chronic heavy drinking, frequent binge drinking episodes (five drinks for men, four drinks for women on 5 or more days in the past month) (National Institute on Alcohol Abuse and Alcoholism [NIAAA], 2018), produce structural brain changes and impairment of cognitive function in some, but not all, individuals (de la Monte & Krill, 2014; Geibprasert et al., 2010; Keil et al., 2015; Kim et al., 2014; Zahr et al., 2011). Neuroimaging studies report a strong interdependence between lifetime alcohol consumption and loss of

white and gray brain volumes. Literature has suggested that 5–6 drinks per day over an extended period of time correspond to mild cognitive impairment and the consumption of 10 or more drinks per day results in moderate cognitive deficits (Ridley, Draper, & Withall, 2013). However, the long-term effects of light-to-moderate drinking, defined as up to one drink per day for women and up to two drinks per day for men, (2015–2020 Dietary Guidelines for Americans, 2015) on the human brain are poorly understood.

Some studies report an association between recent moderate alcohol use and reduced total brain volume, gray matter and hippocampal atrophy, and impaired white matter microstructure, while other studies show no such association (Ridley et al., 2013; Topiwala et al., 2017). These inconsistencies are likely due to (a) disproportional use of cross-sectional research designs; (b) confounds related to comorbid illicit drug use, including nicotine; (b) inaccurate estimates of alcohol intake from self-report; (d) heterogeneity of sample demographics; and (e) insufficient focus on sex-specific outcomes.

Mechanisms of Alcohol-Induced Brain Damage

Although not completely understood, several mechanisms have been proposed to explain ARBD. For example, ethanol-specific mechanisms underlying ARBD have been attributed to oxidative stress and the accumulation of toxic metabolites. Oxidative stress occurs due to an accumulation of free radicals (reactive oxygen species) causing DNA damage, the inhibition of gene expression, and neuronal death. Toxic metabolites of ethanol, such as acetaldehyde and fatty acid ethyl esters, can accumulate and lead to adduct formation, interrupting mitochondrial formation inducing neuronal damage (Crews & Nixon, 2009; Zahr et al., 2011). Further, immune-related inflammatory responses and subsequent neural degeneration may be caused by liver damage due to the synergistic effects of acetaldehyde protein adduct formation and oxidative stress (Zahr et al., 2011). A mechanistic role for implicating neuroinflammation in the pathogenesis and progression of ARBD links neuroimmune signaling and glutamate excitotoxicity to alcohol-related neurodegeneration (Crews & Vetreno, 2014). Studies report that lifetime alcohol consumption correlates with neuroimmune gene expression and signs of neuroinflammation in the hippocampus, amygdala, and ventral tegmental area among individuals with alcohol use disorder (Crews & Vetreno, 2014; Zahr et al., 2011). Readers are referred to the following publications for more detailed reviews (Crews & Nixon, 2009; Crews & Vetreno, 2014; Fadda & Rossetti, 1998; Harper, 2009).

Chronic heavy alcohol consumption also produces thiamine deficiency via decreased thiamine absorption in the gastrointestinal tract, inadequate nutritional thiamine intake (due to poor diet), and impaired thiamine utilization in the cells. Low levels of thiamine pyrophosphate disrupts the following processes: amino acid metabolism interrupting the release of glucose-derived neurotransmitters and carbohydrate metabolism producing a cytotoxic effect through reduction in α-KGDH activity (de la Monte & Krill, 2014; Zahr et al., 2011). The synergistic effects of thiamine deficiency and heavy alcohol use are associated with the loss of neural plasticity and reduction in what matter volume due to a reduction in GABAergic inhibition and increase in glutamatergic excitation (Costin & Miles, 2014; Zahr et al., 2011).

Wernicke–Korsakoff Syndrome

Wernicke–Korsakoff syndrome (WKS), composed of Wernicke's encephalopathy (WE) and Korsakoff syndrome (KS), is one of the most frequently seen neurological consequences associated with heavy, long-term alcohol use (Kim et al., 2014; Kopelman, Thomson, Guerrini, & Marshall, 2009). While the two conditions share some overlapping pathogenesis, WE and KS produce unique clinical phenotypes.

Wernicke's Encephalopathy

WE, an acute, potentially reversible neuropsychiatric condition, is a medical emergency caused by thiamine deficiency (Costin & Miles, 2014; Kopelman et al., 2009). It is marked by a clinical triad of symptoms including ataxia, global confusion, and ophthalmoplegia (Kim et al., 2014). However, most patients present with nonspecific cognitive changes, ocular motor abnormalities, and cerebellar dysfunction. Altered mental state is the most prevalent symptom, which may present as mental sluggishness, impaired awareness of surroundings, difficulty concentration, apathy, and confusion or agitation (Kim et al., 2014; Kopelman et al., 2009). The use of thiamine or thiamine-containing products for the treatment of WKS should be implemented as soon as possible beginning with parenteral or intravenous administration of thiamine for several days, followed by daily oral administration prevents mortality, but does not protect individuals from residual neurological symptoms (Costin & Miles, 2014). Even with prompt treatment, global confusion persists for up to three months, and chronic memory deficits remain thereafter (Costin & Miles, 2014).

Neuropathological features of both acute and chronic WE include global brain atrophy with disproportionate white matter volume loss. Symmetrical hemorrhagic lesions in the mammillary bodies, thalamus, brain stem, hypothalamus, and cerebellum are seen in acute WE, whereas atrophy and brownish discoloration of the mammillary bodies, anterior nuclei, and medial-dorsal nuclei of thalami are more common in chronic cases (de la Monte & Krill, 2014). Magnetic resonance (MR) findings in WE include edema hyperintensities in the gray matter of the periventricular region, mammillary bodies, medial thalamus, and superior/inferior colliculi (Keil et al., 2015; Kim et al., 2014). In the chronic stage, MR findings show brain atrophy and diffuse signal intensity changes in affected areas and cerebral white matter (Kim et al., 2014).

Korsakoff Syndrome

Approximately 80% of patients with acute WE will progress to KS (Costin & Miles, 2014; Keil et al., 2015; Kopelman et al., 2009). As many as 25% of affected cases require long-term psychiatric care (Kopelman et al., 2009). The most characteristic clinical symptom of KS is mental status change (Costin & Miles, 2014; Keil et al., 2015; Kopelman et al., 2009). Memory impairments in KS are characterized by marked inability to form declarative memories (explicit) with less disruption to semantic memory and procedural memory (implicit). Oftentimes, affected individuals exhibit confabulations (involuntary, false or erroneous memories or intrusion errors) (Kopelman et al., 2009).

Morphological changes such as cortical thinning, sulcal widening, mammillary body atrophy, and ventricular enlargement are more severe in KS than WE. A significant decrease in Purkinje cell density in the cerebellar vermis and micro-hemorrhages and gliosis in the periventricular and periaqueductal gray matter are also present and relate to ataxia/unsteadiness and memory dysfunction (Kopelman et al., 2009). Neuroimaging abnormalities are seen in the mammillary bodies, posterior midbrain, medial thalamus, hypothalamus, pons, and hippocampus (Keil et al., 2015) and focal cerebral edema detected on MRI. Anterograde memory deficits are associated with reduced thalamus/hippocampus volume, whereas retrograde and working memory deficits are attributed to frontal lobe dysfunction. Further, cortical damage in the frontocerebellar and limbic circuits (Kopelman et al., 2009) relates to level of impairment in episodic memory.

Marchiafava–Bignami Disease

Originally called the "red wine drinker's encephalopathy," Marchiafava–Bignami disease (MBD) is a rare neurologic disorder associated with chronic heavy alcohol use seen in only 0.01% of patients with alcohol-related diseases (Costin & Miles, 2014). Most prevalent in men between 40 and 60 of age, MBD results in progressive demyelination and necrosis of the corpus callosum (Carrilho, Santos, Piasecki, & Jorge, 2013). Deficiency in thiamine and deficiency in all eight B vitamins have been implicated as possible cofactors, but the exact etiology of MBD is unknown. Although there is no standard clinical presentation of MBD, symptoms include depression, psychosis, hemiparesis, apraxia, and seizures. Untreated symptoms can be fatal or coma inducing (Carrilho et al., 2013; Costin & Miles, 2014).

In the acute phase, individuals with MBD exhibit severe impairment of consciousness, confusion, muscle rigidity, and gait disturbance. Signs of interhemispheric disconnection syndrome are possible (Carrilho et al., 2013; Costin & Miles, 2014). By contrast, the chronic phase is characterized by dementia and gait impairment that can progress over time (Costin & Miles, 2014). Treatment options are limited to replacement of depleted B vitamins and thiamine, corticosteroids, and amantadine with variable response (Kim et al., 2014). Patients who survive should receive rehabilitation and alcohol counseling.

The primary neuropathological features associated with MBD include degeneration and necrosis of the corpus callosum, predominantly at the body, genu, and splenium. Imaging features, consistent with pathology, are edema, demyelination, and later necrosis of the corpus callosum with formation of cystic cavities (Carrilho et al., 2013). Computed tomography (CT) scans reveal diffuse periventricular low density and focal areas of low density in genu and splenium of corpus callosum, and MRI show hyperintense signals within the genu and splenium and adjacent white matter (Kim et al., 2014). The splenium has more myelin than any other part of the corpus callosum, so intramyelinic edema has been proposed as the cause of more frequent lesions in this structure, and cytotoxic edema has also been proposed as a possible mechanism for early stage demyelination (Carrilho et al., 2013; Kim et al., 2014).

Osmotic Demyelination Syndrome (Central Pontine or Extra Pontine Myelinolysis)

Osmotic demyelination syndrome (ODMS) is a disease involving the central portion of the base of the pons (Turnbull, Lumsden, Siddiqui, Lin, & Lim, 2013). Chronic alcoholism is the most frequent underlying condition, yet the exact pathophysiology is not understood (Keil et al., 2015; Turnbull et al., 2013). Typically, ODMS presents with generalized encephalopathy with a period of recovery prior to a second phase of neurological deterioration (Keil et al., 2015; Turnbull et al., 2013). Associated symptoms such as decreased voluntary muscle control, acute changes in mental statues, gaze paresis, and the inability to control facial movements reflect areas of demyelination. A locked-in syndrome, in which the patient is aware but cannot move or communicate due to paralysis of voluntary muscles, may occur in more severe cases; progression to coma or death occurs in 50% of cases (Keil et al., 2015).

Neuropathological findings show demyelination of nerve fibers in the pons without destruction of axons. Extrapontine, symmetrical areas of myelin disruption involving the thalamus, putamen, and cerebellum have also been described. MRI shows abnormal signal in central pons, basal ganglia, thalami, cerebellum, and lateral geniculate; CT reveals low-density lesions in the pons (Keil et al., 2015; Turnbull et al., 2013).

Hepatic Encephalopathy

Hepatic encephalopathy (HE) is a reversible metabolic encephalopathy characterized by psychiatric, cognitive, and motor abnormalities, occurring in patients with advanced liver failure and cirrhosis (Geibprasert et al., 2010; Keil et al., 2015). Pathogenesis has been attributed to the inadequate removal of nitrogenous compounds resulting in the accumulation of ammonia, manganese, and mercaptans (Geibprasert et al., 2010). Hypermanganesemia can induce reactive gliosis and selective neuronal loss in the basal ganglia and midbrain (Geibprasert et al., 2010).

HE presents with various reversible clinical symptoms such as deficits in attention, personality changes (apathy, irritability, disinhibition), motor incoordination, and alterations in consciousness. Frequent disturbances to the sleep–wake cycle with excessive daytime sleepiness, inappropriate behavior, progressive disorientation/acute confusion, and stupor that progresses to coma may occur in severe cases (Geibprasert et al., 2010; Keil et al., 2015). The central nervous system (CNS)-related cognitive changes in HE are attributed to an accumulation of manganese in the globus pallidus, hypothalamus, and anterior midbrain. Edema of the gray matter, in particular the insular cortex, cingulate, and basal ganglia, occurs in the early stages and relates to sleep disturbances and subtle behavioral changes (Geibprasert et al., 2010; Keil et al., 2015). Imaging findings show bilateral symmetrical signal hyperintensity in the basal ganglia (e.g., caudate, putamen, substantia nigra, red nucleus) (Geibprasert et al., 2010; Keil et al., 2015).

Alcoholic Cerebellar Degeneration

Alcoholic cerebellar degeneration is characterized by slowly progressive ataxia and broad irregular gait; other symptoms such as slurred speech, impaired muscle control (dysarthria), and horizontal nystagmus are also reported. Postmortem pathology reveals a loss of Purkinje cells. Imaging studies show both gray and white matter deficits and hypometabolism in the anterior superior cerebellar vermis and evidence of vermal atrophy (Fitzpatrick, Jackson, & Crowe, 2008).

Alcohol-Related Dementia

Alcohol-related dementia (ARD) is a controversial clinical entity. Some argue that ARD is nonspecific neuropathological disorder given the lack of distinct etiologic mechanisms, suggesting symptoms are due to ethanol neurotoxicity, other underlying pathology, or combination of factors (Ridley et al., 2013; Schmidt et al., 2005). Diagnostic criteria were developed to improve the classification of ARD as a syndrome (Oslin, Atkinson, Smith, & Hendrie, 1998). Yet, clinical judgment continues to be a popular approach to diagnosis. Controversy aside, empirical studies reveal a correspondence between cognitive decline and the chronicity/severity of alcohol use (Oslin et al., 1998) caused by glutamate excitotoxicity, oxidative stress, and disruption of neurogenesis (Ridley et al., 2013).

Cognitive deficits in ARD are linked to quantity and recency of use and duration of abstinence, with binge drinking episodes and multiple withdrawals from alcohol exacerbating impairment (Sachdeva, Chandra, Choudhary, Dayal, & Anand, 2016). The neuropsychological profile is characterized by deficits in executive functioning, working memory, and motor speed, with sparing of language abilities (Ridley et al., 2013). ARD is rarely progressive, is most common in middle-aged individuals, and may resolve stabilize following abstinence from alcohol (Sachdeva et al., 2016). The pattern and rate of cognitive recovery is not fully understood; however, recovery of cognitive functioning appears to be related to the amount of recent alcohol use and duration of abstinence (Ridley et al., 2013).

Cognitive deficits typically persist after cessation of drinking as a result of impaired front-cortico-cerebellar functional networks. Neuroimaging evidence shows sulcal swelling, dilation of the ventricles, and prominent gray and white matter loss in the prefrontal cortex, corpus callosum, and cerebellum. Consistent with these findings, results from a single-photon emission CT study report hypometabolism in the frontal cortices, thalami, and basal ganglia. (Sachdeva et al., 2016). However, some partial structural and functional recovery after abstinence has been reported (Ridley et al., 2013; Schmidt et al., 2005).

Conclusions and Future Directions

Although it is well established that excessive alcohol consumption leads to structural and functional damage of the brain, many questions remain concerning long-term effects of alcohol use on brain health. The complex interaction between predisposing traits, environmental factors, and neurological impairments due to the synergistic effects of thiamine deficiency to ethanol neurotoxicity results in neurocognitive impairment and a number of clinical conditions. The complex and often overlapping pathologies make it challenging to achieve an exact diagnosis. Classical syndromes rarely appear isolated, and often overlap, incompletely or atypically. Indeed, multiple patterns of alcohol use, personal and lifestyle factors, and the vulnerability of specific brain regions make research about this issue particularly challenging.

Prospective studies of alcohol use on the brain in both men and women are needed to clarify whether there are sex differences in ARBD and to determine graded risks associated with alcohol consumption. Additionally, further clarification is needed to elucidate the interaction between early onset of alcohol consumption, chronic alcohol exposure, and neurodegeneration. The identification of specific mechanisms underlying ARBD will aid in accurate diagnosis and inform development of disorder-specific interventions.

Foreword

Until the 1970s, there were no books, journals, or university courses on health psychology. Although the field's intellectual roots stretch back to the beginnings of psychology more than a century ago, its formal emergence depended on a convergence of influences (Friedman & Silver, 2007), including psychosomatic medicine, social-psychological and socio-anthropological perspectives on medicine, epidemiology, and medical and clinical psychology. Today, health psychology is a principal area of significant social science research and practice, with vital implications for the health and well-being of individuals and societies. Understanding the explosive trajectory of health psychology is useful to appreciating the strengths of the field and to approaching this new encyclopedia, the *Wiley Encyclopedia of Health Psychology*.

What is the nature of health? That is, what does it mean to be healthy? The way that this question is answered affects the behaviors, treatments, and resource allocations of individuals, families, health practitioners, governments, and societies. For example, if it is thought that you are healthy unless and until you contract a disease or suffer an injury, then attention and resources are primarily allocated toward "fixing" the problem through medications or surgical repairs. This is the traditional biomedical model of disease (sometimes called the "disease model"). Indeed, in the United States, the overwhelming allocation of attention and resources is to physicians (doing treatments) and to pharmaceuticals (prescription drugs and their development). In contrast, health psychology developed around a much broader and more interdisciplinary approach to health, one that is often termed the biopsychosocial model.

The biopsychosocial model (a term first formally proposed by George Engel in 1968) brings together core elements of staying healthy and recovering well from injury or disease (Stone et al., 1987). Each individual—due to a combination of biological influences and psychosocial experiences—is more or less likely to thrive. Some of this variation is due to genetics and early life development; some depends on the availability and appropriate applications of medical treatments; some involves nutrition and physical activity; some depends on preparations for, perceptions of, and reactions to life's challenges; and some involves exposure to or seeking out of healthier or unhealthier environments, both physically and socially. When presented in this way, it might seem obvious that health should certainly be viewed in this broader interdisciplinary way. However, by misdirecting its vast expenditures on health care, the United States gives its residents mediocre health at high cost (Kaplan, 2019). To approach these matters in a thorough manner, this encyclopedia includes four volumes, with Volume 1 focusing on the biological bases of health and health behavior, Volume 2 concentrating on the social bases, Volume 3 centering around the psychological and clinical aspects, and Volume 4 focused more broadly on crosscutting and applied matters.

Key parts of health depend on biological characteristics and how they interact with our experiences and environments. So, for example, in Volume 1, there are articles on injury to the brain, alcohol effects on the brain, nutrition, drug abuse, psychophysiology, and the tools and key findings of neuroscience. Note that even individuals with the same genes (identical twins) can and do have different health and recovery outcomes, and the articles delve into such complexities of health. Of course humans are also social creatures, and people's growth, development, and health behaviors take place in social contexts. So, in Volume 2, there are articles on such fundamental matters as social support, coping, spirituality, emotion, discrimination, communication, psychosocial stress, and bereavement.

Because our approaches to and conceptions of health are heavily influenced by society's institutions and structures revolving around medical care, much of health psychology derives from or intersects with clinical psychology and applied behavioral medicine. Volume 3 covers such clinical topics as psycho-oncology, depression, drug abuse, chronic disease, eating disorders, and the psychosocial aspects of coronary heart disease. Finally and importantly, there are a number of special and cross-cutting matters that are considered in Volume 4, ranging from relevant laws and regulations to telehealth and health disparities. Taken together, the articles triangulate on what it truly means to be healthy.

What are the most promising directions for the future that emerge from a broad and deep approach to health? That is, to where do these encyclopedia articles point? One key clue arises from a unique opportunity to enhance, extend, and analyze the classic Terman study of children who were followed and studied throughout their lives (Friedman & Martin, 2012). These studies revealed that there are lifelong trajectories to health, thriving, and longevity. Although anyone can encounter bad luck, a number of basic patterns emerged that are more likely to lead to good health. That is, for some individuals, certain earlier life characteristics and circumstances help propel them on *pathways* of healthier and healthier behaviors, reactions, relationships, and experiences, while others instead face a series of contingent stumbling blocks. There are multipart but nonrandom pathways across time linking personalities, health behaviors, social groups, education, work environments, and health and longevity. The present encyclopedia necessarily is a compendium of summaries of the relevant elements of health and thriving, but one that would and can profitably be used as a base to synthesize the long-term interdependent aspects of health.

In sum, this encyclopedia is distinctive in its explicit embrace of the biopsychosocial approach to health, not through lip service or hand-waving but rather through highly detailed and extensive consideration of the many dozens of topics crucial to this core interdisciplinary understanding.

Preface

The field of health psychology is a specialty area that draws on how biology, psychology, behavior, and social factors influence health and illness. Despite the fact that the formal recognition of the field is only about a half of a century old, it has established itself as a major scientific and clinical discipline. The primary reason for this is that there have been a number of significant advances in psychological, medical, and physiological research that have changed the way we think about health, wellness, and illness. However, this is only the tip of the iceberg.

We have the field of health psychology to thank for much of the progress seen across our current healthcare system. Let me provide some examples that illustrate the diversity of these important contributions. Starting with a broad public health perspective, health psychologists have been involved in how our communities are planned and how urban development has a significant and direct impact on our health behaviors. That is, if we live close to where we work, play, and shop, we are more likely to walk or bike to our destination rather than drive or take public transportation. Focusing on a smaller, but no less important, source of data, health psychologists are involved in using information obtained from our genes to help counsel individuals to make good, well-informed health decisions that could have an impact on the individual immediately or in the future. Being well-informed can direct a person toward the best possible path toward wellness, whether it be measures aimed at prevention, further monitoring, or intervention.

Of course, there are many other contributions. For instance, data indicates that several of the leading causes of death in our society can be prevented or delayed (e.g., heart disease, respiratory disease, cerebrovascular disease, and diabetes) via active participation in psychological interventions. Knowing that we can improve health status by changing our behaviors seems like an easy "fix," but we know that behavior change is tough. As such, it is not surprising that health psychologists have been involved in trying to improve upon treatment success by examining patient compliance. When we better understand what motivates and discourages people from engaging in treatment or pro-health behaviors, we can improve upon compliance and help individuals adopt more healthy lifestyles. Health psychologists have also played a role in shaping healthcare policy via identifying evidence-based treatments. This work has direct effects on how individuals receive healthcare as well as what treatments are available/reimbursable by insurance companies. Finally, there are also factors beyond medical care to consider (e.g., economic, educational) that can lead to differential health outcomes. Thus, health psychologists likewise examine ways to reduce health disparities, ensuring that the public and government officials are made aware of the impact of the social determinants of health.

I could go on and on, however, examples like this illustrate the significant impact this broad and exciting field has had (and will continue to have) on our understanding of health and wellness. Given the constantly changing nature of the field, it is not possible to be all inclusive; however, the aim of these four volumes is to provide readers an up-to-date overview of the field. Each entry is written to stand alone for those who wish to learn about a specific topic, and if the reader is left wanting more, suggested readings are provided to expand one's knowledge. Volume I, *Biological Bases of Health Behavior,* includes entries that cover topics in the broad areas of neuroscience and biopsychology relevant to health behavior. General topics include degenerative and developmental conditions, emerging methodologies available in clinical research, functional anatomy and imaging, and gene × environment interactions. Volume II, *Social Bases of Health Behavior,* addresses topics related to theories and concepts derived from social psychology. Specifically, topics related to the self, social cognition, social perception, attitudes and attitude change, perception, framing, and pro-health behaviors are included. Volume III, *Clinical Health Psychology and Behavioral Medicine,* covers the applied aspects of the field of health psychology including practical topics that clinical health psychologists face in the workplace, behavioral aspects of medical conditions, the impact of unhealthy behaviors, and issues related to the comorbidity of psychiatric disorders and chronic health concerns. Finally, Volume IV, *Special Issues in Health Psychology,* contains a wide array of topics that are worthy of special consideration in the field. Philosophical and conceptual issues are discussed, along with new approaches in delivering treatment and matters to consider when working with diverse and protected populations.

It is my sincere hope that the *Wiley Encyclopedia of Health Psychology* will serve as a comprehensive resource for academic and applied psychologists, other health care professionals interested in the relationship of psychological and physical well-being, and students across the health professions. I would very much like to thank and acknowledge all those who have made this work possible including Michelle McFadden, the Wiley editorial and production teams, the volume editors, and of course all of the authors who contributed their outstanding work.

Preface Volume 2: Social Bases of Health Behavior

Social context plays numerous critical roles in health processes. Consider the utility of a medical diagnosis if patients do not trust their doctor or take their prescribed medication. Patients may also find that racial and gender biases can lead to different diagnoses and treatments because healthcare providers are influenced by social factors just like everyone else. Outside of medical contexts, researchers have discovered that personality predicts health and longevity and leads to different styles of coping with stressful situations. Turning to health behavior, imagine knowing what you need to do to manage a chronic illness but encountering significant barriers to changing your behavior. Finally, the presence and quality of close relationships can alter physical, as well as mental, health in myriad ways. Volume 2 of this encyclopedia aims to address the broad topic of how social influences get under the skin to affect health.

This volume is the result of an effort to provide a concise, yet comprehensive, overview of the social bases of health. We define "social" quite broadly, including factors that are clearly social in nature (e.g., communication, prejudice, romantic relationships, social support) as well as factors that are fundamentally intrapersonal and yet deeply entangled with one's social context (e.g., emotion regulation, habits, self-esteem, attitudes). We conceptualized the field as loosely falling into the following topical areas (in no particular order): (a) health behavior, (b) social cognitive processes, (c) emotions and emotion regulation, (d) stress and coping, (e) self and identity, (f) healthcare and health communication, (g) health disparities, (h) relationship processes, and (i) social factors in illness. We also include entries that address broad theories of health and health behavior, and further entries address contemporary methodological issues that commonly arise in the study of health from a social perspective.

We were fortunate to amass a set of contributing authors that represents the best and brightest in the field, both rising stars and prominent luminaries. Although space does not allow us to summarize all of the outstanding entries, we highlight a few here in an effort to capture the breadth and quality of the volume that lies ahead. Regarding theoretical contributions, Howard Leventhal and his co-authors provide an overview of nearly a half-century of groundbreaking work on illness representations, and Rick Gibbons and Meg Gerard (with Michelle Stock) outline the prototype-willingness model, their influential model of adolescent health behavior. An entry by Leona Aiken reviews decades of important research on screening behavior, Anita DeLongis (led by Ellen Stephenson) summarizes the large and complex research literature on coping strategies, Roxane Cohen Silver (led by Judith Pizarro Andersen) considers the role of trauma in health outcomes, and Robin DiMatteo (led by Tricia Miller) highlights the importance of effective physician–patient communication. Other key contributors include Alex Rothman (led by Lisa Auster-Gussman and Rachel Burns), who tackles the challenging issue of health behavior maintenance; Christine Dunkel Schetter (led by Alyssa Cheadle and Isabel Ramos), who addresses social bases of the pregnancy experience; Brenda Major (led by Tessa Dover and Jeffrey Hunger), who presents evidence for the negative health consequences of prejudice and discrimination; and Arthur Stone, who discusses the methodological contribution of ecological momentary assessment in health research.

Finally, we dedicate our volume to two contributors who passed away during the preparation of this encyclopedia, both enormous losses to the field of health psychology. Charles Carver co-authored two entries in our volume, one on dispositional optimism (with Maria Mens and long-time collaborator Michael Scheier) and one on the role of personality in coping (with Jamie Jacobs). Carver's work on dispositional optimism was inspiring, interdisciplinary, and highly influential, as evidenced by the nearly 125,000 citations to his work.

Alex Zautra co-authored an entry on physical and social pain (with John Sturgeon and Beth Darnall). Zautra's research illuminated the interplay between physical health and social aspects of life, and his work on resilience was transformative to the field of health psychology. We are indebted to Carver and Zautra for their influences on both our volume and the field, and we are deeply grateful to all of our authors for their role in what we believe to be an important contribution to the social side of health psychology.

Editor-in-Chief Acknowledgments

I would like to publicly recognize and thank my family, Michelle, Ross, Rachel, and Becca for being supportive of my work life while also providing me with a family life beyond my wildest dreams. I love you all very much. I would also like to note my great appreciation and thanks to the faculty and staff of the Doctoral Training Program in Clinical Psychology at Oklahoma State University for providing me with an opportunity to expand my education and for providing extraordinary training. In particular, I would like to thank my late mentor Dr. Frank L. Collins Jr., Dr. Larry Mullins, Dr. John Chaney, and Patricia Diaz Alexander. Further, I am grateful to the University of Mississippi and Texas Tech University (and the colleagues and students I have had the privilege to work alongside) for affording me excellent working environments and the support to do the work I am honored to be a part of. Finally, I would like to recognize and thank the volume editors for their vision and perseverance to this project as well as to each of the contributors for their excellent entries and their dedication to this very important field.

Acculturation and Substance Use

Since the 1970s, the foreign-born population in the United States has rapidly increased, reaching an all-time high of nearly 40 million (13% of the total population) in 2010 (Grieco et al., 2012). Today, the majority of foreign-born individuals residing in the United States originate from what is commonly known as the global south (i.e., Latin America and Asia). Immigrants from the global south typically hold collectivist-based beliefs (i.e., focus on the well-being of the family, clan, nation, or religion), whereas members of the receiving society typically emphasize individualism (i.e., focus on autonomy and self-sufficiency; Hofstede, 2001). The patterns of migration to the United States over the past 50 years have therefore produced cultural divides between immigrants and the society that receives them. As a result of the large and increasing flow of international migrants, coupled with these cultural divides, scholarly interest in acculturation has substantially increased over the last few decades (Schwartz, Unger, Zamboanga, & Szapocznik, 2010).

Acculturation deals with the process of blending into a new culture and refers primarily to the extent to which an individual retains his or her cultural heritage and/or adopts the new receiving culture (Berry, 1980). Acculturation and the stressors that often accompany it affect not only foreign-born individuals but also US-born individuals from immigrant families. Accordingly, there has been a growing interest in work that examines the relationship between acculturation and a wide range of positive and negative indicators of psychosocial functioning (Schwartz et al., 2010). This entry serves as a review of contemporary models of acculturation and the role of acculturation in substance use among adolescents from immigrant families. Our focus on adolescence is driven by our motivation to understand the role of acculturation in the early stages of vulnerability. In addition, this entry focuses particularly on identifying methodological and conceptual limitations that have been prominent in the field of acculturation and on pointing out how the field might best move forward.

Contemporary Models of Acculturation: Bidimensional and Multicomponent Process

Current conceptualizations of acculturation have largely grown out of what is termed the "unidimensional" view, a framework that places the acculturative experience along a single continuum ranging from "completely unacculturated" to "completely acculturated." This continuum is used to describe an immigrant's ability to blend with her/his new cultural surroundings following arrival. Although an individual could feasibly be placed anywhere on the continuum (from low to high), that person's placement essentially assumes that "successful" acculturation involves complete adoption of the receiving culture and forfeiture of their cultural heritage (Gordon, 1964). In contrast to this unidimensional view, contemporary views have increasingly cast acculturation as a bidimensional process (Schwartz et al., 2010). According to Berry's (1980) seminal acculturation model, receiving-culture acquisition and heritage-culture retention represent independent dimensions. In this respect, acquiring the culture of the receiving context does not imply that an individual will discard their own cultural heritage; rather, she/he may judiciously straddle a fence between two cultural worlds, where different cultural streams will be expressed depending on the situation at hand.

Several authors have extended Berry's (1980) original conceptualization, suggesting that acculturation is multidimensional, not only because it contains numerous cultural streams but also because it stretches across at least three relevant components: *cultural practices*, *cultural values*, and *cultural identifications* (Schwartz et al., 2010). *Cultural practices* refer to behaviors such as language use, choice of friends, and cultural customs and traditions. The vast majority of studies and measures in the acculturation literature have focused on cultural practices, emphasizing language use in particular. Extending beyond cultural practices, contemporary conceptualizations of acculturation also emphasize the importance of *cultural values* or belief systems associated with a specific context or group. Cultural values can refer to broad, cross-ethnic group values (e.g., collectivism and individualism) as well as group-specific values such as familism (strength of family ties) and filial piety (bestowing honor upon one's family). The *cultural identifications* component refers to the strength of commitment and attachment a person feels toward her/his cultural heritage and/or the culture of the receiving context.

Although early conceptualizations of acculturation examined at most one or two of these components, more recent arguments suggest that acculturation is best understood as the confluence of several components. Indeed, Schwartz et al. (2010) have suggested a model that crosses the three components of acculturation across two dominant cultural streams and yields a total of six facets of acculturation: US practices, heritage practices, individualist values, collectivist values, US identification, and heritage identification. This blending of all three components with both cultural streams provides a more complete picture that is faithful to the theoretical definitions and original conceptualizations of acculturation (Berry, 1980).

Acculturation and Substance Use

Empirical studies evaluating the relationship between acculturation and substance use among adolescent immigrants are quite limited. Moreover, despite evidence favoring bidimensional over unidimensional approaches to acculturation, the majority of studies linking acculturation to substance use have relied on unidimensional conceptualizations, demographic proxies, and/or measures that tap solely into one of three components of acculturation (Schwartz et al., 2010). Although the findings from these studies have been inconsistent, many have reported that "greater" degrees of acculturation are associated with problematic health outcomes. However, this conceptualization of acculturation leaves unclear whether the effects of acculturation on health outcomes are due to adoption of the receiving culture or to loss/rejection of the heritage culture. As of the summer of 2015, our review indicated only a handful of studies employing a bidimensional conceptualization of acculturation among first- and second-generation adolescent immigrants. Moreover, all of these studies were conducted with Hispanic adolescents. Indeed, our review did not find a single study employing a bidimensional conceptualization of acculturation among immigrant youth in countries other than the United States.

Acculturation and Alcohol Use

Using a validated measure of cultural practices, Unger, Ritt-Olson, Soto, and Baezconde-Garbanati (2009) found that US orientation among Hispanic adolescents was protective against recent alcohol use at a single point in time. However, using growth curve analysis, Unger, Schwartz, Huh, Soto, and Baezconde-Garbanati (2014) found no relationship between US or Hispanic orientations and alcohol use. Similarly, Zamboanga, Schwartz, Jarvis, and Van Tyne (2009) found no significant relationship between US or Hispanic cultural practices and alcohol use initiation or frequency.

Acculturation and Cigarette Use

Using comprehensive measures of Hispanic and US cultural practices, Zamboanga et al. (2009) and Unger et al. (2009, 2014) found significant negative associations between adolescents' Hispanic orientation and cigarette use. However, neither Zamboanga et al. (2009) nor Unger et al. (2009, 2014) found a significant relationship between US orientation and cigarette use.

Acculturation and Illicit Drug Use

For the most part, studies employing a bidimensional approach have found a Hispanic orientation was associated with a lower risk of marijuana use (Unger et al., 2009, 2014) and illicit drug use (a latent variable measured by marijuana, hard drug, inhalant, injecting, and prescription drugs; Schwartz et al., 2011).

Summary

As a whole, studies using bidimensional and multicomponent models of acculturation suggest that the loss of one's heritage practices, values, and identifications poses a greater risk for substance use among Hispanic youth. Adoption of US cultural practices, values, and identifications does not appear to pose a risk for these outcomes. The unidimensional conclusion that "greater acculturation is a risk for substance use" appears to be overly simplistic and misguided. Although the field of acculturation has begun moving toward a bidimensional and multicomponent conceptualization of acculturation, research on the role of acculturation in substance use must still address substantial theoretical and methodological limitations. Next, we outline some of these limitations and discuss future directions for the field.

Understanding the Mechanisms Between Acculturation and Substance Use

To develop culturally based prevention programs, it is essential to understand the developmental mechanisms underlying the relationship between acculturation and substance use. Although several theories have been proposed, we focus here on two of the more promising theoretical models: cultural stress and family functioning/acculturation-gap theories. Below we review these theoretical models and identify future research within each of these areas.

Disentangling Cultural Stress from Acculturation and Other Stressors

A long tradition of researchers has suggested that it is the stress associated with acculturation, rather than acculturation per se, that contributes to wide range of dysfunctional behaviors. Indeed, several theoretical frameworks have attempted to account for the process through which acculturation promulgates psychosocial stress, proposing that conflict between one's heritage and receiving cultures produces perceived/experienced cultural stress. Cultural stress comprises a variety of experiences, including perceived discrimination, negative context of reception, and bicultural stress. As a whole, the literature has consistently found that indicators of cultural stress are linked to increased risk of substance use (e.g., Tran, Lee, & Burgess, 2010).

Studies attempting to flesh out these relationships have found that acculturation is linked with cultural stressors, which in turn are associated with impaired psychosocial functioning and increase the probability of engaging in health risk behaviors (e.g., Juang & Cookston, 2009). Although these studies provide preliminary support for the role of cultural stress as a key mediator of the relationship between acculturation and substance use, it is possible that cultural stress may also function as a moderator. Specifically, the acculturation process for youth experiencing greater cultural stress may lead to feelings of being overwhelmed. Alternatively, some have posited that acculturation may instead moderate the relationship between cultural stress and psychosocial functioning. People who try to assimilate into the dominant culture but are rejected may experience the most distress (Staerklé, Sidanius, Green, & Molina, 2010). As a consequence, immigrant youth who adopt US cultural orientations may experience the negative impacts of discrimination and living in an unwelcoming context of reception. On the other hand, youth who retain and value their cultural heritage may be more likely to experience the negative impacts of cultural conflict within their own ethnic group. For example, Deng, Kim, Vaughan, and Li (2010) found that the relationship between perceived discrimination and delinquent behavior was higher for adolescents who strongly endorsed their heritage culture. The reverse pattern was found for US cultural orientation.

Moving forward, to develop a more comprehensive model, an imperative first step is to separate the "process of acculturation" from the underlying "process of cultural stress" and determine whether both contribute independently or interdependently to maladaptive outcomes. It is also essential to identify the exact nature of their relationship with one another (i.e., mediation, moderation, or both). In addition, it is important to note that studies to date have yet to determine whether culturally specific stress is unique from other forms stress (e.g., normative developmental and family economic stress). Research has also yet to disentangle the effects of these various stressors on various forms of psychosocial functioning. Thus, an additional step for future research is to evaluate the relative contributions that cultural stress and other stressors, in conjunction with the process of acculturation, exert on youth adaptation.

Family as a Developmental System

A critical step for future research requires conceptualizing the family as a holistic and constantly evolving system. Of relevance to the current entry, research in the past decade has focused on clarifying the ways in which caregivers encourage children to gravitate toward specific aspects of their cultural heritage and to avoid aspects of the receiving cultural context (Portes & Rumbaut, 2006). Umaña-Taylor, Bhanot, and Shin (2006) have referred to this phenomenon as *familial ethnic socialization*. Several studies have found that the presence of heritage cultural symbols, such as activities in the home, increases the likelihood that children and adolescents will retain or adopt their heritage culture (Umaña-Taylor et al., 2006). Regarding acquisition/rejection of US culture, however, there is evidence that caregivers' socialization attempts are less effective in shaping youths' US cultural adoption. Peers, school, and media may play a greater role than youths' primary caregivers in shaping US cultural adoption. Although scholars have emphasized the role adolescents have in transmitting US values and culture (Padilla, 2006), studies have yet to empirically examine whether adolescents have an impact on their caregivers' acquisition/retention of US and heritage cultures.

Over and above focusing on the direct role caregivers may have in shaping their child's acculturation process, researchers have highlighted that caregiver–child gaps in acculturative processes can affect family processes, cultural stress, and mental health outcomes. For example, differential acculturation theory (DAT) (Szapocznik & Kurtines, 1993) proposes that gaps between the adolescents' and caregivers' acculturation disrupt the basic emotional climate of the family. The original iteration of DAT was unidimensional, positing these gaps as emerging as adolescents, who are encouraged to adopt US cultural practices, beliefs, and norms in school, typically adopt US culture more rapidly than their caregivers, who typically settle into ethnic enclaves and avoid having to adapt to US culture (Schwartz, Pantin, Sullivan, Prado, & Szapocznik, 2006). More recent conceptualizations of DAT have employed a bidimensional approach, suggesting that family problems can emerge (a) when adolescents adopt US culture more than their caregivers or (b) when caregivers retain the heritage culture more than their adolescents do. Regarding US culture acquisition, caregivers may perceive certain US-based behaviors and/or attitudes their children have adopted as disrespectful or as a rejection of traditional ways of behaving (Portes & Rumbaut, 2006). In contrast, with regard to heritage-culture retention, adolescents' loss of their cultural heritage may make it difficult for adolescents and caregivers to communicate with each other.

Although unidimensional studies have provided mixed support, studies employing bidimensional approaches have supported DAT. For example, Unger et al. (2009) found that greater caregiver–youth discrepancies in US cultural practices were associated with recent cigarette use, whereas greater caregiver–youth discrepancies in both US and Hispanic cultural practices were associated with greater recent and lifetime alcohol and marijuana use. The effect of US discrepancies on substance use was partially mediated by levels of family cohesion. Additionally, using latent growth curve modeling, Schwartz et al. (2016) found that larger, and increasing, caregiver–adolescent gaps in Hispanic practices, collectivist values, and ethnic identity predicted poorer family functioning and greater risk for binge drinking. In contrast, larger and increasing gaps in individualist values and US identity predicted *more favorable* family functioning (and lower odds of binge drinking) over time.

As a whole, future research should continue to conceptualizing the family as a developmental system and recognize that adolescents and their caregivers are not only concurrently undergoing acculturation (Berry, 1980) but are actively working to influence each other's acculturation process. Thus, it is essential for future research to follow at least three research directions. First, it is important to further explore adolescent-to-caregiver and caregiver-to-adolescent ethnic and US socialization process by identifying the direction(s) of effects and identifying potential differences in family interactional patterns that may promote or inhibit ethnic and US socialization. Second, it is essential to provide further empirical evidence for DAT across different immigrant groups and contexts, including contexts outside the United States. Third, we should endeavor to understand the relationship between adolescent–caregiver and caregiver–adolescent ethnic and US socialization attempts over time and determine how these attempts relate to increasing adolescent–caregiver differences in US and heritage cultural adoption/retention.

Further Conceptual and Theoretical Considerations

Bicultural Integration

Although the acculturation process represents a critical task for first- and second-generation immigrants, recent research has suggested that the acculturation process extends beyond simply adopting (or not) the receiving culture and retaining (or not) the heritage culture. More specifically, first- and second-generation immigrants are also tasked with reconciling and integrating potentially conflicting heritage and receiving cultural streams across each cultural component (i.e., practices, values, identification). An unwillingness or inability to integrate across cultural streams into a cohesive mosaic may lead to problematic outcomes. Taken together, the contemporary conceptualization of acculturation paints an increasingly complex model that includes both endorsement of heritage and receiving cultural streams separately for identification, practices, and values as well as the capacity for integrating each component across cultural streams (see Figure 1).

Bicultural identity integration (BII), or the capacity and willingness to blend (vs. compartmentalize) and harmonize (vs. view as being in conflict) two potentially divergent cultures,

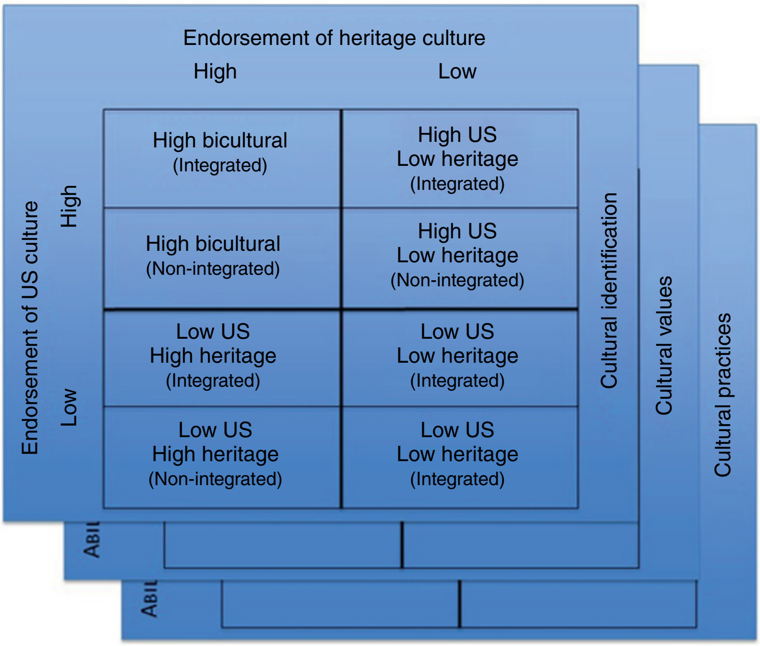

Figure 1 Multidimensional model of Acculturation. Note. The multiple layers represent a focus on several separate components of acculturation.

represents a domain of cultural integration that has received considerable attention, particularly in relation to psychosocial functioning. Indeed, a growing literature has evaluated the relationship between BII and mental health outcomes (for a review, see Huynh, Nguyen, & Benet-Martínez, 2011). Most recently, Schwartz et al. (2015) found that adolescents who maintained high levels of BII over time reported higher self-esteem, greater optimism, fewer depressive symptoms, and more favorable family relationships.

Despite this burgeoning area of research, there are a number of areas in which the links between BII and outcomes can be further extended and expanded. First, whether BII reflects an ability or capacity or a developmental construct remains a debated issue. Although recent evidence indicates that the ability to integrate multiple cultures may be stable over time (Schwartz et al., 2015), that study was limited to recently immigrated Hispanic adolescents. The findings may differ across ethnic groups, subgroups, and generation status. Additionally, and as previously stated, bicultural integration is not solely limited to cultural identification. Thus, a more complete conceptualization of acculturation will require research to extend beyond BII to cultural practices and values as well. Additionally, future studies should further explore the relationship between BII and cultural stressors. Indeed, biculturalism may represent a precarious situation where one feels pushed to adopt the receiving culture and pressured to retain one's heritage. Although experimental studies suggest individuals high in BII may be better equipped to handle cultural pressures (e.g., Mok & Morris, 2010), more research is necessary to evaluate the developmental relationship between acculturation, bicultural integration, cultural stress, and psychosocial functioning.

Acculturation as a "Multidimensional" Construct

Although contemporary models have shifted away from a unidimensional perspective and toward a bidimensional conceptualization of acculturation, some scholars have argued acculturation can involve more than two dimensions (Ferguson, Iturbide, & Gordon, 2014). Indeed, it is possible that individuals may draw on more than one heritage culture and/or immigrate to a context of reception that involves more than just one receiving culture, or a combination of the two. Scholars have typically embraced the term triculturalism to refer these situations; however, the number of distinct and recognizable cultural streams could extend beyond three. Triculturalism may emerge when ethnic-minority migrants (a) gravitate (or are directed) toward the receiving-society ethnic group to which they are most similar, (b) were part of a minority group within their country or region of origin, or (c) come to reside in a context where a hybrid "third" culture has emerged. For example, Chicano culture is a blend of Mexican and US cultures but is distinct from both, and British Indian culture is distinct from both traditional British and Indian cultural streams.

As a whole, triculturalism extends the bicultural conceptualization of acculturation. As such, for each component (practices, values, and identifications), the process of acculturation spreads across the multiple cultural streams in which the immigrant is contextually embedded. Concurrently, the immigrant is tasked with retention of one or more heritage cultures and adoption of one or more receiving cultures, as well as integrating these various cultural streams, all while coping with cultural stressors. Although triculturalism does introduce additional complexity for immigrants, preliminary research indicates that immigrants generally manage fairly well in these situations (Ferguson et al., 2014). However, additional research is necessary not only to identify the various cultural streams with which specific groups are confronted within specific contexts of reception but also to further explore how the increased difficulty and stressors involving three (or more) dimensional acculturation is associated with psychosocial functioning.

Methodological Concerns

Over and above these future theoretical and conceptual directions, it is critical for the field of acculturation to acknowledge (and deal with) prevalent methodological limitations that interfere with our efforts to understand the relationship between acculturation and drug use.

Understanding Effects of the Receiving Context

To begin with, as highlighted by Schwartz et al. (2010), many studies have made the often implicit assumption that each context of reception is equally welcoming and inviting. Context of reception refers to the individual's perception of the overall valence that the receiving society directs toward an immigrant group and the opportunity structure available to that group (Portes & Rumbaut, 2006). Although immigrants in a negative context of reception are likely to feel isolated, have difficulty finding jobs, and experience discrimination or perceive hostility, those in positive context of reception are able to aspire to succeed and achieve the "American Dream." Thus, immigration and acculturation can be conceptualized as the interaction between a specific immigrant group and the context in which they are received (Schwartz et al., 2010). Given the variability in the opportunity structure, degree of openness, hostility, and acceptance across receiving contexts (both within and across countries), it is important for research to evaluate and take into account the effects that different types communities have on immigrants.

Within-Group Diversity

Over and above the importance of context of reception, it is critical to acknowledge the high variability that exists within ethnic groups when it comes to examining acculturation. Inconsistent findings across studies may reflect a lack of consideration of these within-group differences. When studying Hispanic/Latino populations, the specific nationality of group members is important for many reasons. To begin with, immigrant groups such as Asians and Hispanics vary not just in terms of national origin but also in socioeconomic status, culture, dialect, history in the United States, skin tone, and ability to fit into mainstream US society, as well as many other factors. These factors may separately or jointly influence the acculturation process and/or the cultural stressors with which a person is likely to be confronted. Thus, these factors can result in very different immigrant experiences that may influence the acculturation process and therefore also influence psychosocial functioning, family relationships, and risks for substance use. Moreover, it is critical for future research to jointly take into account these within-group differences across various contexts. For example, the acculturation experience in Miami is likely different for Cubans, who account for the majority of the Hispanic population, have been aided by the "wet foot, dry foot" law that allows them to stay legally in the United States, and hold the majority of political and economic power (Stepick, Grenier, Castro, & Dunn, 2003), than for other Hispanic groups.

Measuring Substance Use

In addition to conceptualizing and measuring acculturation, there are important measurement considerations with regard to substance use. Specifically, it is essential to move beyond using simple dichotomous measures of drug use and composite scores that aggregate across different types of substances. For the most part, much of the literature looking at the relationship between acculturation and substance use has relied on "yes/no" coding procedures for lifetime and/or current use. Although this often is done as a result of underreporting or low base rates, it is important to recognize that using solely dichotomized outcome variables obscures important developmental mechanisms. More specifically, using yes/no variables makes it impossible to differentiate between stages of substance use (e.g., initiation, experimental use, problematic). Additionally, it is essential for future research to avoid using "composite scores" that aggregate across multiple types of substances, thereby masking potentially theoretical and developmentally meaningful differences.

The Need for Longitudinal and Large Epidemiological Studies

Perhaps two of the greatest methodological concerns moving forward pertain to study design. Specifically, the majority of the acculturation literature has relied on cross-sectional studies and community samples. Given that acculturation, broadly, represents the process of change in immigrants' cultural orientation as they adapt to life in a new cultural context, acculturation is inherently a developmental process (Schwartz et al., 2010). For this reason, it is essential for research to employ longitudinal studies that capture the progression of each component (across relevant cultural streams). Indeed, it is important to recognize that cultural components are interrelated but independent processes. Thus, change in each cultural component may proceed at different rates, in one component and not another, or in different directions (e.g., adoption of US cultural practices yet rejection of individualist values). Additionally, much of what we know about the relationship between acculturation and substance use emerges from disparate individual studies conducted in diverse parts of the United States. As a result, it is essential to design and implement large-scale epidemiological studies employing measures bidimensional, multicomponent, and well-validated measures of acculturation as opposed to unidimensional markers of acculturation and demographic proxies that previous epidemiological studies have traditionally employed (Schwartz et al., 2010).

Conclusion

As a whole, the acculturation literature suggests that losing one's heritage practices, values, and identifications is more detrimental toward substance use than adopting US cultural practices, values, and identifications. However, the scarcity of empirical studies, coupled with conceptual and methodological problems outlined in this entry, has hampered our understanding of the processes linking acculturation with substance use. Although there is considerable work to be done, we hope that the present entry will serve to stimulate innovative and informative work that further illuminates the relationship between acculturation and substance use.

Accurate Interpersonal Perception

Lauren J. Human

Department of Psychology, McGill University, Montreal, QC, Canada

Social relationships play an important role in individual functioning, shaping both psychological and physical health (e.g., Cohen, 2004). However, the more specific relationship processes that underlie these broader associations remain to be understood. One factor that may play an important role is the accuracy of interpersonal perceptions—how accurately we see and are seen by others. Specifically, being able to accurately perceive others' personality traits, such as kindness and sociability, and emotions, such as happiness and anxiety, may benefit our social interactions and relationships in ways that in turn promote better psychological and physical health. Further, being perceived accurately by others may also benefit our health and well-being. This entry considers these possibilities by selectively reviewing key research on mental and physical health-relevant correlates and consequences of accurate interpersonal perceptions, considering how accuracy relates to (a) relationship or social functioning, (b) psychological functioning, and (c) physiological functioning for both perceivers and targets.

Defining Accuracy

First, what does it mean for an interpersonal perception to be accurate? To determine whether perceptions of someone's personality or emotions are accurate, perceptions need to be compared to some type of accuracy validation measure or criterion. However, when forming impressions of real people, there is rarely one single objective criterion what for a person is truly like or what they are really feeling. As such, interpersonal perception research typically takes a "realistic accuracy" approach (Funder, 1995). Specifically, this approach utilizes a criterion, or combination of criteria, that represent a realistic approximation for what a person is like or what they are feeling, often relying upon self-reports, but also obtaining close other or behavioral indicators where possible. Thus, the degree of accuracy in a perceiver's impression of a target can be defined as the extent to which the impression maps on to a realistic indicator for what the target is like or what they are feeling. Of note, although interpersonal perceptions generally tend to contain some accuracy, there are individual differences in how accurately

people see and are seen by others (see Human & Biesanz, 2013). Thus, individuals may vary in how accurately they view and are viewed by others, and this variability may in turn have implications for social, psychological, and physical functioning.

A Brief Consideration of the Role of Bias

Although often accurate, interpersonal perceptions usually also involve some degree of bias, such as positive bias or assumed similarity. In turn, these biases may have their own implications for relationships and for psychological and physical health. Indeed, there is evidence that positivity bias and assumed similarity are associated with positive relationship processes, both in first impression contexts (e.g., Human, Sandstrom, Biesanz, & Dunn, 2013) and in romantic relationships (e.g., Luo & Snider, 2009). Given how important social relationships are to psychological and physical health (e.g., Cohen, 2004), such biases could therefore be very beneficial to individual functioning. As support, greater levels of positivity and assumed similarity in first impressions are associated with better psychological health, including higher levels of subjective well-being and self-esteem and lower levels of depression (Human & Biesanz, 2011). Thus, biased impressions of others may benefit psychological health, yet it remains to be seen whether such biases are in turn linked to physical health outcomes or related processes.

Importantly, accuracy and bias can be independent in interpersonal perceptions (see Gagné & Lydon, 2004 for review). For example, you may view a new acquaintance as more kind and intelligent than she actually is, but still be able to tell that she is more kind and less intelligent than another new acquaintance, thereby helping you to decide which person would be a better friend versus colleague. Thus, the argument that positive bias may benefit psychological and physical health does not imply that accuracy would be maladaptive. Instead, the potential consequences of accuracy may be independent of any consequences of bias.

Consequences of Accuracy: Potential Benefits

What are the consequences of accuracy for social, psychological, and physical functioning? This section will consider the evidence suggesting that accuracy may have benefits for each of these aspects of individual functioning, considering implications for both perceivers and targets.

Relationship or Social

There is growing evidence that accurate perceptions of others may have positive relationship or social consequences, independently of the benefits of positive bias or assumed similarity. In particular, among new classmates in large university courses, forming more accurate first impressions of personality was associated with greater liking initially and up to 3 months later and with spending more time together throughout the semester (Human et al., 2013). Thus, forming a more accurate first impression may facilitate relationship initiation. This may be because accurate first impressions could promote experiences such as familiarity, which fosters perceived knowing, increased social comfort during interactions, and, ultimately, greater liking (Reis, Maniaci, Caprariello, Eastwick, & Finkel, 2011). In turn, accuracy and corresponding experiences could set the stage for more positive and frequent future social interactions, promoting relationship development.

Furthermore, accuracy is argued to benefit close relationships by fostering communication and a shared reality (e.g., Ickes & Simpson, 1997). Indeed, greater accuracy in close relationships is associated with greater relationship satisfaction and positive outcomes (e.g., Luo & Snider, 2009; Neff & Karney, 2005), indicating that accuracy may promote relationship quality and maintenance. For example, more accurate personality perceptions among newlyweds promote a lower likelihood of divorce over time, at least for wives (Neff & Karney, 2005). Thus, accuracy does appear to carry positive social consequences, for both new and long-term relationships, although a better understanding of the mechanisms linking accuracy to positive social outcomes is needed.

Psychological Consequences

Given the generally positive links between accuracy and social outcomes, in both new and close relationships, it seems likely that accuracy could in turn be highly beneficial to the psychological health of the individuals involved in these social relationships—the perceivers and targets. But is there evidence to support this?

Perceivers

There are several reasons why perceiving others accurately could benefit psychological health. Specifically, the practical benefits of greater accuracy, such as improved communication, could enhance psychological well-being by enabling individuals to more effectively navigate their social worlds. In addition, the positive, relationship-enhancing consequences of accuracy could carry benefits to perceivers: if perceiving others accurately enhances relationship initiation and quality, then accuracy might in turn benefit perceiver psychological adjustment. Finally, forming accurate impressions of others may carry its own direct psychological benefits. For example, people tend to enjoy perceiving familiar stimuli (Reis et al., 2011), which accurate perceptions may facilitate. Thus, forming accurate perceptions of others may have social and psychological benefits that in turn promote mental health.

However, the evidence linking the formation of accurate perceptions to psychological health is mixed. On the one hand, there is evidence that forming more accurate perceptions of others' nonverbal behavior (e.g., reading emotion from facial expressions) is associated with better psychosocial functioning (see Hall, Andrzejewski, & Yopchick, 2009 for review). There is also evidence that forming more accurate personality perceptions is associated with better psychological functioning (Human & Biesanz, 2011). However, this appears to be due to forming more normative perceptions of others (e.g., viewing others as similar to the average personality profile), rather than achieving greater distinctive accuracy (an understanding of others' unique, differentiating traits). Thus, it is unclear whether accurate perceptions of specific others promote psychological adjustment or if a generalized understanding of other people is sufficient. Further, much of this work has been cross-sectional in nature, making it difficult to draw inferences about the direction of the associations between accuracy and psychological health.

Targets

Does being perceived more or less accurately relate to psychological health? Here, there is much stronger evidence that accuracy is associated with better psychological functioning. For example, individuals who are better nonverbal encoders (able to accurately express their emotions nonverbally) tend to demonstrate better psychological adjustment (e.g., Friedman, Prince, Riggio, & DiMatteo, 1980). Further, greater psychological well-being is associated with having one's personality be more accurately perceived by new acquaintances and close others (see Human & Biesanz, 2013 for review). These findings are often interpreted as suggesting that well-being promotes being perceived more accurately, and there is prospective data to support this interpretation (Colvin, 1993). Nevertheless, it is also highly plausible that being perceived accurately in turn benefits well-being.

To elaborate, people who are viewed more accurately may experience boosts to well-being because of the indirect social and direct psychological benefits of being accurately perceived. Specifically, if being accurately perceived promotes being better liked in first impressions (Human & Biesanz, 2011; Human et al., 2013) and relationship quality in close relationships (Neff & Karney, 2005), then targets of accurate perceptions are likely to experience enhanced psychological well-being. Further, being accurately perceived could also directly benefit well-being by enhancing experiences of self-verification (being perceived in line with one's self-views). Indeed, self-verification can be a subjectively pleasing, sought-after experience, even when feedback is negative (see Kwang & Swann, 2010). Thus, the inter- and intrapersonal benefits of being perceived accurately may help to promote psychological health. Again, more research on this topic is needed, particularly research that can disentangle causality and examine mechanisms.

Biological Processes

Perceivers

To date, there has not been much direct examination of whether forming accurate perceptions of others is associated with physical health or health-relevant processes. However, one group has found that more accurate perceptions of a romantic partner's attitudes are associated with both greater relationship satisfaction and lower ambulatory blood pressure (e.g., Sanbonmatsu, Uchino, & Birmingham, 2011). Further, more indirect evidence comes from work on expressive suppression—the tendency to hide or refrain from expressing one's emotions to others. Specifically, interacting with a target who is engaging in suppression can result in enhanced physiological reactivity for perceivers, such as increased blood pressure responses (Butler et al., 2003). This negative effect of suppression on perceivers may be at least in part because suppression may hinder a perceiver's ability to accurately perceive the target, which could in turn be psychologically and physiologically distressing for perceivers. Over time, such negative physiological responses could accumulate to carry negative physical health consequences. Thus, perceivers who are not particularly adept at accurately perceiving others, or who tend to interact with targets who are difficult to perceive, may come to experience worse physical functioning.

Targets

There has also been relatively little work examining whether being perceived accurately relates to physical health, yet initial evidence suggests there may be links. For example, adolescents whose daily experiences are viewed more accurately by their parents demonstrate better inflammatory regulation (Human et al., 2014) in the form of glucocorticoid sensitivity—the extent to which cortisol is able to dampen the production of inflammatory proteins. In addition, there is evidence that receiving information that is self-verifying, even when negative, promotes more positive physiological responses, such lower blood pressure reactivity (Ayduk, Gyurak, Akinola, & Mendes, 2013).

In addition, just as expressive suppression can elicit greater physiological reactivity in perceivers, there is also evidence that engaging in suppression can result in greater blood pressure reactivity for the target (Butler et al., 2003). Again, this may be driven in part by the stressful experience of not being able to accurately express oneself and in turn be accurately perceived. Thus, targets who have difficulty accurately expressing themselves to others, or who interact with perceivers who have difficulty accurately perceiving them, may experience negative physiological consequences. In contrast, accurately expressing oneself to others may promote more positive physiological profiles during social interactions, in turn promoting physical health over time. This is a critical area for future research, which would benefit from more experimental and longitudinal studies that examine additional relationship contexts as well as other biomarkers and clinical health outcomes.

Potential Downsides to Accuracy

Importantly, it is also possible that accurate interpersonal perceptions could carry some negative consequences. Specifically, greater accuracy in perceptions of close others' thoughts and feelings has been linked to worse relationship quality in some cases (e.g., Simpson, Orina, & Ickes, 2003). This is argued to occur when accuracy exposes individuals to relationship-threatening information (Ickes & Simpson, 1997). For example, accurate perceptions of a partner's relationship-threatening thoughts and feelings during a conflict discussion can lead to declines in feelings of closeness (Simpson et al., 2003). This could in turn have negative consequences for psychological and physical health. Indeed, more accurate perceptions of a romantic partner's relationship perceptions have been linked to greater depression (Overall & Hammond, 2012). Further, adolescents who more accurately perceive their parent's behaviors during interactions together, which may contain relationship-threatening information, report worse psychological functioning and exhibit pro-inflammatory profiles (Human et al., 2016). Although the direction of the associations is unclear in these studies, it seems plausible that perceiving others accurately may carry costs to psychological and physical health, at least when accuracy exposes individuals to negative relationship information.

In addition, it is possible that being perceived accurately could have negative implications in some cases. In particular, if one's relationship-threatening thoughts or behaviors are accurately perceived by a close other, this could be detrimental to the target as well. More generally, having one's negative traits and experiences be perceived by others may have negative consequences, especially when rejection risk is high (Kwang & Swann, 2010). For example, those with low self-esteem feel less valued by their dating partner when they disclose a personal failure to them (Cameron, Holmes, & Vorauer, 2009). Thus, in some cases, accurate self-expression and, in turn, being seen accurately may backfire, resulting in negative social, psychological, and physiological consequences for targets.

However, when people high in self-esteem disclose negative information, they experience positive social and psychological consequences (Cameron et al., 2009). Further, even individuals who may be most at risk to experiencing negative consequences by being viewed accurately (e.g., those with negative self-views) do not always experience such downsides. For example, although individuals who are lower in self-esteem feel less valued when they disclose a failure, their dating partner does not actually appear to perceive them less positively (Cameron et al., 2009). Further, individuals with more negative self-views have more positive implicit and behavioral responses to negative than positive feedback (Ayduk et al., 2013). Overall, then, more accurate interpersonal perceptions may have some negative consequences for relationships, perceivers, and targets, but in general accuracy seems to be more beneficial than not. Perhaps the ideal scenario is to pair accurate perceptions with positively biased perceptions, which is both possible and can have synergistically positive associations with social processes (e.g., Luo & Snider, 2009).

Conclusion

Overall, interpersonal perceptions play a central role in social and psychological functioning, and there is preliminary evidence that such perceptions may in turn play a role in biological processes related to physical health. In general, but with some exceptions, accurate interpersonal perceptions appear to promote positive social outcomes, which in turn may benefit both perceiver and target psychological and physical health. Although to date there is little work directly examining the links between accurate perceptions and biological outcomes, initial work suggests accurate perceptions are linked to more positive physiological profiles, making this an important topic for future research. In particular, longitudinal and experimental studies that track the influence of accuracy on health-relevant biological processes (e.g., cardiovascular, endocrine, and immune functioning) and clinical health outcomes are needed. In sum, examining the role of accuracy in interpersonal perceptions may help shed light on how social interactions and relationships come to influence mental and physical health.

Affective Forecasting

Elinor Flynn, Arpine Hovasapian, and Linda J. Levine

Department of Psychological Science, University of California Irvine, Irvine, CA, USA

People often face decisions that have major repercussions for their health and well-being. They must decide whether to undergo elective surgery or risk developing a hereditary disease, whether to take a vacation or put their money into savings, or whether to break up with their partner or stay put. To make such decisions, people do not merely tally objective costs and benefits. They also try to anticipate how happy or unhappy potential outcomes will make them. They select options that they expect will make them happy and avoid those that they expect will make them miserable. The greater the anticipated emotional impact of an outcome, the more effort people devote to attaining or avoiding it. Thus, predicting emotion, known as "affective forecasting," plays a major role in decision making, and inaccurate predictions can lead to poor choices (Loewenstein, 2007). This entry reviews when and why people show biases in affective forecasting, over- or underestimating the emotional impact of future events, with an emphasis on forecasts related to health.

Affective Forecasting and Health

The accuracy with which people predict their future feelings has powerful implications for understanding a wide range of health issues including decisions about vaccination (Chapman & Coups, 2006), addiction (Loewenstein, 2005), genetic testing and cancer screenings (Peters, Laham, Pachter, & Winship, 2014), engaging in risky sexual behaviors (Ariely & Loewenstein, 2006), and end-of-life medical decision making (Ditto, Hawkins, & Pizzaro, 2005). In fact, people's expectations about future feelings can even be the strongest predictor of their decisions about health. For example, university employees' decisions to get a flu shot were predicted more strongly by their anticipated worry and regret should they later come down with the flu than by their perceived risk of actually getting the flu (Chapman & Coups, 2006).

Physicians also need to understand how predicted emotion influences patients' decisions and that these predictions can be inaccurate. Moreover, physicians themselves may be biased

when predicting how their patients will respond emotionally to health-related outcomes. People can be subject to the same types of errors when forecasting others' emotional reactions as they are when forecasting their own (see Peters et al., 2014 for review). Policy makers evaluating the value and ethics of administering diagnostic tests for incurable conditions, such as Huntington's disease, can also benefit from an understanding of biases in affective forecasting. People's views about the value of such tests often depend on beliefs about the emotional impact of receiving positive test results. Thus, it is critically important for patients, healthcare providers, and policy makers to understand when and why predictions about future emotion are likely to be inaccurate and result in misguided or unsatisfying decisions.

Overestimating the Emotional Impact of Future Events

In pioneering work on affective forecasting, Timothy Wilson, Daniel Gilbert, and their colleagues have shown that whether people are predicting their reaction to the breakup of a relationship, achieving or being denied tenure, or the victory or loss of their favored sports team, they have a persistent tendency to overestimate the emotional impact of future events – an error referred to as the "impact bias." People expect positive events to have a greater positive emotional impact than those events later turn out to have. They expect negative events to be more devastating than they later turn out to be (e.g., Gilbert, Pinel, Wilson, Blumberg, & Wheatley, 1998; Wilson & Gilbert, 2003). People have also been shown to overestimate the emotional impact of a wide range of medical conditions including paraplegia, hemophilia, kidney disease, and diabetes. People awaiting HIV test results overestimate how happy they will feel if the test comes back negative and how distressed they will feel if the test comes back positive (Peters et al., 2014).

Two key mechanisms have been proposed to explain overestimation in affective forecasting: focalism and adaptation neglect. Focalism refers to people's tendency to focus too much on salient features of a single emotion-eliciting event when they are predicting how they will feel. In doing so, they fail to consider that other more mundane concerns and events will also occupy their attention in the future and mitigate the intensity of their emotional response (Wilson, Wheatley, Meyers, Gilbert, & Axsom, 2000). Schkade and Kahneman (1998) demonstrated this phenomenon in a study of college students' perceptions of how happy they would be if they lived in California versus the Midwest. Both Californians and Midwesterners predicted that people living in California would be more satisfied with life, when in fact the two groups rated their life satisfaction similarly. The discrepancy was due to the excessive focus of both groups on climate and the outdoors when making their predictions. When these features were prominent, predictors paid less attention to other factors such as academic opportunities, job prospects, and financial circumstances, which were among the variables rated most important to life satisfaction by individuals who were actually living in California and the Midwest.

Adaptation neglect also contributes to overestimation in affective forecasting (Gilbert et al., 1998; Wilson & Gilbert, 2003). When predicting the emotional impact of future events, particularly negative events, people tend to overlook the psychological resources and coping strategies they will draw on in the face of adversity to help them adjust to the new circumstances. Gilbert et al. (1998) found that across a wide range of situations, from failing to get tenure to receiving negative feedback about one's personality, people consistently overestimated the duration of negative emotion in part because they failed to anticipate the strength of their "psychological immune system" to combat distressed feelings.

Focalism and adaptation neglect can lead to inaccurate forecasts about the emotional impact of health outcomes. When healthy people predict what their general level of happiness would be if they had a serious illness, they often focus too much on their feelings specifically about that illness and underestimate the countervailing influence of other aspects of life, such as family and work, on their overall well-being. Healthy people also consistently overestimate the negative impact that becoming disabled would have on their well-being, a robust finding known as the "disability paradox" (Ubel, Loewenstein, & Jepson, 2005). Even after taking into account that disabled patients may adjust their interpretation of well-being and using momentary assessments of mood instead of relying on global self-reports, the well-being of disabled and chronically ill people is generally higher than healthy individuals expect it to be. Similarly, when people undergo medical testing, for instance, to determine whether they are carriers of genetic diseases, they tend to undergo a period of shock and distress after receiving a positive diagnosis, but later return to their baseline levels of well-being. Overestimating future distress can render patients risk averse and lead them to avoid diagnostics such as genetic testing and opt out of potentially beneficial treatments (Peters et al., 2014).

Overestimating future distress also makes it hard for people to predict their future preferences when making decisions about end-of-life medical treatment. For example, nursing home residents with varying levels of health and functioning were presented with health scenarios, such as being confined to bed or experiencing severe confusion (Winter, Moss, & Hoffman, 2009). The residents indicated their ideal number of future years of living with these conditions. Those who were currently in the best health indicated they would want to live significantly less time with these conditions than those in the worst health. Thus, healthier residents viewed declines in their health as more intolerable than did individuals who had experienced some of these health problems themselves. Healthier residents did not anticipate the extent to which people adapt to declining health and maintain the will to live. More generally, studies examining people's desire for life-sustaining treatment have found considerable variation in their preferences over time, further calling into question people's ability to accurately anticipate their future feelings and preferences (Ditto et al., 2005).

Investigators have explored how to promote more accurate forecasts. Focusing narrowly on the most uncomfortable or stressful elements of a condition can lead people to fail to consider the many aspects of their lives that will remain unaffected by their condition. Consequently, one strategy for reducing focalism and improving forecasts asks people to consider the wide range of activities and situations they will be engaged in before predicting their future level of emotional well-being (e.g., Wilson et al., 2000). Interestingly, although this strategy has proved successful in other situations, defocusing exercises have been shown to be ineffective, and even to backfire, in forecasts about disability. Asking people to imagine how becoming paraplegic or undergoing amputation below the knee would impact various aspects of their life, including spiritual life, romantic relationships, and social ties, actually resulted in *lower* subsequent estimates of well-being (Ubel et al., 2005). Thus, defocusing may not be a promising way to help people think about chronic disability.

Interventions aimed at reducing adaptation neglect have proven more successful than those aimed at reducing focalism for promoting accurate forecasts of emotional responses to illness and disability. When participants reflected on a prior life event that had inspired great happiness or great sadness and then considered whether those feelings had become stronger or weaker over time, they predicted that their quality of life, if they were to become paraplegic, would be significantly higher (Ubel et al., 2005). These findings suggest that for improving affective forecasts concerning health, interventions that enhance awareness of adaptation may be more fruitful than interventions that reduce focalism. Halpern & Arnold (2008) advised that when consulting with a patient who has just received a difficult diagnosis, physicians ought to first attend to the patient's emotional distress and then encourage the person to reflect on coping strategies they used to get through other challenges in life. Urging patients to allow a significant amount of time to pass between an initial consideration of healthcare options and making a final decision may also combat adaptation neglect.

In summary, events often elicit short-lived emotional responses that are followed by relatively quick adaptation. As people's goals and expectations change, and as other events capture their attention, they think about the focal event less often. But people often fail to take these changes into account when predicting their emotional responses. They expect to think about positive and negative outcomes more than they actually do (focalism) and fail to anticipate how quickly they will adapt to negative outcomes (adaptation neglect). As a result, they tend to overestimate the impact that events will have on their overall emotional well-being (e.g., Gilbert et al., 1998; Wilson & Gilbert, 2003; Wilson et al., 2000).

Underestimating the Emotional Impact of Future Events

Although people often overestimate the emotional impact of future events, the opposite bias has also been demonstrated. Research on "empathy gaps" shows that when people are in a "cold," affectively neutral state, it can be hard for them to anticipate the intensity of future "hot" emotional and physiological states. As a result, they underestimate the power of those future feelings to drive their thinking, preferences, and behaviors (e.g., Loewenstein, 2007; Van Boven, Loewenstein, & Dunning, 2005). People have been shown to underestimate the intensity of their future urges to eat, smoke, drink alcohol, gamble in Las Vegas, and engage in risky or unethical sexual behavior (see Loewenstein, 2007 for review). For example, compared with men who were not aroused, men who were sexually aroused reported being more likely to be able to imagine having unprotected sex, being attracted to a 12-year-old girl, and slipping a woman a drug on a date (Ariely & Loewenstein, 2006).

People also underestimate the intensity of both emotional pain, such as embarrassment, and physical pain. Van Boven et al. (2005) found that people underestimated the influence embarrassment would have on their own and others' willingness to engage in public performances such as miming or dancing. Similarly, Read and Loewenstein (1999) evaluated participants' willingness to undergo a painful task in the laboratory (immersing a hand in ice water) for monetary payment. Participants who had immersed their hand in ice water a week prior asked for significantly less compensation than those who had immersed their hand just moments before. A group who had never done the task demanded the lowest payment of all. Although participants understood that the task was painful, those who had completed it a week ago, or had never completed it, had a hard time recalling or imagining the degree of pain and consequently underestimated the intensity of future pain.

Even after recognizing forecasting errors, people do not permanently adjust their preferences. Christensen-Szalanski (1984) asked pregnant women about their preferences regarding the use of anesthesia during childbirth at several time points: weeks before giving birth, while in labor, and afterward. Weeks before going into labor and during the early stages of labor, many women expressed a preference for natural childbirth without anesthesia. However, as the labor continued and their discomfort increased, the women's preferences shifted toward desiring medication. The women had experienced an empathy gap between their idea of how natural childbirth would feel and how it felt in reality. Most striking, however, were the women's evaluations 1 month after childbirth. By this point, their preferences had returned to their pre-labor position, and they again favored childbirth without anesthesia, which suggests that they again underestimated the level of pain they had experienced during childbirth.

Interpersonal empathy gaps may arise between physician and patient when discussing treatment options. For instance, physicians in an affectively "cold" state may fail to appreciate the degree of pain a patient is experiencing and therefore under-prescribe pain medication. Empathy gaps may also help to explain the callous bedside manner of certain physicians, a source of complaint for many patients and their families. After many years of handling similar cases, physicians may have adapted to negative health outcomes and thus may have difficulty anticipating the emotional impact of the news they bear (Loewenstein, 2005).

Identifying People's Forecasting Strengths and Weaknesses

Findings concerning the impact bias and empathy gaps reveal a clear tension in the research literature on affective forecasting. It is highly unlikely that people would show an impact bias, overestimating the emotional impact of future events, and simultaneously show an empathy gap, underestimating the impact of future emotion on their thinking, preferences, and behavior. For instance, if people predict that singing in public will be more embarrassing than it later turns out to be (impact bias), it is unlikely that they will underestimate their reluctance to sing (empathy gap). Moreover, people sometimes forecast emotion with striking accuracy (Levine, Lench, Kaplan, & Safer, 2012, 2013). To address these inconsistencies, researchers have examined the context in which an emotional experience occurs, the specific features of emotion people are asked to predict, and the procedures that researchers use to assess forecasting accuracy. This work sheds light on important moderators of the magnitude and direction of affective forecasting biases.

Lench, Safer, and Levine (2011) found that focalism can lead to either over- or underestimating the emotional impact of events depending on the context in which the event occurs. Students who were in a romantic relationship predicted how they would feel if they broke up with their partner. One group predicted how they would feel on February 7th and the other group predicted how they would feel on February 14th. Weeks later, those who had broken up with their partners reported their actual feelings on either February 7th or 14th. Students who rated their levels of distress on February 7th showed the expected impact bias—they had exaggerated how distressed they would feel. But students who rated their feelings on February 14 felt *worse* than they had anticipated, showing a reversal of the impact bias. When making their predictions, students underestimated how the connotations surrounding Valentine's Day would conspire to focus their attention on their lack of a relationship and intensify their negative emotions. Thus, the context in which an event occurs can determine the direction of bias in affective forecasting.

The magnitude and direction of forecasting bias also depends on the feature of emotion people are trying to predict: intensity versus duration or frequency. The impact bias is believed to characterize predictions about all of these features of emotion, and most forecasting studies do not distinguish between them (Wilson & Gilbert, 2003). However, in a series of studies and a meta-analysis of forecasting research, Levine et al. (2012, 2013) showed that although people overestimated when making judgments that encompassed the *duration* of future emotion (how happy they would feel in general), they were strikingly accurate when judging the *intensity* of future emotion (how happy would they will feel about a specific event). For example, people overestimated their reaction to the outcome of the 2008 US presidential election when they were later asked to report how they were feeling in general without reference to the election. This bias was eliminated, and participants were far more accurate, when they were asked, "How happy are you feeling about Barack Obama being elected President?" Indeed, they showed a slight but significant tendency to underestimate emotional intensity, revealing an empathy gap rather than impact bias. These findings suggest that mispredicting the duration or frequency of emotion, rather than its peak intensity, accounts for people's tendency to overestimate the emotional impact of events.

This distinction has important implications for decision making. Peak intensity provides an index of how good or how bad an experience will be, whether one has the resources to cope with it, and the amount of effort it is worth expending to achieve or avoid it (Fredrickson, 2000). Indeed, the intensity of emotion people expect to feel while an experience is occurring is often a primary determinant of whether they engage in an activity or avoid it (e.g., potentially painful medical procedures). Even when making life-altering decisions concerning career, marriage, and children, people consider the peak positive and negative feelings that different choices will bring about, as well as longer term effects on their emotional well-being. Thus, accuracy in predicting emotional intensity bodes well for decision making (Levine et al., 2012, 2013).

Further research is needed, but three factors may contribute to greater accuracy in predictions of emotional intensity compared to duration or frequency. First, as emotional intensity increases, attention narrows to focus on central or salient features of events at the expense of more peripheral features (for a review, see Levine & Edelstein, 2009). People also tend to focus on an event's salient features when predicting the intensity of their feelings. Thus, the features of an emotion-eliciting event that are central at the time when people are attempting to predict their future emotional reaction to an event are also likely to be salient when they later experience the event, promoting accurate forecasts. Second, people may draw on their appraisals of an event's importance when attempting to predict the intensity of their emotional response. Stability in people's appraisals of the importance of events for their goals would contribute to accuracy in predicting the intensity of emotion. Third, the peak intensity of past emotional episodes is remembered more accurately than their duration (e.g., Fredrickson & Kahneman, 1993), providing a better basis for prediction (Levine et al., 2012, 2013).

Finally, the degree of bias people display in forecasting emotion depends on how researchers conceptualize accuracy and on the procedures they use to assess accuracy. A meta-analysis of affective forecasting studies showed that although people are often inaccurate in their forecasts in an absolute sense, they are more accurate in a relative sense (Mathieu & Gosling, 2012). That is, people who predict they will feel the greatest emotion often end up feeling the greatest emotion, even if the absolute degree of emotion experienced ends up being less than expected.

Levine et al. (2012) found that procedures commonly used to assess forecasting accuracy can artificially increase the magnitude of the impact bias. In most forecasting studies, researchers ask participants to imagine that an event has occurred and rate how they will feel in general after a specified period of time. After that period of time has passed, researchers ask participants to report how they are feeling in general without reference to the focal event. Levine et al. found that in the context of having just been asked to imagine a specific future event, most participants interpret the request to predict how they will feel *in general* as asking how they will feel when they are later thinking about that specific event. When the intended meaning of the question was clarified, participants still overestimated the impact of events on their general emotional state, but the magnitude of bias was dramatically reduced. Thus, future research on affective forecasting should assess people's ability to predict specific features of their emotional experiences and ensure that they clearly understand the features they have been asked to predict.

In conclusion, life is much harder when one cannot foresee what lies ahead, and people's inability to accurately predict the emotional consequences of their choices can lead to poor decisions and unhappiness. The research literature contains conflicting findings concerning the magnitude and direction of forecasting biases. However, taking a more nuanced approach to investigating people's ability to predict specific features of emotion helps to resolve these seemingly contradictory findings and sheds light on people's forecasting strengths and weaknesses. Recent findings suggest that people are fairly accurate at predicting the intensity of emotion they will experience in the future when emotion-eliciting events come to mind and may even underestimate that intensity (Lench et al., 2011; Levine et al., 2012). But people tend to exaggerate how frequently they will think about emotional events, and they neglect to consider the strategies they will use to cope with their emotions. As a result, they often overestimate the frequency and duration of their emotional responses (Wilson & Gilbert, 2003, 2005). Given that people predict some features of emotion more accurately than others, further research is needed to identify which features people spontaneously forecast in order to make decisions in their daily lives. Understanding sources of accuracy and bias in affective forecasting can help healthcare professionals guide people as they confront decisions concerning predictive genetic testing, end-of-life medical provisions, treatments for addiction, and other health-related issues.

Elinor Flynn is a doctoral student in the Psychology and Social Behavior Department at the University of California, Irvine. She received a BA with honors in English from Princeton University. Her research focuses on the factors that influence the development of children's emotion regulation, how emotions influence judgment and decision making, accuracy and bias in predicted emotion, and moral psychology.

Arpine Hovasapian is a doctoral candidate in the Psychology and Social Behavior Department at the University of California, Irvine, where she also received an MA in social ecology. Her research investigates the processes by which emotions are expressed, communicated, and regulated, with a focus on the interpersonal context. Specifically, she studies the nonverbal expression of pride and joy, how sharing life experiences with others influences emotions, and the effects of reappraisal on memory for pain.

Linda J. Levine is a professor of psychology and social behavior at the University of California, Irvine. She received an MEd from Harvard University and PhD from the University of Chicago, both in psychology. Her research focuses on the cognitive and motivational processes that evoke emotions; how emotions influence the features of events people attend to, find important, and later remember; biases in predicting and remembering emotions; and the development of children's ability to regulate emotions.

Social relationships are a central component of human existence; they influence the way we think and act in nearly every situation. The *quality* of our relationships is also important for both mental and physical health. For example, people whose relationships are more stable and secure, and those with larger social networks, are generally happier and healthier. Yet not everyone approaches relationships in the same way. Some people are relatively self-reliant and independent, choosing to maintain distance from relationship partners; others continually seek support from their relationships and need relationship partners to be available at all times. How do these kinds of differences, also known as *individual differences in attachment*, influence physical health?

In this entry, we discuss how a person's *attachment orientation*, or characteristic approach toward close relationships, is associated with health behaviors and outcomes. Our main focus is individual differences in *adult* attachment and their implications for health, rather than early childhood attachment to a primary caregiver. We also focus on individual differences in close relationship processes, as opposed to close relationships more broadly (see Ge, Lembke, & Pietromonaco's entry in this volume for a review of intimate relationships and physical health outcomes). First, we provide an introduction to attachment theory and describe how social-personality researchers typically study attachment orientation in adults. Next, we discuss the state of current research linking adult attachment with health. We then turn our attention toward the mechanisms that may underlie these links to explain *how* and *why* individual differences in attachment might be related to physical health. We conclude by highlighting future theoretical and methodological directions that can help elucidate when and for whom attachment processes influence health.

What is Attachment?

Attachment theory was originally conceptualized to describe the emotional bond between an infant and his or her primary caregiver and the anxiety that occurs upon separation from that caregiver (Bowlby, 1969). Social-personality psychologists later noted the many similarities between a child's first relationship with caregivers and subsequent social relationships (e.g., with friends, small groups, coworkers, and especially romantic partners; Hazan & Shaver, 1987). Over the last several decades, these observations have contributed to the emergence of attachment theory as a dominant framework for understanding thoughts, feelings, and behaviors in close relationships across the lifespan.

Attachment researchers also highlight the importance of individual differences in the quality of close relationships across the lifespan, otherwise known as *attachment orientation*. These differences are generally conceptualized by a person's position on two relatively independent dimensions: attachment-related anxiety and avoidance. The *anxiety* dimension reflects "hyperactivation" of the attachment system and often manifests in an obsessive concern over the availability of attachment figures. People with higher levels of attachment anxiety tend to have more negative views about the self and others, worry about being abandoned, and become easily overwhelmed by interpersonal stressors (Mikulincer & Shaver, 2008). The *avoidance* dimension is characterized by chronic attempts to deactivate or inhibit the attachment system (Edelstein & Shaver, 2004). People with higher levels of avoidance have more negative views of others (but not necessarily the self), are uncomfortable with physical and emotional intimacy, and try to minimize the experience and expression of distress. People with low levels of both anxiety and avoidance are considered "secure" and are typically comfortable with interpersonal closeness and intimacy. Secure individuals are more likely to have relationships that are characterized by trust and commitment compared with their insecure (anxious and avoidant) counterparts. As described next, one's attachment orientation also plays a critical role in physical health throughout the lifespan.

State of the Current Research Linking Attachment Orientations with Physical Health

Individual differences in attachment have been consistently linked with physical health outcomes. Attachment-related anxiety is a particularly robust correlate of physical health conditions that involve the cardiovascular system, such as stroke and heart attack. For example, people with high levels of attachment anxiety may have lower levels of cardiac vagal tone (Diamond & Hicks, 2005), which has been linked with early mortality and other negative health outcomes. Associations between anxiety and cardiovascular function may be attributed, in part, to chronic exposure to high levels of stress, which can impact a variety of physiological processes. In this vein, anxious people also report more physical health symptoms, such as headaches and digestive issues (Feeney & Ryan, 1994); anxious individuals with a diagnosed illness, such as irritable bowel syndrome, also report more severe symptomology compared with less anxious people.

Attachment avoidance has been less consistently linked with physical health, but avoidant people may still be at greater risk for physical health problems. Characteristics of avoidant attachment—such as suppressing negative emotions—contribute to a number of health problems, especially those involving pain, such as migraines and rheumatoid arthritis. In addition, like attachment anxiety, avoidance is associated with poor heart rate regulation. For instance, more avoidant individuals have decreased vagal tone (McWilliams & Bailey, 2010), which also puts them at higher risk for cardiovascular problems. However, much remains to be understood about the mechanisms that may underlie attachment-related differences in health, that is, *how* and *why* attachment may be associated with physical health outcomes. We turn to these potential mechanisms in the following sections.

Mechanisms Linking Individual Differences in Attachment with Physical Health Outcomes

How might individual differences in attachment influence physical health? In the following sections, we focus on four of the most commonly investigated mechanisms that have strong implications for health and well-being: social support, health behavior, emotion regulation, and physiological response systems.

Social Support

Attachment orientations have been linked with social support, which is a strong predictor of health. For instance, people with stronger social support networks consistently report fewer health problems, including fewer cardiovascular conditions, lower rates of infectious disease, and even lower mortality rates from cancer than those without such support. Importantly, attachment orientations influence people's perceptions about the *availability* of social support: anxious people often feel a lack of support from close others, despite evidence to the contrary; avoidant people are less likely to acknowledge that they need support at all (Ognibene & Collins, 1998). Securely attached people view others as reliable sources of support and tend to make accurate appraisals about the amount of social support that is available to them (Ognibene & Collins, 1998). Differences in beliefs about the availability of support could be an important link between attachment orientation and physical health outcomes.

Attachment-related differences in physiological responses to social interactions in everyday life can also affect physical health. For instance, anxious adults exhibit increases in blood pressure while engaging with friends, indicating a state of hyperarousal not typically seen among less anxious individuals (Gallo & Matthews, 2006). Avoidant people similarly show a marked increase in blood pressure during relationship conflict compared with those who are less avoidant (Gallo & Matthews, 2006), which may reflect attempts to stifle emotions or avoid intimate conversation. Although these individual differences in regulatory systems may seem minor at first glance, the cumulative effects of stress can have a major impact on health across the lifespan (Maunder & Hunter, 2001; Robles, Brooks, Kane, & Schetter, 2013). Yet, despite the importance of social interactions for health and well-being, surprisingly little research has been conducted to examine whether differences in social support or social interactions underlie attachment-related differences in physical health outcomes.

Health Behavior

Individual differences in attachment are associated with a range of behaviors that directly impact health, including diet and eating habits, smoking, risk taking, and sexual behavior. For example, people with higher levels of attachment anxiety report more distress about their weight than less anxious individuals in the same weight range, indicating a preoccupation with body image. Yet anxious individuals report exercising *less* than their nonanxious counterparts (Ahrens, Ciechanowski, & Katon, 2012). Moreover, women with anorexia nervosa (restricting and binge–purge subtypes) or bulimia nervosa report significantly higher levels of anxiety and avoidance than women without a diagnosed eating disorder (Illing, Tasca, Balfour, & Bissada, 2010). Attachment anxiety is also associated with greater symptom severity and poorer treatment outcomes among women with an eating disorder, regardless of the subtype (Illing et al., 2010). These associations suggest that there may be some overlap in the mechanisms that contribute to attachment insecurity and disordered eating. Specifically, restrictive eating behavior may be a way to create distance from the self, a characteristic of avoidant attachment; overeating or binging, in contrast, may be an expression of unregulated emotion, which is related to anxious attachment (Zachrisson & Skårderud, 2010).

Avoidance is also associated with risky health behaviors, including smoking and not wearing a seat belt (Ahrens et al., 2012; Zachrisson & Skårderud, 2010), both of which can contribute to poor health outcomes. Failure to wear a seat belt increases the likelihood of suffering a serious injury in a car accident; long-term smoking sharply increases the probability of health issues, including breast, lung, and throat cancer (Silverberg & Ratner, 2015). Perhaps not surprisingly, both risk behaviors reflect some degree of compulsive self-sufficiency or self-reliance, a key characteristic of avoidant attachment. Smoking is often used to reduce anxiety; not wearing a seat belt could reflect the rejection of others' concerns about safety or of societal norms more generally.

Both attachment avoidance and anxiety have also been linked with risky sexual behavior, which could contribute to long-term health outcomes by increasing rates of sexually transmitted infections (STIs). As an example, anxious women are less likely to know details about their partners' sexual history and are more likely to have consensual but unwanted sexual encounters (Ahrens et al., 2012; Maunder & Hunter, 2001). These differences might reflect anxious women's need for acceptance and approval, which could make it difficult for them to say "no" to a partner or to engage in conversations about safer sex practices. Among young adults, attachment avoidance has been linked with endorsement of casual sex (Gentzler & Kerns, 2004) and increased likelihood of engaging in sexual intercourse with a stranger, which could increase risk for unplanned pregnancy and contracting STIs.

Finally, there are attachment-related differences in the extent to which people report health symptoms and follow instructions given by a physician. Although anxious people are more likely to report health issues than those who are secure or avoidant (Ahrens et al., 2012), they may become frustrated if medical problems persist and may even sabotage their own treatment (Feeney & Ryan, 1994). In contrast, avoidant people who experience chronic pain are less likely to seek help in general and may be less likely to comply with treatment (Mikail, Henderson, & Tasca, 1994). Secure people with chronic pain disorders are more likely to see a doctor, comply with a prescribed course of treatment, and seek social support when dealing with pain (Mikail et al., 1994). Thus, attachment-related differences in health behavior may be an important reason for attachment-related health disparities. Health interventions that align with a person's attachment orientation may, therefore, be more effective than general interventions. Perhaps anxious people would respond more favorably to group interventions (e.g., Weight Watchers or group therapy). Anxious individuals' need for approval from group members could increase their motivation to achieve health goals. Avoidant individuals, in contrast, might be more receptive to interventions that do not include others (e.g., self-education or informational videos).

It is important to note, however, that many studies of attachment-related differences in physical health behaviors utilize relatively small samples that are homogenous with respect to participant age and other important demographics (e.g., social class). More research is needed with larger and more diverse samples to determine whether extant findings are generalizable to the population as a whole.

Emotion Regulation

When experiencing a strong emotion, such as anger, fear, or excitement, physiological alterations occur in multiple systems of the body (e.g., cardiac functioning, blood pressure, stress levels). Depending on how often and the degree to which an emotion is experienced, fluctuations in regulatory systems can have a direct impact on health. Moreover, insecurely attached people are more likely to use emotion regulation strategies that either exaggerate or inhibit emotions, which can have the consequence of *increasing* negative emotions, stress, and physiological reactivity.

For instance, anxious individuals are more likely to utilize strategies centered on managing negative emotions, such as rumination, and often envision worst-case scenarios when attempting to control emotions (Mikulincer & Shaver, 2008). Doubts about a partner's availability can trigger repetitive worry about abandonment that further exacerbate painful feelings and thoughts. Avoidant individuals learn early in life that expressing emotions or seeking support from others can lead to rejection. As a result, people with avoidant attachment orientations try to limit their distress by suppressing their emotions and by not seeking support in order to avoid rejection or unwanted closeness (Edelstein & Shaver, 2004). In contrast, people with a secure attachment orientation generally report less negative emotional reactions to distressing situations and are more likely to use support-seeking strategies to regulate their emotions, which, as described earlier, can have important health benefits.

The association between insecure attachment and poor emotion regulation skills may reflect the influence of stress on neural processes. Stress is linked with low cell density in the hippocampus, an area of the brain that assists in emotion regulation (Mikulincer & Shaver, 2008). Higher levels of stress may reduce the density of cells in the hippocampus and impact one's ability to effectively process and handle emotions. Similar to disorders that have accompanying emotion regulation difficulties (e.g., depression and PTSD), both anxious and avoidant attachment are associated with lower cell density in this region of the brain (Quirin, Gillath, Pruessner, & Eggert, 2010). However, it is not yet clear whether emotion regulation and stress lead to lower cell density, or whether lower cell density in this region of the brain leads to poor emotion regulation and stress (see section on biological mechanisms for further discussion of attachment and stress). Thus, more research is needed to determine the directionality of these associations.

In addition to reduced hippocampal cell density, attachment anxiety is associated with increased activity in the anterior temporal pole, a brain region associated with sadness and emotional memory retrieval (Quirin et al., 2010). Overstimulation of these regions, which can happen during relationship conflict, can make it difficult for people to recover memories. The association between anxious attachment and emotional memory retrieval may explain why anxious individuals find it difficult to recall positive memories during conflicts (Dolan, Lane, Chua, & Fletcher, 2000); this difficulty may, in turn, increase sadness and stress.

Physiological Response Systems

Biological processes may provide another important link between individual differences in attachment and health outcomes. When an environment is perceived as threatening or uncontrollable, the hypothalamic–pituitary–adrenal (HPA) axis is activated, and its product, the steroid hormone cortisol, is released into the bloodstream. Although short-term stress responses are generally adaptive, more chronic HPA activation can be problematic for health. People with maladaptive stress response patterns are at greater risk of cardiovascular disease, stroke, and lower well-being. Importantly, there are attachment-related differences in the basic functioning of the HPA axis. For example, insecure individuals report more stress and display an abnormally high cortisol response during disagreements with their romantic partner compared with secure adults (Kafetsios & Sideridis, 2006). Attachment avoidance has also been associated with lower levels of estradiol (Edelstein, Kean, & Chopik, 2012), another steroid hormone that can help to attenuate physiological stress responses.

Individual differences in attachment also influence the body's ability to effectively defend against infection, disease, and illness. To illustrate, attachment anxiety is linked with multiple indicators of a disrupted immune response during relationship conflicts. This may be a result of anxiously attached individuals' generally poor conflict management skills and their tendency to be more psychologically aggressive during conflict (Turner & Langhinrichsen-Rohling, 2011). Turner and Langhinrichsen-Rohling (2011) suggest that anxious individuals' aggressive tendencies might result from attempts to coerce their partner to meet their needs or keep their partner from withdrawing during conflicts. However, psychological aggression in an attempt to keep one's partner close and prevent abandonment can make relationship conflicts even worse. Not surprisingly, more negative conflicts are associated with greater stress, and this stress can often be seen at the biological level. Indeed, psychological aggression during conflict is linked with decreased immune cell function and larger increases in interleukin-6 (IL-6, a common measure of immune functioning) up to 18 hr after a conflict (Péloquin, Lafontaine, & Brassard, 2011). Increased IL-6 levels, in turn, are linked with a number of poor health outcomes, including cardiovascular disease, diabetes, and even some forms of cancer (Kiecolt-Glaser et al., 2005). Similar associations have been uncovered with other measures of immune functioning; for example, people with higher levels of attachment anxiety have fewer helper and killer T cells, which aid in the destruction of cells in the body that are infected with cancer or viruses or that have been damaged in some way.

Trans-epidermal water loss is an indicator of wound healing (skin barrier recovery) and provides yet another measurement of an individual's immune system functioning. In one study, couples experienced a relatively painless tape-stripping procedure before participating in a conflict discussion (Robles et al., 2013). The amount of trans-epidermal water loss was measured for 2 hr after skin disruption. Among women, higher levels of attachment anxiety predicted *faster* wound healing, but among men, higher anxiety predicted *slower* wound healing. Robles et al. (2013) posit that providing and receiving support may be more threatening for anxious men than for anxious women due to gender differences in social norms and socialization pressures, which could decrease the efficiency of anxious men's immune system functioning.

Avoidant attachment has been less consistently linked with immune function. In one study, avoidant individuals produced more IL-6 in response to relationship conflict and had a greater pro-inflammatory cytokine response (Gouin et al., 2009), suggesting a limited ability to fight off infection and inflammation. Although some cytokines are anti-inflammatory and are good for maintaining overall health, pro-inflammatory responses accelerate disease progression and are associated with poorer health outcomes (Kiecolt-Glaser, Gouin, & Hantsoo, 2010). However, in another study, avoidant attachment was not associated with immune functioning (Kiecolt-Glaser et al., 2010).

It is important to note that measures of stress, cortisol reactivity, and immune function should be considered in the broader context of biomarkers that, if dysregulated, *could* have implications for poor health outcomes. As an example, it is not yet clear whether the association between attachment insecurity and cardiovascular disease can be explained by a heightened stress response, unhealthy behaviors such as smoking, a lower likelihood of healthcare utilization, or a combination of all of these factors (and likely others). It does seem clear, however, that biological processes can help to explain links between attachment and health. It will be important for future research to assess both psychological and physiological processes to better understand the influence of adult attachment orientation on health outcomes. Such integrative research is an ambitious endeavor, but it is essential for theory development.

Future Directions

Situating Attachment Theory and Health Within a Dyadic Framework

To date, most studies of attachment and health have examined relations among preventative behaviors, stress-related emotions and behavior, and physiological and neuroendocrine responses to interpersonal stress at the individual level. Recently, however, researchers have attempted to situate the effects of attachment orientations on health within a relational, or *dyadic*, framework. A dyadic framework is critical because many of the proposed mechanisms linking close relationships with health (e.g., support, perceived partner responsiveness, relationship satisfaction) are hypothesized to occur between relationship partners (Jaremka et al., 2013). Generally, one romantic partner's positive psychological characteristics and health behaviors are thought to benefit his/her partner's physical well-being.

Pietromonaco, Uchino, and Dunkel Schetter (2013) argue that individual differences in attachment interact with relationship processes to influence physical health outcomes. According to their theoretical model, individual differences in attachment influence interpersonal behavior in stressful situations, such as major life transitions (e.g., pregnancy and parenthood) and acute relationship conflicts. For instance, in a stressful situation, avoidant adults may be less likely to seek out support from a romantic partner and more likely to try to suppress their emotions. As a result, avoidant adults may feel particularly stressed; their stress response system may become overly active, and/or they may engage in unhealthy behavior. Greater stress responses and deleterious health behaviors, in turn, can increase the likelihood for poor health outcomes and disease. Importantly, this model also accounts for the influence of a partner's dispositions and behavior on an individual's health. For example, an avoidant person may be less likely to provide support to a loved one who is particularly stressed; she/he may even undermine a partner's efforts to fix a problem. These kinds of interactions could increase feelings of stress, and the associated physiological stress responses, in turn increasing the likelihood of poor health outcomes and disease.

Although there is growing empirical support for Pietromonaco et al.'s (2013) model, important questions remain to be addressed by future research. For instance, the psychological and physiological variables assumed to mediate associations between attachment orientations and health outcomes are not often tested. Little is known about how both partners' attachment orientation might predict relationship processes (e.g., responsiveness, satisfaction, commitment) and health behavior that lead to poorer physical health outcomes over time. Parts of this model have been tested, but it has yet to be evaluated in full. Even less is known about pathways linking attachment orientations to dyadic interactions, and ultimately to health, among middle-aged and older adults. Most studies of attachment involve younger adults and couples; the challenges that middle-aged and older couples encounter are often unique to their stage in life and differ from that of a younger population. Perhaps the consequences of these processes *accumulate* over time, only arising after people have been in relationships for many years (as would be the case for middle-age and older adults). Other age-graded responsibilities (e.g., children, work, retirement, caregiving) may also exert additional stress that is not well accounted for by the theoretical model.

Future research on attachment and health outcomes should implement dyadic and longitudinal research designs and focus on more objective measures of health. For instance, people with anxious attachment styles report more health symptoms, but it is unclear whether they are simply more likely to report poorer health, or if they objectively experience more health symptoms. Another fruitful avenue for future research is examining the developmental antecedents of the attachment–health link. In addition to focusing on self-reported health among insecure individuals, it is important to look at early childhood attachment experiences as they relate to the diagnoses of specific diseases in adulthood.

Examining Prospective Associations Between Attachment and Physical Health

Much of our discussion thus far has focused on links between individual differences in attachment and health in cross-sectional and isolated, short-lived settings (i.e., during a single interaction task or a laboratory stressor). However, many of the mechanisms that are hypothesized to link attachment to health, such as allostatic load (i.e., the long-term effects of chronic stress exposure), reflect phenomena that unfold over time. Indeed, attachment processes and experiences at one point in time may be related to physical health at a later point in time. For instance, memories of higher quality care in childhood are related to better self-rated health, fewer chronic illnesses, and lower depression over a 4-year period (for adults in their 60s) and over a 10-year period (for adults in their 40s; Chopik & Edelstein, 2015). Attachment insecurity in childhood also predicts the likelihood of reporting physical health symptoms 30 years later. Adults who were anxiously attached in childhood are seven times more likely to report inflammation-related diseases (i.e., coronary heart disease, asthma, diabetes, stroke, and hypertension) and three times more likely to report nonspecific symptoms (i.e., migraines, chest pains, fainting spells, indigestion, and backache) compared with adults who had a secure attachment style in childhood (Puig, Englund, Simpson, & Collins, 2013).

Although prospective data are crucial to understanding these linkages, longitudinal studies that examine attachment, health, and possible mediators between the two are relatively rare. Longitudinal data are particularly important because they can help parse out which factors are most strongly related to health and well-being and provide further evidence of the enduring effects of attachment on health. Yet even prospective studies are not without flaws. For example, multiple mechanisms are rarely tested within the same study to assess the relative contributions of each—an important consideration given the overlap among many explanatory variables. To illustrate, secure attachment is associated with healthier behavior and greater feelings of social support, two variables that may be (a) intercorrelated (e.g., people with greater social support may also exercise and/or diet more) and (b) predict health independently of each other. But which is more likely to explain the link between attachment and health—health behavior, social support, or both? Examining prospective links while examining multiple mechanisms is often the best approach to disentangling exactly what is driving a specific association.

Another limitation of these studies is the tendency to focus on the "book ends" of life—either late adolescence/early adulthood or older adulthood, so the processes associated with health in middle adulthood are less clear. Additionally, most studies are correlational, so relatively little is known about the causal direction of any associations. Future research could make greater use of longitudinal data to provide stronger tests of the various mechanisms hypothesized to link attachment to physical health and to better understand the causal direction of attachment–health associations.

Conclusion

Close relationships have important implications for physical health and well-being, and higher quality social relationships are consistently related to better physical health. In this entry, we presented evidence that individual differences in how people approach relationships can have important health consequences. Overall, both attachment anxiety and avoidance are associated with a greater risk for the development of disease and chronic illness. Anxiously attached people generally report more physical health symptoms and seem particularly vulnerable to conditions that involve the cardiovascular system. Attachment avoidance has been less directly related to physical health, although there is limited evidence of a link between attachment avoidance and physical conditions involving pain. But *how* does one's attachment orientation or feelings about close relationships influence their physical health?

Researchers are just beginning to examine the processes that might help to explain why attachment is associated with health outcomes. In this entry, we discussed several factors that impact health and well-being: perceptions of social support, health behaviors, emotion regulation, and physiological and neuroendocrine response systems. Examining these mechanisms (and others) can provide greater insight into both relationship *and* health-related processes and how they interact in different contexts.

Going forward, research on attachment-related differences in health should begin to address several key limitations. First, future research should implement dyadic designs that include both couple members to elucidate how people's attachment styles influence their own and their partner's health. Second, future research should adopt longitudinal designs to examine how attachment–health associations unfold over time. Longitudinal studies are necessary to understand the directional nature of attachment–health findings and to capture the developmental course of health from early childhood to late adulthood. Addressing these limitations and investigating the multiple pathways linking attachment orientations to health can help people live not only longer but also happier lives as well.

Author Biographies

Onawa P. LaBelle is a PhD candidate in psychology at the University of Michigan. Ms. LaBelle is interested in close relationships processes, positive emotions, and physical and mental health outcomes. Her current work examines the benefits of gratitude for insecurely attached individuals in at-risk populations (e.g., recovery from alcoholism, sexual minorities).

Britney M. Wardecker is a PhD candidate in psychology at the University of Michigan. Britney's research interests broadly focus on close relationships, hormones, and stress and health. More specifically, she examines how people respond to stressful situations and how hormones are tied to people's experiences in close and intimate relationships, such as romantic and parent–child relationships.

William J. Chopik, PhD, is an assistant professor at Michigan State University. Dr. Chopik researches how relationships—and the people in them—change over time. He focuses on how factors both inside (biological, hormonal) and outside (social roles, geography) of people influence their approach to social relationships.

Robin S. Edelstein, PhD, is an associate professor at the University of Michigan. Her research focuses on individual differences in emotional experience, regulation, and reactivity. She is particularly interested in how emotional processes unfold in interpersonal contexts and the implications of emotional processes for close relationships, behavior, and physiology.

Bereavement

Mary-Frances O'Connor

Psychology Department, University of Arizona, Tucson, AZ, USA

Bereavement is the period after the death of a loved one. It is distinguished in bereavement research from grief and mourning. Grief is the emotional, cognitive, and physiological experiences that occur during bereavement and therefore has wide individual differences. Mourning is the term given to the outward behaviors in which people engage in during bereavement.

Why does grief happen? One of the primary theories used to explain the grief reaction is attachment theory (Bowlby, 1969). Attachment theory proposes that individuals seek proximity to each other after a period of bonding (in particular, bonding of an infant to a caregiver and pair-bonded monogamous adults). The proximity-seeking functions to keep the infant safe, and in later childhood and adulthood, serve as a safe haven to seek during distress and as a secure base from which to confidently explore the world. The absence of the attachment figure is therefore distressing, and concerted effort is made to reunite with the loved one. This effort at reunion is very useful when the separation is temporary, but in the case of death, reunion is not possible. Nonetheless, the desire to reunite with the deceased loved one, even though the bereaved person knows that it is not possible, may originate with the strong motivation to seek proximity that is present in attachment bonds established during infant bonding or pair bonding.

In adulthood, working models representing the attachment figure are often utilized in lieu of physical proximity. These working models, or schemas, allow for longer periods of separation, while still maintaining a sense of security. Schemas of the attachment figure often incorporate aspects of the self as well (e.g., a pair-bonded adult relationship has a schema not only for the other [husband] but also for the self [wife]). Therefore, intense grief after the death of a loved one usually occurs in cases where the deceased was an attachment figure and the death affects the bereaved person's own identity.

Early theories about the stages of grief (initially adapted from theories of terminal illness) suggested that bereaved individuals passed through denial, bargaining, anger, depression, and acceptance (Kubler-Ross, 1969). This older theory was influential because it shed light on grief as a possible phenomenon for empirical study. However, more recent empirical work has shown that bereaved individuals do not necessarily pass through these stages sequentially nor

does everyone experience each stage. For example, acceptance arises early in bereavement and continues to increase as the reality of the death is incorporated into the bereaved person's current working models of the world. A more recent theory suggests that bereaved individuals oscillate between focusing on the loss and focusing on the restoration of the new chapter of life after the death (Stroebe & Schut, 1999). The capacity to oscillate between these two distressing aspects of bereavement seems to predict adaptation, with more time spent focusing on restoration as adaptation continues. Adaptation in grief, or the integration of the fact of the death event and its consequences, can be seen when the bereaved is able to once again experience joy, derive meaning in life, and pursue important interests, such as work, caring for family members, or social activities.

Empirical work from a seminal prospective study of bereavement has shown that several trajectories of adaptation can be distinguished (Bonanno et al., 2002). The importance of this work is that it incorporated individual's functioning prior to the illness or death of the loved one. This enabled the authors to differentiate individuals based on characteristics observed prior to bereavement and following the death event at several time points. Patterns of adaptation include (a) individuals depressed prior to the loss who remain depressed following the loss (chronic depression), (b) individuals who become depressed only after the loss and remain depressed (chronic grief), and (c) individuals who become depressed only after the loss then improved (depressed improved). Notably, the majority of individuals fall into the category of (d) resilient. Despite the distress of acute grief, the resilient group does not show depression at any point during the study. It is worth noting that this research was done prior to the conceptualization of complicated grief symptomatology (discussed below). Consequently, depressive symptoms served as the primary variables of interest.

Factors that help and hinder adjustment following the loss of a loved one have been identified through empirical research, although there is not always agreement between studies on all factors. Social support is clearly a great resource during bereavement and aids in adjustment. Insecure attachment style, and dependency on the deceased, also predicts poorer adjustment than secure attachment, and so does the kinship relationship of the deceased. The loss of a child predicts the poorest adjustment, followed by the death of a spouse, compared with other relationship categories. Other factors (religiosity, sex, age, unexpectedness of the death) vary by research study as to whether they assist in adjustment, and this may be because they interact in complex ways with other factors. Secondary losses, such as changes in financial status and housing, often follow the death of a loved one. Coping with these types of additional stressors hinders adjustment to the loss.

Complicated grief is a term given to the disorder that arises when acute grief does not become integrated into the working models of the bereaved person. There are a number of different names that have been used for this disorder, reflecting the development and refinement of measuring of this phenomenon by the clinical science community. These names include traumatic grief, prolonged grief, and pathological grief and are associated with slightly different symptom sets. The DSM-5 has included this disorder in the section on disorders that require further research, and it is termed persistent complex bereavement disorder (PCBD).

PCBD includes criteria based on an individual having experienced the death of a loved one followed by one or more of the following symptoms on more days that not for at least 12 months following the loss (or 6 months for children): persistent yearning/longing for the deceased, intense sorrow, preoccupation with the deceased, and/or the circumstances of death (American Psychiatric Association, 2013). They must also endorse six or more symptoms that indicate clinically significant reactive distress to death (e.g., marked difficulty accepting the death and excessive avoidance of reminders of the loss) and social or identity disruption (e.g., a desire to die in order to be with the deceased and feeling alone or detached from other individuals since the death). DSM-5 requires that the grief reaction must be beyond cultural, religious, and/or age-appropriate norms to avoid pathologizing a normal response to a common, yet very distressing, experience.

Less than 10% of the general bereaved population develop complicated grief, although that number increases significantly to approximately one fifth of those who lose a child or a spouse (Kersting, Brähler, Glaesmer, & Wagner, 2011). This highlights the resilient nature of most individuals who have this nearly universal experience of bereavement. Recent research has developed psychotherapeutic treatments specifically to address complicated grief, with efficacy demonstrated through several randomized controlled trials. These include complicated grief therapy, which combines a variety of psychotherapeutic approaches, including principles of cognitive behavior therapy (especially exposure to the aspects of the death that are avoided), interpersonal therapy, and motivational interviewing (especially focusing on creating a future that is meaningful and positive). Other trials have utilized cognitive behavioral therapy in individual, group, and Internet settings. Across several studies, exposure appears to be a critical ingredient, over and above the effect of cognitive restructuring. Thus far, mixed results have been reported for the pharmacological treatment of complicated grief (e.g., antidepressants), but benzodiazepines are not an effective treatment strategy.

Although grief is a universally experienced emotion, the expression of grief varies widely across history, culture, religion, and geography. Recent concerns have emerged that the "medicalization" of grief has developed along with a mismatch between the intense experience and slow natural adaptation following the loss and contemporary Western culture. Current Western culture values productivity, happiness, and progress. The grieving person only sporadically exhibits these qualities during bereavement, and there is often a denial and censorship by society regarding grief and loss. On the other hand, research shows that for those who experience complicated grief, the recognition that their experience is not normative and can be treated comes as a relief.

Physiological changes accompany bereavement, most likely due to the intensely stressful nature of the experience, and the intense emotions that it often engenders. The physiological systems that have been affected in empirical studies include the sympathetic and parasympathetic autonomic nervous system and the endocrine and immune systems. These changes include increases in heart rate, cortisol, and circulating levels of inflammation and decreases in heart rate variability and specific immune cell types. These changes are most pronounced in the first 6 months after the death of a loved one and then typically return to previous levels (or put differently to the level of matched nonbereaved individuals). The physical symptoms most often noted by bereaved individuals include difficulty sleeping, reduced appetite, and pangs of grief often accompanied by crying.

Presumably because of these changes in the stress response systems of the body, the "widowhood effect" also occurs during bereavement. This is the term for the phenomenon whereby the death of a loved one increases the morbidity and mortality of the survivor. The widowhood effect has been empirically demonstrated since the 1960s, and improved statistical modeling that accounts for a host of covariates has continued to document it. Broadly speaking, the increased risk for men after the death of a spouse is approximately twice the risk of their married counterparts, and the increased risk is approximately 1.5 times for women. The term "broken-heart phenomenon" has also been used, but the widowhood effect is preferred because the effect is on all-cause mortality, and not just cardiovascular health. In addition, the term "broken-heart phenomenon" has also become synonymous with takotsubo cardiomyopathy, which often, but not exclusively, occurs in the wake of a loved one's death.

Future research on bereavement should continue to focus on dismantling clinical interventions that treat complicated grief, in order to determine the effective components of treatment. Additional interventions that would reduce morbidity and mortality during the period of greatest risk, such as cardioprotective medications, should be studied. Finally, the similarities and differences in grief between different types of loss experiences (death, divorce, job loss, loss of health, etc.) may clarify the key dimensions of this universal experience.

Conflicting Health Information

The explosive growth of the Internet, social media, and traditional news outlets has provided people with unprecedented access to health information (Fox, 2011). This expanded access has had both positive and negative effects. It has enabled laypersons to become more empowered consumers of healthcare. At the same time, however, it has altered the health information seeking behaviors of individuals and members of their social network (Fox, Duggan, & Purcell, 2013) and exposed the public to an ever-increasing supply of low-quality and often contradictory health information (Eysenbach, Powell, Kuss, & Sa, 2002). For example, a national survey found that 71.5% of the general public endorsed the view that "there are so many recommendations about preventing cancer, it's hard to know which ones to follow" (Niederdeppe & Levy, 2007).

Conflicting health information burdens both laypersons and experts alike with the task of evaluating what information is credible. It also has other potentially deleterious effects. As researchers, healthcare providers, and government organizations have affirmed, conflicting health information can cause confusion about what health-related behaviors are appropriate to engage in and therefore expose individuals to harms resulting from indecision or misguided decisions (Wansink, 2006). Conflicting health information can also lead people to distrust health professionals, discount valid health information, and forego potentially beneficial medical interventions (Kienhues, Stadtler, & Bromme, 2011; Theroux & Taylor, 2003). Furthermore, it can negatively impact medication adherence (Carpenter et al., 2010; Carpenter, Elstad, Blalock, & DeVellis, 2014) and individuals' decisions to engage in even healthy behaviors for which there is clear consensus—for example, consuming fruits and vegetables (Nagler & Hornik, 2012).

Yet despite emerging evidence and consensus on the growth and negative effects of conflicting health information, surprisingly little is known about the magnitude and mechanisms of these effects. The construct of "conflicting information" has neither been defined conceptually nor measured systematically. The dearth of rigorous studies on the prevalence and effects

of conflicting health information is attributable to several factors, including the lack of a standardized definition, the absence of validated and reliable measures of the phenomenon, and a lack of theoretical models to explain its causes and effects.

In this entry we address these current deficiencies by summarizing insights from the available literature, with the aim of (a) proposing a working definition and conceptual typology of conflicting health information; (b) distinguishing conflicting health information from related terms, such as misinformation, ambiguous information, and confusing information; and (c) briefly discussing potential theoretical models that could serve as a starting point for efforts to develop theoretical frameworks to guide future research and to enhance our understanding of the antecedents, processing, and effects of conflicting health information.

Working Definition

Previous empirical research on conflicting health information offers few insights about how this phenomenon should be conceptualized or operationalized. Some studies have identified a primary source of information, such as a prescribing physician, and then examined whether other sources present information that conflicts with this primary source (Carpenter et al., 2014). Other studies have identified contradictory health messages and asked respondents to indicate how frequently they were exposed to those messages (Nagler & Hornik, 2012). In all of these studies, however, the meaning of conflicting health information has been implicitly assumed rather than explicitly defined. A coherent working definition is thus a primary need for further research on conflicting health information.

We propose defining conflicting health information in terms of health-related propositions. By "propositions" we mean statements or assertions about a health-related issue. Propositions may originate from either a single source or multiple information sources and may either be actively sought by an individual (e.g., through an Internet search) or passively encountered (e.g., through an overheard conversation).

"Conflicting health information" can then be operationally defined as two or more health-related propositions that are logically inconsistent with one another. The Oxford Dictionary (n.d.) defines the term "conflicting" as "at variance," "incompatible," or "contradictory." We take the defining feature of "conflicting" to be that the propositions are discrepant such that a person could not simultaneously act upon or believe both propositions at once. For example, if two propositions differed on one point, such as the recommended age to initiate mammography screening (age 40 or 50), a woman could not initiate screening at both age 40 and 50. Similarly, if a person found a proposition online that "vaccines cause autism" and the person's physician told him/her that "vaccines do not cause autism," the person could not simultaneously believe both propositions.

Conceptual Typology

Proceeding from this operational definition, conflicting health information can be further classified according to four fundamental dimensions: the substantive issue of conflict, the number of conflicting sources, the degree of evidence heterogeneity, and temporal inconsistency. The first dimension of conflicting health information, the *issue of conflict*, is the specific health topic for which conflicting propositions exist. Issue is an important dimension because people's reactions to conflicting information may vary based on the topic. For example, people may have more negative reactions when conflicting information applies to cancer prognosis as opposed to cancer screening. The second dimension is *multiplicity* or the number of different sources of conflicting information. Conflicting information may be present in a single source, such as a cancer screening guideline that includes both of these propositions (Moyer, 2012):

> The U.S. Preventive Services Task Force recommends against prostate-specific antigen (PSA)-based screening for prostate cancer. The potential benefit does not outweigh the expected harms.
>
> If your patient does raise the issue of PSA screening, or if you believe his individual circumstances warrant consideration of PSA screening, be sure to discuss it with him thoroughly, so he can make an informed decision. The USPSTF strongly recommends that you do not order a PSA test without such a discussion. The decision to start or continue PSA screening should reflect your patient's understanding of the possible benefits and expected harms and should respect his preferences.

On the other hand, conflicting propositions may also exist across multiple sources, such as a PSA screening guideline released by a national task force versus a differing guideline published on a prestigious cancer center's website. Multiplicity is potentially important because people may react differently if they encounter conflicting information from a single source versus multiple sources, and people's negative reactions may increase or plateau as the number of conflicting sources increases.

The third dimension, *evidence heterogeneity*, is the extent to which conflicting information originates from similar versus differing evidentiary types. This attribute is important because individuals may process conflicting information differently when it comes from homogenous sources, such as various health professionals, as opposed to heterogeneous sources, such as health professionals versus family members. The fourth dimension, *temporal inconsistency*, is the extent to which conflicting propositions about an issue exist at the same point as opposed to different points in time. Conflicting information that is temporally inconsistent (i.e., asynchronous or separated over time) may produce different behavioral effects than conflicting information that is temporally consistent (i.e., synchronous or occurring at the same point in time). Temporally inconsistent (asynchronous) conflicting information, furthermore, may have varying effects depending on its frequency—that is, the extent to which a person is exposed to the conflicting information. For example, if conflicting cancer screening guidelines emerge every 5 years, this may have less of a negative effect on a person's screening behavior than if conflicting screening guidelines emerge every year.

This proposed definition and conceptual typology of conflicting information has potential utility as a framework to guide future research on this phenomenon. The magnitude of the effects of conflicting information may depend on its various properties (issue of conflict, multiplicity, evidence heterogeneity, temporal inconsistency). The mechanisms by which conflicting health information affects health judgments, decisions, and behaviors may also depend on these properties. All of these possibilities remain to be explored in future research studies, and the typology can help organize these efforts. Furthermore, although our proposed conceptual typology focuses on properties of conflicting information itself, the factor that exerts the greatest influence on people's responses may not be the objective existence of conflict in information but people's perceptions of such conflict.

Related Phenomena

Our working definition can be used to help differentiate conflicting information from related phenomena, including misinformation, ambiguous information, and confusing information.

Misinformation is defined as "false or inaccurate information, especially that which is deliberately intended to deceive" (Oxford Dictionary, n.d.). The American Dietetic Association (ADA) released a position statement that defined food and nutrition misinformation as "erroneous, incomplete, or misleading science without any scientific basis at all" (Wansink, 2006). The ADA further stated that conflicting food and nutrition information "can be disseminated naively or with malicious or self-serving intent" (Wansink, 2006). Thus, misinformation is conceptually distinct from conflicting information because it (a) focuses on the accuracy of a proposition and (b) makes attributions as to the motive for information dissemination. Our proposed definition of conflicting information examines the degree of conflict rather than the accuracy of two propositions and makes no attributions about how or why the information was disseminated.

The term *ambiguity* signifies another related but distinct phenomenon. Ambiguity itself has multiple meanings; the conventional dictionary definition is "open to more than one interpretation" or "having a double meaning" (Oxford Dictionary, n.d.). In behavioral decision theory, however, the term "ambiguity" refers to a specific feature of risk information pertaining to a lack of reliability, credibility, or adequacy and giving rise to epistemic uncertainty (Ellsberg, 1961). In this conception, ambiguity can arise from conflicting information and other limitations including missing or insufficient data or other limitations in data reliability. Conflicting information is conceptually distinct from ambiguous information because a single proposition may be ambiguous, but conflicting information cannot exist for a single proposition; conflicting information only exists when there are multiple propositions. However, it is likely that individuals are more likely to interpret ambiguous health propositions as conflicting than unambiguous propositions.

The term *confuse* is defined as making "something more complex or less easy to understand" (Oxford Dictionary, n.d.). Thus, confusing information could be defined as information that is difficult to understand. Similar to ambiguous information, a single proposition may be considered confusing; by definition, however, two propositions are needed for conflicting information to exist. Like ambiguous information, it is also likely that propositions that are confusing are more likely to be interpreted as conflicting. Thus, although one may assign the attributes of being confusing or ambiguous to health propositions, those propositions would not be considered conflicting unless they involved two or more health propositions that directly contradicted one another.

Theoretical Models

Currently, we lack theoretical models and frameworks to explain the antecedents and mechanisms of effect for conflicting information in the health domain. Theories from various disciplines can shed light on these problems, but thus far have not been applied to understanding the phenomenon of conflicting *health* information. We now briefly review theoretical perspectives that may serve as useful starting points for this effort.

Behavioral decision theorists since Ellsberg (1961) have conceptualized conflicting information as one source of ambiguity in risk information. Ambiguity, in turn, leads to a set of responses that include pessimistic appraisals of the benefits and risks of alternative choice options and avoidance of decision making—a phenomenon known as "ambiguity aversion." This phenomenon has been demonstrated in multiple decision-making domains, both in and outside of healthcare. For example, higher levels of perceived ambiguity have been strongly associated with lower beliefs that cancer is preventable (Han et al., 2007; Han, Moser, &

Klein, 2006) and lower intentions toward future uptake of screening mammography (Han et al., 2007). Conflicting information as a specific source of ambiguity, furthermore, seems to evoke greater avoidance of decision making than ambiguity arising from information that is merely missing or unreliable; for this reason, some researchers have distinguished "conflict aversion" from ambiguity aversion (Smithson, 1999). This finding shows how ambiguity theory, as conceptualized in behavioral decision research, provides a useful framework for understanding the phenomenon of conflicting health information. Our conceptual typology may complement this theoretical framework by decomposing conflict into discrete constituent dimensions (i.e., issue of conflict, multiplicity, evidence heterogeneity, and temporal inconsistency). It is possible that these different dimensions exert varying influence on ambiguity aversion as classically characterized.

Theories of decision making, such as fuzzy-trace theory (Reyna & Brainerd, 1995), also have great potential relevance and value for the study of conflicting health information. Fuzzy-trace theory posits that people form two types of cognitive representations of information: a verbatim representation and a gist representation. The verbatim representation reflects the precise, often quantitative, aspect of the information received (e.g., 10% of patients who take medication X experience side effect Y), whereas the gist representation captures the essential "bottom-line" meaning of the information, as understood by the receiver, in qualitative terms (e.g., medication X can cause side effect Y). Fuzzy-trace theory is salient for the study of conflicting information because it suggests that gist representations of health information may lead patients to perceive information as conflicting even when, in fact, it is not. Moreover, it suggests that other factors, such as an individual's level of health literacy, could interfere with the processing of health information and could lead to inaccurate gist representations. Additional work is needed to identify the person-level factors that may influence how individuals process and react to conflicting information. For example, perceptions of the salience of conflicting information and trust of information sources may influence how individuals process and react to conflicting information.

Another potentially useful theoretical perspective comes from artificial intelligence research that has produced mathematical formulas for how conflicting information is incorporated into existing knowledge systems (Benferhat, Kaci, Le Berre, & Williams, 2004; Cantwell, 1998; Lin, 1996). These formulas can be weighted by the trustworthiness of sources. The main construct of interest in this area is belief revision that focuses on how new information is incorporated into a knowledge base and the way in which conflicting information from different sources is identified and integrated into a given knowledge base. However, these theories focus on knowledge integration in computer systems and treat actors as rational. Yet human beings often do not act rationally with regard to their health, and their belief revision processes in the face of conflicting information will likely operate differently than what has been described in the artificial intelligence domain. Computational theories of conflicting information, despite their well-developed nature and relevance, would require significant adaptation in order to be applied to a health context.

These and other theories have clear relevance to understanding the phenomenon of conflicting health information, but they accommodate this phenomenon only indirectly. The critical need moving forward is for an integrative theoretical model that provides a more direct, coherent account of the causes and effects of conflicting information. Truly advancing our understanding of conflicting information requires synthesizing diverse insights about conflicting information—from multiple fields of inquiry—into a unified theory or model. Although existing theories provide useful lenses for understanding the causes and effects of conflicting information, exactly how to integrate these theories is unclear and represents a fundamental research need. In addition to theory development, valid and reliable measures of conflicting health information are needed. Measure development in this area should focus on assessing each of the four dimensions of conflicting information described previously. Additional measurement work should focus on assessing subjective perceptions of various aspects of conflicting health information (e.g., trustworthiness of conflicting information sources) that may influence individuals' decisions and health behaviors.

Research on the nature, extent, causes, and effects of conflicting health information can ultimately serve as the foundation for the development of interventions to help individuals, including patients and clinicians, better manage conflicting health information when making decisions about their health. The working definition and conceptual typology of conflicting health information presented in this entry are offered as a first step toward a comprehensive program of research on this increasingly important problem.

Coping Strategies

Ellen Stephenson and Anita DeLongis

Department of Psychology, University of British Columbia, Vancouver, BC, Canada

Much of current theory and research on coping stems from a transactional model of stress and coping (Folkman, Lazarus, Gruen, & DeLongis, 1986), in which coping is defined as thoughts and behaviors used to manage the internal and external demands of a stressful situation. Earlier theories took a more hierarchical approach and conceptualized coping as referring exclusively to adaptive responses that were contrasted with maladaptive responses (e.g., defending, fragmenting; Haan, 1969; Menninger, 1963; Vaillant, 1977). Transactional models expanded the conceptualization of coping to include a broader set of cognitive and behavioral responses to stress. How a given situation is appraised determines whether the individual experiences it as stressful. Situations that are appraised as threatening or taxing available coping resources are experienced as stressful and necessitate a coping response. These coping responses are not viewed as inherently adaptive or maladaptive. Instead, the answer to whether a given coping strategy is effective is expected to vary by person and situation (DeLongis & Holtzman, 2005).

Coping Strategies

Several ways of categorizing coping strategies have been proposed (see Skinner, Edge, Altman, & Sherwood, 2003). Coping responses are frequently categorized in terms of their focus or function (O'Brien & DeLongis, 1996). Problem-focused coping describes direct efforts to solve the problem at hand, whereas emotion-focused coping involves attempts to lessen the emotional distress associated with a stressful situation (Lazarus & Folkman, 1984). Relationship-focused coping describes a third coping function and includes efforts to manage and maintain important social relationships during periods of stress (e.g., O'Brien, DeLongis, Pomaki, Puterman, & Zwicker, 2009). Another key method for describing coping strategies is in terms of approach or avoidance (Roth & Cohen, 1986). Within this framework, coping strategies are differentiated based on whether cognitive and emotional activity is oriented either toward or away from threat. Stanton and her colleagues have argued that approach-

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

oriented emotion-focused coping must be distinguished from avoidance-oriented emotion-focused coping. Emotional approach coping involves actively processing and expressing emotions rather avoiding them (Austenfeld & Stanton, 2004). Similar to the approach/avoidance framework, coping can also be described in terms of strategies involving engagement or disengagement. Engagement responses are oriented toward either the source of stress or toward one's emotions and thoughts, whereas disengagement describes responses that are oriented away from the stressor or one's thoughts or emotions (Compas, Connor-Smith, Saltzman, Thomsen, & Wadsworth, 2001). These examples are just some of the ways coping strategies can be categorized. Within these broader categories, many more specific coping strategies have also been described (e.g., planning, denial, support seeking, empathic responding, positive reappraisal, emotional expression).

Coping as a Process

Coping is a dynamic process that can involve the use of various coping strategies at different phases of a stressor. For laboratory stressors that are typically acute in nature due to the constraints of the experimental setting, the coping process can be relatively brief. However, most life stressors are either chronic or stress-event sequences. Given this, coping most often involves a cascade of cognitive and behavioral responses to a sequence of stressful events. For example, coping with cancer might start with the response to a perception of symptoms, followed by coping with the diagnosis and then treatment, which are related but separate stressors. There are many additional stressors typically experienced by cancer patients, including changes in family relationships, and these may all involve very different coping responses.

Coping strategies can operate synergistically, with one form of coping facilitating or hindering the use or effectiveness of other strategies. For example, emotion-focused coping may be necessary to manage emotions before an individual can effectively engage in problem-focused coping. A patient receiving a negative diagnosis may need to first engage in emotion-focused coping to reduce the perceived threat. This strategy may in turn facilitate understanding important treatment information and effectively allow engagement in problem-focused coping efforts. Another example involves relationship-focused coping facilitating problem-focused coping. Caregiving spouses of patients with Alzheimer's disease reported that by engaging in perspective taking and empathy for their spouse, they were able to generate better solutions to problems posed by the disease (DeLongis & O'Brien, 1990).

Coping was traditionally conceptualized as a response to stressful events that occurred in the past or that were occurring in the present. However, another way of reducing stress and regulating emotion is to avoid stressful situations or prevent them from occurring (Gross & Thompson, 2007). Individuals can also use proactive coping strategies to build up resources to help them cope with stressors that they might encounter in the future (Aspinwall & Taylor, 1997). Future-oriented coping strategies are sometimes further categorized depending on the certainty and temporal proximity of future events. For example, Schwarzer and Knoll (2003) distinguish between *anticipatory coping* (efforts to deal with a critical event that is certain or fairly certain to occur in the near future), *preventive coping* (efforts to deal with an uncertain threat potential in the distant future), and *proactive coping* (efforts to prepare for upcoming challenges that are potentially self-promoting). Incorporating both the antecedents and consequences of stressful events provides a fuller perspective on the coping process.

Choosing an Effective Coping Strategy

Although it is tempting to look for the "perfect" coping strategy, no one strategy is ideally suited to all contexts. Whether a particular coping strategy is "effective" depends on how we define successful coping. For example, problem-focused coping is likely to be effective in solving the problem or eliminating the stressful situation. There are some situations, such as the death of a loved one, where the source of the stress cannot be eliminated. In these situations, where successful coping may be defined in terms of reducing psychological distress, emotion-focused strategies are needed. If maintaining relationships with close others is an important outcome defining successful coping, then relationship-focused coping efforts may be necessary. Indeed, most stressful situations likely need all three forms of coping for successful resolution of the stressor. However, sometimes a stressor presents competing demands that conflict or favor different coping responses. For example, coping strategies that maximize individual well-being may come at a cost to the people involved.

The time frame used to evaluate the effects of a particular coping strategy can influence whether it is adaptive or maladaptive. That is, the same strategy can have different short-term and long-term effects. Avoidance can be useful in reducing distress in the short term, but if the stressor persists, this strategy can hinder long-term adjustment. For example, although processing emotions can be adaptive in the shorter term, continuing to engage in emotion processing over the longer term may become ruminative and therefore less beneficial in terms of adjustment (Austenfeld & Stanton, 2004). Other strategies may increase distress in the short term but promote adaptation in the long term. For example, husbands' use of empathic responding is associated with increased marital tension on the same day as family stress occurs, but reduced tension the following day (O'Brien et al., 2009). This suggests that we need to consider both short- and long-term outcomes in order to fully understand the coping process. What is effective in the short term may be ineffective in the long term, and vice versa.

Which coping strategy is used and whether it is effective is determined by a combination of situational and personality factors. Some situations tend to be appraised in a particular way (e.g., threat vs. challenge appraisal; threat to agency vs. threat to communion), and this appraisal is associated with which coping strategies are used (Franks & Roesch, 2006; Pow, Lee-Baggley, & DeLongis, 2016). However, successful adaption often involves tailoring the coping response to the demands of the situation (Lee-Baggley, Preece, & DeLongis, 2005) and knowing when to persist with a given strategy or shift to other coping strategies (Chen & Miller, 2012). For example, in situations where perceived control is high, problem-focused coping tends to be the preferred strategy—but if actual control is low, other coping strategies are more effective Zakowski, Hall, Klein, & Baum, 2001). Some people show greater flexibility in their ability to match their coping response to the situational context, and others tend to employ certain coping strategies or are more skilled at using specific coping strategies (Cheng, Lau, & Chan, 2014; Lee-Baggley et al., 2005).

Coping Within a Social Context

There is growing recognition that coping is a social process (e.g., Revenson, Kayser, & Bodenmann, 2005). Although interpersonal conflicts are one of the most common sources of daily stress (Bolger, Stadler, Paprocki, & DeLongis, 2010), social relationships also play an important role throughout the coping process (DeLongis & Holtzman, 2005). Findings from several studies have highlighted the role of social support in times of stress (e.g., DeLongis, Holtzman, Puterman, & Lam, 2010; Uchino, Bowen, Carlisle, & Birmingham, 2012). Even if no support is provided from another person, perceiving that social support is available can be an important coping resource that helps reduce distress and facilitate coping (e.g., Pow, King, Stephenson, & DeLongis, 2016). Although some researchers distinguish between individual and dyadic forms of coping (e.g., Badr & Acitelli, 2017), social influences can have an even more pervasive effect throughout the coping process. The social context can affect how stressors are appraised, which coping strategies are used, and whether they are effective (DeLongis & Holtzman, 2005). Individuals can cope in ways that provide a good or bad fit with the coping strategies used by others involved in the situation. For example, although avoidance may be associated with poorer adjustment overall, couples in which one partner was high in avoidance and the other was low in avoidance reported better dyadic adjustment (Badr, 2004). This suggests that spouses can cope in ways that buffer against the negative effects of what might otherwise be maladaptive coping strategies. Although existing research examining the fit between coping strategies of involved others has focused primarily on dyads, this perspective could be applied to wider social networks such as provider–patient–spouse triads or larger family systems.

The social context surrounding the coping process can be extended to include cultural influences. The effectiveness of a given coping strategy must also be considered within its cultural context. Although some aspects of the coping process are considered culturally universal, there are also cultural differences in the degree to which individuals are exposed to certain types of stressors, how these events are appraised, which coping strategies are used, and whether these coping responses are considered effective (Chun, Moos, & Cronkite, 2006).

Summary

Although some coping strategies are more consistently associated with successful adaption than others, there is no one coping strategy that is universally adaptive or maladaptive. Contextual factors play an important role in determining the coping strategies used and the outcomes of the coping process. The nature of the stressful situation, the personality of the individual, and social context can all influence whether or not a particular coping strategy is employed and whether or not it is effective.

Author Biographies

Ellen Stephenson is a PhD student in the Department of Psychology at the University of British Columbia. Her research focuses on understanding how couples and families come together to cope with stress. She has examined ways in which close relationships can facilitate successful coping and individual adjustment (e.g., reduced pain and functional impairment) and the consequence stress and coping can have for relationship outcomes (e.g., divorce and marital satisfaction).

Anita DeLongis is a professor in the Department of Psychology at the University of British Columbia. Her research in health psychology focuses on stress, coping, and social support. Her current work spans a number of areas including rheumatoid arthritis and chronic pain, spinal cord injury, stress in stepfamilies, stress among emergency medical personnel, health behaviors such as condom use, and psychological reactions to global pandemics.

Coping with Chronic Illness

Up to the mid-twentieth century, the leading causes of sickness and death were acute and infectious diseases, such as malaria, tuberculosis, and influenza, that resulted from contaminated water and food and poor hygiene. Until public health advances brought these conditions under control, there was little physicians could do. Now, particularly in developed countries, few people die from acute infections. Does that mean that there is less illness? To the contrary, approximately 117 million American adults are living with a chronic condition, the most prevalent being cardiovascular and pulmonary diseases, cancer, and diabetes. This number is expected to grow as the nation's life expectancy increases and baby boomers age. By 2030, the number of adults over the age of 65 will double, accounting for 20% of the population. As such, the number of people living with chronic illnesses is expected to rise to over 160 million by 2040.

What Is a Chronic Illness?

> Alana was diagnosed with multiple sclerosis (MS) in her mid-20s while she was in social work school. Symptoms halted within a few years. She married, had children, and developed a career nearer to her heart – landscape design. In her late 40s, symptoms reemerged, and within five years she was having trouble walking, forcing her to give up her landscape business and move to a one-level house. She continues to be involved in her temple and sees her extended family often but wonders what the next decade will bring.

Chronic diseases are enduring health conditions that cause disruptions in daily activities and have no cure. Some are degenerative in nature, marked by increasing disability and pain (e.g., MS, rheumatoid arthritis), while others can be managed with treatment (e.g., hypertension, diabetes, HIV/AIDS). According to the commonsense framework of illness representations (Leventhal, Brissette, & Leventhal, 2003), which describes the ways ordinary people think

about disease, chronic and acute illnesses can be distinguished along four dimensions: cause, timeline, illness identity, and outcomes. The *cause* of many chronic diseases is a result of lifestyle and health behaviors, such as diet and exercise; in contrast, acute diseases are often caused by bacteria or injuries. Acute diseases are considered short term, whereas chronic illnesses have a longer *timeline* with a slow onset and long-term trajectory. Consequently, the *identity* of a chronic illness is less concrete: the causes, trajectory, and symptomology are often unpredictable or unobservable. Take the case of hypertension—people may not recognize its symptoms, although clinically elevated blood pressure is dangerous for one's health. Finally, the *outcomes* of chronic illness, as compared with infectious diseases, are not clear-cut. Even with treatment, most chronic diseases remain incurable. Many are progressive, often involving chronic or intermittent pain, increasing physical disability, and lifelong illness management.

MS, the disease Alana was diagnosed with, provides a prototypical illustration of a chronic disease. MS is a chronic neurological condition, in which the myelin sheath, a protective covering surrounding nerve fibers in the central nervous system, deteriorates. Patients with MS alternate through periods of symptom relapse and remission. They experience a range of physical (pain, fatigue, difficulty walking, sexual impairment, paralysis) and psychological (increased depression, uncertainty, anxiety, cognitive impairments) symptoms that are difficult to predict and often worsen over time. As the cause and cure of MS remain unknown, current treatment is mostly geared toward management of symptoms and decelerating illness progression.

The Stresses of Chronic Illness

As chronic diseases progress, patients experience changes related to social relationships, work, and daily life. Many psychological frameworks have described challenges individuals with chronic illnesses encounter. Illness creates disruptions in many areas that impinge upon a patient's life, in areas of work or finances, social relationships, sex life, and personal development. For example, when women with rheumatoid arthritis, a disabling autoimmune disease, strongly identified with roles at work or as parents, illness intrusions affected their psychological well-being to a greater degree. This finding suggests that disease-related disruptions call into question aspects of one's identity.

Moos and Holahan (2007) describe an *adaptive tasks* framework that separates the impact of illness into two broad categories: illness-related tasks and general life-related tasks. Illness-related adaptive tasks include managing symptoms and treatment and developing relationships with healthcare professionals. General adaptive tasks include maintaining an emotional balance, a positive self-image, and relationships with loved ones as well as preparing for an uncertain future.

What Is Adaptation to Illness?

Stanton and Revenson (2011) describe adaptation to illness in a number of ways. First, adaptation is multifaceted and dynamic. Second, people can feel both negative and positive emotions throughout their illness trajectory. Third, the process of adjustment is heterogeneous; not everyone experiences identical challenges, and each individual brings different personal and psychological resources "to the table." Another explanation for this heterogeneity is that adaptation depends on context. Context includes the medical aspects of the illness (Has the person lost an essential functional ability, such as walking or remembering things? Is the treatment making one sick and to what degree?), aspects of the social environment (Are there people that can provide support?), and availability of resources (Does the patient have health insurance? Does she live in a home environment that allows for independence?).

Cognitive Adaptation to Chronic Illness

Taylor (1983) proposed a theory of cognitive adaptation that continues to ground research on psychosocial adjustment to illness today. Based largely on interviews with a sample of women with breast cancer, Taylor delineated three essential processes that promote adaptation to illness: *making meaning of the illness, regaining mastery, and restoring self-esteem.*

Meaning making

Encountering a life-altering stressor, such as an illness, creates inconsistencies in our beliefs about the world, self, and personal goals. At this time, people initiate cognitive processes, such as "meaning making," to align those recent experiences with existing belief systems. The search for meaning often entails efforts to answer existential questions, like "Why me?" In Taylor's (1983) study, most of the breast cancer survivors were able to provide some explanation as to why their cancer occurred. Having (any) explanation was more strongly related to adjustment than *not* having one; the type of attribution made (self or environment) did not matter as much. Park (2010) echoed this early finding in a review of over 75 studies: successful meaning making had a positive impact on adjustment to stressful life events, including living with or caring for someone with a chronic illness. Meaning making leads to increases in personal resources, such as optimism, self-efficacy, and self-esteem. Incidentally, these three personal resources have been shown to promote adjustment among people with various chronic illnesses like diabetes, cancer, and arthritis.

Mastery

Mastery refers to an individual's perception of control over life events and capability to achieve desired outcomes. In attempts to control the illness, the possibility of recurrence, or the side effects of treatment, the breast cancer patients in Taylor's (1983) study exerted mental (e.g., positive thinking) and behavioral (e.g., dietary changes) coping efforts, which built a sense of mastery. Mastery protects individuals against depressive symptoms and increases quality of life in studies of many illnesses, such as diabetes, lung and cardiac disease, arthritis, cancer, and HIV. An increased sense of personal control mitigated the negative effects of stress on mental health, possibly through the use of more adaptive coping strategies. A randomized controlled trial, designed to improve symptom management in patients diagnosed with late-stage cancers, found that an increased sense of mastery was related to lower levels of fatigue and pain, particularly when participants felt confident in their ability to use the coping techniques taught in the intervention. People who have high mastery are more likely to feel capable of utilizing active coping strategies, such as reframing life challenges in a more positive light or using problem-solving skills.

Restoring self-esteem

Chronic illness can diminish self-esteem. Some people report feeling betrayed by their bodies. Surgery and treatment often cause permanent changes in physical appearance and self-concept. Thus, it is critical to restore self-esteem. Taylor (1983) found that people cope with threatening events by comparing themselves with less fortunate others to maintain a positive outlook. These *downward comparisons*, in turn, result in increased self-esteem. In Taylor's study of breast cancer patients, most women were able to make these downward comparisons by finding a target for comparison that was worse off than they were. For example, women who had a lumpectomy (removal of the tumor only, conserving the breast) compared themselves with those who had a mastectomy (invasive surgery to remove the entire breast). Those who had a mastectomy compared themselves with patients whose cancer metastasized (spread to vital organs). It was always possible to find someone in a situation more severe than one's own.

Theories of Coping

Coping has been a widely studied in social, personality, developmental, clinical, and health psychology (see entries on Coping Strategies and Coping Styles in this volume) and is essential to understanding adjustment to chronic illness.

The Stress and Coping Paradigm

Perhaps the most well-known theory of coping is Lazarus and Folkman's (1984) stress and coping paradigm, in which coping is defined as "constantly changing cognitive and behavioral efforts to manage specific external and/or internal demands that are appraised as taxing or exceeding the resources of the person" (p. 141). There is a lot to consider in this definition. First, like the process of adaptation, coping is dynamic. People can utilize different coping strategies depending on context or phase of illness. For example, a newly diagnosed cancer patient may use different coping strategies than when he or she is at a more advanced stage of illness. Second, coping involves cognitions (thoughts, beliefs) and behaviors (actions). A person with multiple sclerosis, like Alana, may engage in active attempts to seek social support or change her environment (behavior) as well as efforts to reframe the illness (cognition). Third, stressors can be external (changing one's work schedule because of chemotherapy) or internal (worry about progression of illness). Fourth, though coping and adaptation are related, they are not the same concept. That is, we cannot make a priori determinations about whether a specific coping strategy is effective; rather, the success of a coping strategy depends on context.

The stress and coping paradigm proposes that the type of coping strategies used, or the decision to "cope" at all, is based on *psychological appraisals* of the stressor. Individuals first evaluate whether or not an event qualifies as a stressor in a process called *primary appraisal:* What does this stressor mean for my health? Is it a threat (future stressor), loss (past stressor), or challenge? Then, in a process known as *secondary appraisal*, they decide whether they have the resources to cope with the stressor: Can I control it? Have I experienced this before and what did I do then? Based on these appraisals, individuals choose one or more coping strategies in response to the stressor. After attempts to cope with a stressor, individuals reappraise whether coping efforts have been successful, and the appraisal-coping cycle begins anew.

In the original stress and coping theory, coping efforts were classified as either problem or emotion focused. Problem-focused coping refers to efforts to change the situation by resolving or minimizing the stressor (e.g., planning, seeking support). Emotion-focused coping refers to managing the emotional distress caused by the stressor, particularly if the stressor is uncontrollable. Emotion-focused coping involves expressing and processing emotions, minimizing the stressor, self-soothing (e.g., drinking, shopping), and seeking emotional support. However, many coping efforts contain aspects of both problem- and emotion-focused coping (e.g., asking for social support), so this distinction has become less important. A more complex definition, *emotional approach coping*, involves processing and expressing emotions (Stanton, 2011).

Approach Versus Avoidance

A second approach classifies coping strategies as *approach* or *avoidance* (Carver, 2007). These categories refer to an individual's motivation to either confront or avoid a stressor. Approach-oriented strategies are active (i.e., seeking social support, problem solving), whereas avoidance-oriented strategies are geared toward escape (i.e., denial, abusing drugs and alcohol).

A Combination Approach

Moos and Holahan (2003) combined the focus of coping (approach vs. avoidance) with the type of coping (behavioral vs. cognitive). Behavioral coping refers to strategies used to change situations, whereas cognitive coping involves changing thoughts or perceptions of stressors, resulting in four categories of coping strategies: *behavioral approach* (i.e., seeking social support), *cognitive approach* (i.e., positively reframing the situation), *behavioral avoidance* (i.e., using drugs and alcohol), and *cognitive avoidance* (i.e., engaging in denial or minimization).

It is worthwhile to note that these three theories overlap. For example, the strategy of positive reappraisal could be considered an emotion-focused coping strategy, an approach-oriented coping strategy, or a cognitive approach coping strategy.

Coping and Adaptation: What Works?

Though no single coping strategy is effective for all people all the time, research suggests that avoidance-oriented coping is associated with poorer illness adjustment than approach-oriented coping. Much of this evidence comes from cross-sectional studies, and, therefore, causality cannot be established. However, a number of systematic reviews indicate that specific coping strategies affect mental health in different ways. In many studies, avoidant strategies have been associated with increased anxiety and depression among people with MS (like Alana), malignant melanoma (type of cancer with a poor prognosis), heart failure, and HIV/AIDS.

Does approach-oriented coping confer salutary (positive) benefits on adjustment? Problem-solving coping has been associated with decreased physical symptoms, negative affect, depressive symptoms, and fatigue—that is, better mental and physical health. Similarly, seeking social support also has been associated with positive adjustment to illness, although the magnitude of this relationship is often smaller than the one between avoidance-oriented coping (i.e., denial) and negative adjustment. Thus, approach-oriented coping might increase adjustment through the reduction of negative emotional states such as depression and fatigue.

The positive effects of approach-oriented coping depend on contextual factors, such as stage of illness. For example, among HIV/AIDS patients, behavioral approach-oriented coping, such as seeking information about treatment, was more effective at earlier points in the disease trajectory. Similarly, the association between approach-oriented coping and adjustment among people with late-stage cancers is not as strong when compared with those with early-stage cancers. One reason for this may be that later stages of illness present different challenges (i.e., making end-of-life arrangements) than earlier stages (i.e., deciding between treatment options).

Posttraumatic Growth as Adjustment

Studies examining adaptation to illness mostly focus on indicators of negative adjustment, such as depressive symptoms and anxiety. In this context, “good” adjustment refers to fewer symptoms or lower anxiety. In comparison, fewer studies look at positive outcomes, although that has changed in recent years.

Posttraumatic growth (PTG) refers to a positive change experienced as a result of adversity, which reflects higher levels of psychological functioning. People who report PTG find themselves transformed as a result of illness, often by building a reservoir of personal strength, acquiring a better appreciation of life, or strengthening relationships with family and friends.

Research has found a relationship between coping with illness and PTG. Approach-oriented strategies (e.g., acceptance, positive reappraisal) are associated with PTG, whereas avoidant strategies (e.g., escape, self-blame) are not. Although studies examining the construct of PTG have been primarily conducted with cancer populations, approach-oriented coping (positive reappraisal, seeking emotional support, and acceptance) has been associated with greater PTG among individuals with a number of diseases, including MS, rheumatoid arthritis, heart disease, and HIV/AIDS. Consequently, one should consider both positive and negative aspects of adaptation to illness.

Dyadic Coping

Most studies on coping with chronic diseases have focused on individual coping efforts. Recently, an interest has developed in how couples cope with a chronic illness, as a unit (Revenson & DeLongis, 2011). Patient and partner psychological distress are related; as one partner’s distress increases, so does the other partner’s. A systematic review of studies of cancer patients found that women experienced more distress than men—whether they were the cancer patients or partners (Hagedoorn, Sanderman, Bolks, Tuinstra, & Coyne, 2008). This is likely reflective of the gender difference in depression found in the general population, with women reporting and experiencing greater depression (whether they have a physical illness or not). Overall, the meta-analysis results highlight the need for researchers to examine the impact of illness on the patient and partners, as well as the mutual influence of patients and partners on each other (Revenson & DeLongis, 2011).

Dyadic coping (Bodenmann, 2005) refers to the idea that when an adverse event occurs, couples evaluate the event as a shared stressor, combining their resources to cope with the problem together. Dyadic coping draws on the stress and coping model (Lazarus & Folkman, 1984) described earlier.

Relationship-focused coping, a form of dyadic coping, involves cognitive and behavioral efforts to resolve stressors while keeping close relationships intact. Two types of relationship-coping strategies are often studied: *protective buffering* and *active engagement*. Protective buffering refers to suppressing one’s own worries in order to minimize the other partner’s distress or to avoid relationship conflict. For example, a husband undergoing cancer treatment may hide his fears of dying in order to keep his wife from worrying. A number of studies have shown that protective buffering is harmful to the person doing the protecting. Active engagement, however, involves including one’s partner in dialogue about stressful circumstances to generate solutions that are acceptable to both parties. Active engagement may benefit patients by allowing them to reclaim a sense of personal control over the events surrounding their illness; it may benefit partners by reducing feelings of helplessness.

Consider Alana, the woman diagnosed with MS we referred to earlier. She may involve her husband in various decision-making discussions about treatment options, the children's needs, and her career plans. This engagement, in turn, may prove better not just for patients like Alana but also for a couple's overall relationship satisfaction. Protective buffering may not necessarily yield the same benefits. Women often refrain from asking their ill husbands for emotional support to protect them from experiencing additional distress, even at the cost of the women's own emotional well-being.

The *systemic transactional model* (STM) of coping (Bodenmann, 2005) provides a framework for dyadic research that has been utilized in many studies. When faced with a shared stressor, partners respond both individually and as a collective unit. At the individual level (see the stress and coping paradigm above), a person's cognitive appraisal of a dyadic stressor is shaped by his or her own needs and concerns. Based on these appraisals, a stress communication process is triggered, whereby each person communicates his or her own stress to the partner in hopes of receiving emotional and/or practical support. At the dyadic level, the couple copes to manage aspects of the illness together. In the STM, adjustment includes both individual-level outcomes (e.g., distress) and dyad-level outcomes (e.g., relationship quality).

The STM distinguishes among different types of dyadic coping. Positive dyadic coping includes shared problem solving, information seeking, emotional expression, practical support, mutual commitment, and task delegation. Negative dyadic coping involves ignoring requests for support as well as avoiding the problem and the partner. Joint problem solving (a form of positive dyadic coping) was associated with decreased cancer-related distress and increased marital adjustment among women with metastatic breast cancer and their husbands; mutual avoidance (a form of negative dyadic coping) was related to poorer adjustment. A longitudinal study of couples facing breast cancer corroborated these findings and also suggested that certain types of dyadic coping may benefit one partner and not the other. Specifically, patients may experience increased distress when they are delegated tasks by their partners, whereas *partners* might benefit when patients delegate tasks to them. One reason for this may be that being delegated tasks by one's partner reduces the caregiver's feelings of helplessness, not necessarily the patient's. Although the study of dyadic coping is complex, there is solid evidence that a chronic illness is a challenge, shared by both patients and their intimate partners, and that studying dyadic processes within this context is a warranted endeavor.

Family Coping

According to *family systems theory*, the family is a unitary system, composed of related individual parts that influence each other. A family member's diagnosis is likely to create both individual and shared stressors, calling for readjustment on the part of the entire family, not just the person who is ill or the spouse. As the scope of this topic is vast, we focus only on parents and siblings coping with a child's illness.

Studies on the psychological impact of childhood illness have documented increased post-traumatic stress, depressive symptoms, and anxiety among parents. Moreover, parents reported the greatest uncertainty, anxiety, depressive symptoms, and post-traumatic stress immediately after their child's cancer diagnosis. Some parents continued to experience these sequelae 5 or more years after the diagnosis. Mothers often report more stressors than fathers, as they are likely to provide more care to the ill child.

Particular parental coping strategies are more effective at specific stages of illness. Avoidance-oriented coping strategies are most functional at early stages of the child's illness when parents reported feeling overwhelmed by the diagnosis and the uncertainty it brings. When children are in treatment, however, avoidant coping was related to increased psychological distress, and approach-oriented coping was related to decreased distress. A number of studies have shown that elevated parental distress poses psychological implications for the child. For example, parental distress is related to depressive symptoms and may interfere with parents' management of their child's treatment regimen.

Sibling Coping and Adaptation to Illness

There is mixed evidence on psychological adjustment of siblings of chronically ill children. A few studies found little difference in functioning between siblings of ill and healthy children in the same family. Other studies established that siblings of ill children have greater symptoms of depression and anxiety, engage in fewer peer interactions, exhibit increased behavioral problems, and use more avoidant coping. These findings suggest that siblings of ill children may retreat "inward" and be less likely to actively seek support when needed.

Female siblings are more vulnerable to psychological distress, which may be due in part to the notion that they take on increased household responsibilities because their mother is caring for the ill child. Older siblings are at higher risk than younger siblings for psychological distress, especially when the ill child had a life threatening. Because of their cognitive ability to understand consequences of a chronic condition and its toll on the parents and the family, older siblings may be more likely to suppress feelings. Conversely, parents may be more likely to give older siblings more responsibility, thinking them better able to care for themselves than younger siblings.

Future Directions in Coping and Adaptation to Illness

Coping with chronic illness is a complex psychological process for individuals, dyads, and families. What we *do* know is that coping is shaped by many factors, including psychological factors (e.g., mastery) and illness stage (e.g., time of diagnosis, treatment phase). However, many unanswered questions remain. We know little about how coping processes unfold over time as many studies employ cross-sectional designs, studying individuals or families at one point in time. Often, only one illness is studied. Are there differences in coping and adaptation processes that are consistent across illnesses? The adaptive tasks model suggests that there are similar challenges across illnesses, but we have little data to support this. Future work would benefit from including immediate family members, examining factors that promote and hinder family adaptation to chronic illness, and using longitudinal methodologies. This information is critical for the development of cost- and time-efficient interventions geared toward improving the psychological well-being of those living with a chronic illness and their loved ones, starting at diagnosis and continuing beyond.

Counterfactual Thought

Counterfactual thoughts contrast reality to an imagined alternative: “what might have been” had some action or circumstance been other than it really was. For instance, an individual might think “if only I had stopped smoking sooner” or “at least we caught it early” when receiving a cancer diagnosis. Counterfactuals are a pervasive part of our mental landscape. Their evaluative nature facilitates causal reasoning. For instance, the counterfactual “if only I hadn’t been speeding, I wouldn’t have gotten into the accident” identifies speed as the cause of the accident, rather than weather conditions or a distracted driver. Counterfactuals therefore influence the formation of future intentions and subsequent behavior (e.g., intentions to obey speed limits and actually obeying speed limits in the future; for a review see Epstude & Roese, 2008; Roese, 1997; Roese & Epstude, 2017).

Counterfactuals can identify alternatives that are either better than reality (*upward counterfactuals*) or worse than reality (*downward counterfactuals*). Upward counterfactuals are generally related to self-improvement motivations (Roese, 1997), as they identify ways that an outcome might have been improved and thus suggest strategies to improve future outcomes (e.g., “if only I’d stretched first, I wouldn’t have gotten injured” suggests that stretching will reduce future injury). Upward counterfactuals facilitate the generation of intentions (Roese, 1994; Smallman & Roese, 2009) but are associated with negative affect and underpin the emotional experience of regret (Gilovich & Medvec, 1995). In contrast, downward counterfactuals are related to self-enhancement motivations and generally improve affect (Roese, 1997). For instance, the thought “at least I don’t need surgery” might make one feel better about having a minor injury. Exceptions to this pattern occur when the outcomes are ongoing rather than final. In these cases, individuals may focus more on similarities rather than differences between reality and the imagined alternative (Markman & McMullen, 2003). The team that is losing by one point at halftime, the student who almost gets an A on the first quiz, and the dieter who is almost at his goal weight may all feel hopeful and motivated rather than dejected if they perceive

ongoing opportunity to reach these goals, whereas the team with a narrow lead or the driver who narrowly missed an accident may feel apprehensive rather than overjoyed if they perceive continued threat. All counterfactuals can be structured either as *additive* counterfactuals, focused on the addition of actions that might have occurred, but didn't (e.g., "If only I had exercised more …"), or as *subtractive* counterfactuals, focused on the deletion of actions that did occur, but should not have (e.g., "If only I hadn't consumed so much alcohol …").

Two broad factors increase the likelihood of counterfactual generation: the valence (positive or negative) of an outcome and the ease of simulating alternatives. Counterfactuals are more likely following negative events, failure, or unmet goals (Roese, 1997). In general, counterfactuals are most likely to be generated when an alternative is easy to imagine and would clearly have led to another outcome (Kahneman & Miller, 1986). Unusual events are more likely to elicit counterfactuals: individuals are more likely to generate counterfactuals about a driver's route when he got into an accident if the driver took a detour rather than his typical commute (Kahneman & Miller, 1986). Finally, events that more nearly occurred are more likely to prompt counterfactuals: a student who got an 89% is more likely to generate counterfactuals about the exam than a student who got an 87%, because the former grade is closer to having been an A (Roese, 1997).

Given their strong links to emotional experience and decision making, counterfactuals play a broad and varied role in health. At times, counterfactuals can have deleterious effects: upward counterfactuals and the related emotion of regret are associated with various negative mental health outcomes, including depression, anxiety, and problems coping with traumatic events. Additionally, although counterfactual thought is a common and important cognitive process in healthy populations, particular health conditions are associated with deficits in counterfactual thought. Counterfactuals can also have mental health benefits, including promoting a sense of meaning in life. Furthermore, because of their important role in causal reasoning and future planning, counterfactuals can benefit health decisions, changing behavior by either strengthening behavioral intentions or increasing motivation and persistence.

Mental Health and Well-Being

Both excess and deficient counterfactual thought are associated with a broad range of negative outcomes. Mental disorders that are characterized by emotional distress or challenges in coping generally involve excessive or extreme responses to upward counterfactuals. In contrast, other disorders such as schizophrenia and neurological conditions including Parkinson's disease show deficits in counterfactual thought. However, both upward and downward counterfactuals can facilitate coping and enhance well-being.

Excessive Counterfactual Thought

Thoughts of "what might have been" are associated with emotional distress, even among healthy populations. Depression and anxiety are particularly associated with increased counterfactual generation. Although depressed and nondepressed individuals generate the same number of counterfactuals when given explicit instructions, Quelhas and colleagues found that depressed individuals generate more counterfactuals spontaneously, that is, when asked to describe their thoughts without specific instructions to think about "what might have been." Likewise, participants high in social anxiety are more likely to generate upward counterfactuals about social events compared with those low in social anxiety. The relationships between counterfactuals, anxiety, and depression are not due simply to the presence of ruminative thinking in depression. In a nationally representative phone survey conducted in 2009, Roese and colleagues found that high levels of regret predicted depression and anxiety better than excessive rumination and the interaction between regret and repetitive thoughts was highly predictive of general distress (Roese et al., 2009).

Other research has focused on the role of chronic deficits in personal control in counterfactual thought. In the 1990s, Markman and colleagues found that perceived control mediated the association between depression and increased generation of controllable counterfactuals. Thus, these authors suggest that increased counterfactual generation is a response to greater chronic motivations for control among depressed participants.

In addition to the greater prevalence of counterfactual thought, depression is also associated with more negative responses to upward counterfactuals. For example, severely depressed participants generate counterfactuals that are less controllable and less reasonable, compared with mildly or moderately depressed participants. These less reasonable and controllable counterfactuals are less useful for managing ongoing behavior. Thus, although counterfactual thoughts can be functional, people with depression may generate less functional or potentially dysfunctional counterfactual thoughts.

Beyond its connections to depression and anxiety, excessive counterfactual thought directly contributes to insomnia. A series of recent studies by Schmidt and colleagues have shown that generating counterfactuals about the day's negative events at bedtime increases difficulty in falling asleep. This effect emerges even when individuals are randomly assigned to generate counterfactuals, suggesting a causal effect of these thoughts on insomnia, and when controlling for rumination and anxiety in correlational studies.

In short, excess counterfactual thought, particularly when not tailored to improving future outcomes, is associated with a range of emotional disturbances.

Counterfactuals and Coping

Just as increased upward counterfactuals are associated with emotional dysfunction and dysregulation, they also are associated with impaired coping with traumatic events. Given that counterfactuals are elicited by negative events (Roese, 1997) and have emotional consequences, counterfactual thoughts are particularly important in contexts of trauma. Preoccupation with alternative outcomes (counterfactual thinking) is a central component of the ruminations of trauma victims. Increased counterfactual thinking has been linked to distress and anxiety for individuals who had lost a spouse or child in an automobile accident or a child to SIDs, been a victim of assault, or experienced a miscarriage.

One particularly influential aspect of counterfactuals is the tendency for trauma survivors to generate counterfactuals focused on how their own actions might have allowed them to avoid the event, fostering self-blame. Research by Branscombe and colleagues found that generating counterfactuals focused on how a victim of sexual assault might have avoided the incident increases victim blaming both by observers and victims. Among rape victims, those who generated more self-focused upward counterfactuals had lower well-being. Importantly, this relationship was mediated by self-blame: counterfactuals increased self-blame but not blame for the rapist or social factors, which led to deficits in coping. However, even in contexts in which self-blame is not focal, trauma is associated with increased upward counterfactual thought. Victims of terror attacks in Israel who were diagnosed with PTSD generated more upward counterfactuals, even though there was no particularly obvious self-blame for the incident (Gilbar, Plivazky, & Gil, 2010).

However, downward counterfactuals are more likely when individuals have a goal of regulating and improving affect following distressing events (Roese, 1997). Furthermore, downward counterfactuals may facilitate coping and psychological well-being by helping individuals to feel better about an outcome or by increasing meaning in life. Individuals who thought counterfactually about an important life event (e.g., how they might not have met a close friend) or how they might not have been born found these events or their life as a whole more meaningful than individuals who thought factually about the same event. In some cases, therefore, counterfactuals offer emotional benefits, particularly in the case of downward counterfactuals.

Deficits in Counterfactual Thought

Although excessive upward counterfactual thought is associated with emotional difficulties, other disorders show impoverished counterfactual thinking, which can cause difficulties with problem-focused cognition and reduced negative affect following negative outcomes.

In the mental health context, counterfactual impairment is best documented in schizophrenia. Research by Roese and colleagues shows that schizophrenia patients are less able to activate counterfactual thoughts relative to healthy control participants. When asked to generate counterfactual thoughts about a recent negative experience, schizophrenia patients described fewer counterfactuals compared with control participants. Additionally, research using the Counterfactual Inference Test (CIT), which presents scenarios that typically elicit a counterfactual response, found that schizophrenia patients had more difficulty drawing counterfactually driven inferences about social events compared with control participants. Importantly, diminished counterfactual thinking partially mediated the impaired social functioning experienced by the schizophrenia patients, thus highlighting the role that counterfactual thinking plays in regulating behavior and successfully negotiating the psychosocial world.

Furthermore, even when individuals with schizophrenia were provided with counterfactual thoughts, these counterfactuals did not strengthen relevant behavioral intentions. That is, after reading a negative event (e.g., missed a doctor's appointment) and the associated counterfactual (could have written it on my calendar), healthy control participants showed the expected pattern: a negative event paired with an upward counterfactual increased intentions to perform the behavior. In contrast, schizophrenia patients did not show an increase in the likelihood of performing that action in the future. Given that the deficits in counterfactual thinking did not appear to be the result of general cognitive impairment, researchers believe that impaired frontal lobe activity in particular may explain diminished counterfactual thinking in schizophrenia patients.

Diminished counterfactual thinking is also associated with Parkinson's disease (McNamara, Durso, Brown, & Lynch, 2003). Parkinson's patients generated fewer spontaneous counterfactuals in a thought-listing task and performed worse on the CIT compared with age-matched healthy control participants. Again, diminished counterfactual thinking significantly correlated with measures of frontal lobe functioning, indicating that an inability to generate counterfactuals might be related to frontal lobe dysfunction.

Together, this research suggests that frontal lobe impairment may partly explain why counterfactual thinking is diminished in schizophrenia and Parkinson's patients. More broadly, the possibility that counterfactual thinking is processed in the frontal lobe is supported both by neuropsychological theory and research on patients with brain lesions or damage (Camille et al., 2004; Gomez-Beldarrain, Garcia-Monco, Astigarraga, Gonzalez, & Grafman, 2005). In general, the frontal lobes are involved in social functioning, decision making, planning-related cognitions, and the integration of emotion with decision making processes, functions also served by counterfactual thinking. Patients with prefrontal cortex lesions showed impaired spontaneous counterfactual thinking but were capable of cued counterfactual thinking and indirect counterfactual inferences. Thus, it appears that damage to the prefrontal cortex is particularly detrimental to self-generated counterfactual thoughts (Gomez-Beldarrain et al., 2005). Additional research has focused on the orbitofrontal cortex and its role in counterfactual thinking and the counterfactually induced emotion of regret, with studies showing that lesions in this area are associated with reductions in regret following a gambling task (Camille et al., 2004).

Accordingly, certain health problems may be associated with impairments in counterfactual thinking and related processes. Given that counterfactual thinking can be helpful in changing behavior, improving future outcomes, and increasing motivation and persistence, additional steps may be needed to elicit these functional aspects of counterfactual thinking that are not typically required in a healthy population.

Health Decisions and Health-Relevant Behaviors

Counterfactuals can hinder sound judgment, as they can alter evaluations in “irrational” ways (e.g., missing a flight by 5 or 50 min is objectively equivalent, but they feel different because of counterfactual thought). In addition to their emotional and mental health implications, counterfactuals can bias decision making such as blame and responsibility judgments during jury or medical treatment decisions. However, a more recent approach emphasizes the functional aspect of counterfactual thinking in regulating behavior via monitoring, managing, and coordinating behavior (Epstude & Roese, 2008; Roese, 1994; Roese & Epstude, 2017).

However, not all counterfactuals serve this preparative function. Upward counterfactuals that focus on taking action (e.g., if only I had gotten tested sooner) and counterfactuals following negative outcomes that involve future opportunities for action are most likely to be functional. Put simply, counterfactuals are most helpful when dealing with the actions one can take to address a problem that might occur again in the future (for a review, see Epstude & Roese, 2008; Roese & Epstude, 2017).

Upward counterfactuals facilitate changes in behavior in multiple ways. First, by providing insight and information about how a negative outcome might have been avoided, counterfactuals can strengthen intentions to change the behavior, increasing the likelihood of changing future behavior (Roese, 1994; Smallman & Roese, 2009). Second, counterfactuals that elicit negative affect can increase motivation and persistence on a task (Markman, McMullen, & Elizaga, 2008).

Counterfactuals and Behavior

According to the functional perspective, a primary function of counterfactual thought is problem solving. When individuals fail to reach a goal or encounter a problem, counterfactuals highlight behaviors that might correct those problems and facilitate goal achievement. For example, a person with a weight-loss goal might go grocery shopping while hungry, resulting in a cart full of junk food. Counterfactual thoughts such as “if only I had eaten before I went shopping” or “if only I had a shopping list” provide behaviors that could help avoid a recurrence of the situation and restart progress toward the weight-loss goal. In this way, counterfactuals help individuals evaluate a problem and offer new actions that will facilitate future improvement.

Originally, counterfactual-driven behavior change focused on academic (e.g., exam performance; Nasco & Marsh, 1999) and problem-solving (e.g., anagrams; Markman et al., 2008; Roese, 1994) behaviors. For example, after receiving exam grades, students who generated upward counterfactuals about their exam performance increased their grades on a subsequent exam (Nasco & Marsh, 1999). Upward counterfactuals increased students' feelings of control over the situation and made them more likely to perform the behaviors specified in the counterfactual, which in turn improved subsequent exam performance. Counterfactuals about anagram performance improved subsequent performance due to both the strategic thoughts (i.e., the useful tips to improve their anagram score) and also because of changes in motivation and subsequent effort (Roese, 1994; see also Markman et al., 2008).

Behavior change can occur for health-relevant behaviors as well. A series of studies examined whether counterfactual thinking could be an effective antismoking strategy (Page & Colby, 2003). In these studies, participants read a negative smoking scenario (describing a smoking-induced abnormal lung growth) then generated counterfactuals and rated affective responses about the scenario and indicated their willingness to participate in a smoking-related behavioral test (a lung capacity test) either immediately or after a 2- or 7-day delay. Although upward counterfactuals did not increase their willingness to sign up for the lung capacity test, additive counterfactuals did. Importantly, this increase occurred both immediately and after a 2- or 7-day delay, although the effect weakened over time. Although this finding differs from findings that upward counterfactuals increase behavior change, it supports the second tenet of the functional theory of counterfactual thinking, which predicts that additive counterfactuals should also increase behavior change.

Although so far we have focused on positive behavioral change, counterfactuals may also increase the likelihood of engaging in negative behaviors. Recently, Effron and colleagues have shown that counterfactuals that focus on the "sinful road not taken" can provide justification for unhealthy food choices. That is, considering less virtuous alternatives to one's past behavior (i.e., counterfactual sins) gives individuals the freedom to indulge (e.g., "I could have had a burger at lunch, but I didn't, so I can have ice cream tonight"). Additionally, since counterfactuals increase goal pursuit, there is no guarantee that they will increase behaviors related only to healthy goals; instead, they might help one pursue hedonic goals and increase the likelihood of enacting relevant unhealthy behaviors. For example, an individual who believes that his insistence on using a condom disrupted a previous sexual experience may think, "If only I hadn't stopped to talk about using a condom, things might have gone better," and thus be more likely to engage in unprotected sex in the future. Finally, even for healthy or adaptive goals, counterfactuals may help individuals identify unhealthy behaviors to achieve that goal. For instance, an individual with a healthy weight-loss goal might adopt a starvation "cleanse" diet, or a student hoping to improve class performance might abuse stimulants.

In short, counterfactuals can change future behavior. However, there are multiple pathways to behavior change. The first involves strengthening relevant behavioral intentions, which in turn increases the likelihood of performing the desired behavior in the future. The second involves increasing motivation and persistence toward future behavior.

Counterfactuals and Intentions

One-way behavior change might occur is by strengthening intentions that are directly related to the behavioral outcome. That is, after a negative outcome (getting a particularly bad sunburn), a counterfactual thought ("if only I had worn sunscreen") might provide insight regarding the usefulness of a particular action (wearing sunscreen), which prompts the relevant behavioral intention ("in the future I will wear sunscreen"), and consequently influences performance of that particular behavior (wearing sunscreen).

Upward counterfactuals strengthen relevant behavioral intentions in a variety of contexts. Students who generated upward counterfactuals about a recent negative academic performance (e.g., thinking about how they could have studied their notes after failing an exam) had higher intentions to perform success-facilitating behaviors in the future (e.g., saying they would be more likely to study their notes before the next exam; Roese, 1994). Similarly, pilots who generated upward and self-focused counterfactuals about their own near-accident flying incident had stronger intentions to perform behaviors that would have helped them avoid the incident (Morris & Moore, 2000).

Recent research by Smallman and colleagues (e.g., Smallman & Roese, 2009) using a reaction-time paradigm found that upward counterfactuals were more likely to activate and strengthen relevant behavioral intentions across a wide range of negative events, including academic, social, and health behaviors. However, it is important to note that not all counterfactuals are equally likely to strengthen relevant intentions. In particular, counterfactuals that are more detailed or include specific behaviors are more likely to strengthen intentions compared with counterfactuals that are more general or include traits. For example, after getting into a drunk-driving accident, the counterfactual "if only I had called a cab" is more likely to strengthen intentions compared with the counterfactual "if only I had acted more responsibly."

Within health-relevant intentions, Epstude and Jonas (2015) examined the consequences of counterfactual thinking and regret in HIV-positive men. Results showed both harmful and helpful consequences. Counterfactuals and regret about their HIV status had a negative impact on well-being. Yet these counterfactuals also identified potential safe-sex behaviors, strengthening their safe-sex intentions for the future. This finding is particularly interesting because it focuses on an irreversible event (i.e., contracting the HIV virus). Typically, counterfactuals are most functional in the context of repeatable events, which allow for the application of the counterfactually driven insight to a future situation. These findings broaden that perspective, such that individuals might learn from non-repeatable events, as long as a future situation arises where the application of that knowledge is appropriate (e.g., future sexual encounters).

Similarly, research on binge drinking has found that counterfactual thinking can decrease intentions to binge drink (Baek, Shen, & Reid, 2013). In this study, participants generated counterfactuals in response to a binge drinking public service announcement. Although additive counterfactuals (actions that could have been taken) are typically more functional, this research demonstrated that subtractive counterfactuals (actions that should not have been taken) can also be functional depending on the message framing. That is, when researchers used a gain-framed appeal (beneficial outcomes of responsible drinking), additive counterfactuals lowered binge drinking intentions. But when a loss-framed appeal (harmful outcomes of irresponsible drinking) was used, subtractive counterfactuals lowered binge drinking intentions. Accordingly, message framing may be an additional factor to consider when trying to elicit functional counterfactual effects.

These findings describe one possible mechanism, the strengthening of behavioral intentions, through which counterfactual thinking can facilitate behavior change. Given the importance of intentions in other behavior-prediction theories (e.g., theory of planned behavior) and their prevalence in studying health-relevant behaviors, counterfactuals might serve as a cognitive tool to activate or strengthen a relevant behavioral intention.

Counterfactuals and Motivation

A second way that counterfactual thinking can influence performance is by increasing motivation and persistence. The negative affect produced by a counterfactual can increase motivation and persistence toward satisfying achievement goals. Unlike changes in intentions, motivational influences may result from both upward and downward counterfactuals (Markman & McMullen, 2003; Markman et al., 2008). First, increased motivation may occur when upward counterfactuals are considered in an evaluative manner, in which an individual contrasts the better alternative to the lesser reality. For example, a student who gets a C on an exam might feel bad after comparing it to the A he could have gotten, which motivates him to work harder. Additionally, increased motivation may occur when downward counterfactuals are considered in a reflective manner, in which an individual focuses mainly on the worse alternative (imagining it is true), without comparing it to the better reality. For example, a student who just barely gets a C on an exam might focus solely on how she nearly failed the test, motivating her to work harder.

Mechanisms that increase motivation and persistence toward goal attainment should be particularly relevant in the health domain. While health practitioners can provide information and tools for improving health outcomes, patients must have the motivation and persistence to work toward these goals. For example, researchers examined whether counterfactual thinking can increase a person's motivation to read and process food label information (Aboulnasr & Sivaraman, 2010). Results showed that counterfactual thinking increased participants' motivation to process this information systematically. Participants who generated counterfactuals examined both health claims and nutrition information more carefully and were more likely to use this information when evaluating the products. Importantly, these motivational effects may last up to seven days after counterfactual generation, indicating that the counterfactual-driven motivational boost may extend beyond the immediate time frame.

Importantly, these two pathways (strengthening relevant intentions and increasing motivation) may work together to change behavior and increase the likelihood of reaching one's goals. For example, a negative event (e.g., driving while intoxicated) might prompt counterfactual thoughts (e.g., "if only I had called a cab"). These thoughts provide useful insights about how an outcome might have been avoided, which can strengthen intentions to enact these behaviors in a future similar situation. However, these thoughts may also heighten negative affect (i.e., the person feels even worse about the situation), which in turn increases motivation and persistence related to these behaviors. Like a steering wheel and a motor, intentions and motivation may work together to change behavior and facilitate goal attainment.

Conclusion

Counterfactual thoughts, identifying alternatives to reality, play a wide and varied role in health. Both excessive counterfactual thought and deficits in counterfactual thought are associated with impaired mental health, with the former being associated with emotional dysfunction and the latter with frontal lobe damage characteristic of schizophrenia and Parkinson's disease. However, counterfactuals can also be beneficial: downward counterfactuals about worse outcomes can promote well-being and meaning in life, and upward counterfactuals can facilitate healthy behavior by facilitating the formation of behavioral intentions and increasing motivation. Whether counterfactuals are beneficial or harmful to health depends on a number of factors, including the structure of the counterfactual thought, the specific behaviors identified, and potentially the broader context of these thoughts, such as whether a particular outcome is repeatable or final. Given their importance to health and their frequency in daily life, counterfactuals thus require thoughtful and nuanced consideration in health psychology.

Couple-Relationships and Cancer Adaptation

Hoda Badr and Zeba Ahmad

Icahn School of Medicine at Mount Sinai, New York, NY, USA

The past three decades have seen major increases in cancer survival through improvements in early detection and treatment. There are now over 14.5 million individuals alive today with a history of cancer, and this segment of the population continues to grow rapidly (Office of Cancer Survivorship, 2015). Today, two-thirds of cancer patients can expect to live 5 years or more after diagnosis. It is therefore important to begin to think about their quality of life (QOL) during and after cancer, starting from the point of diagnosis (Office of Cancer Survivorship, 2015).

QOL is a multidimensional construct encompassing physical, psychological, and social well-being. In cancer, social relationships are the most studied factor contributing to QOL (see Manne & Badr, 2008). For survivors who are married or in a committed relationship, their relationship with their partner (spouse or significant other) is often their primary coping resource, and studies have shown that survivors frequently rely on their partners to provide caregiving and emotional support (e.g., Keefe et al., 2005).

In the United States, approximately 4.6 million people care for a partner or family member with cancer at home (National Alliance for Caregiving, 2009). As the primary setting for care has shifted from hospital to home, family members have found themselves replacing skilled healthcare workers in the delivery of care. In addition to undertaking complex care tasks and providing emotional support, partners must cope with the grief and loss associated with their loved one's life-threatening illness. Most assume their role with little or no formal preparation and training and have low self-efficacy for caregiving. This is problematic because lower levels of caregiver self-efficacy are associated with increased psychological distress (Grov, Dahl, Moum, & Fosså, 2005). Caregivers also frequently encounter communication difficulties with patients, which can adversely affect the coordination of care as well as the quality of their relationship and QOL. Given the above, this chapter will review the QOL challenges facing cancer patients and their partners, discuss the impact of cancer on couple relationships, and posit directions for future research.

QOL Challenges Faced by Cancer Patients and Their Partners

Physical Well-Being

Although the goal of most cancer treatments is to improve or maintain physical functioning and overall QOL, patients often experience physical symptoms that persist long after treatment ends. Cancer patients have reported an average of 11–13 concurrent symptoms including pain, fatigue, labored breathing, nausea, shortness of breath, lack of appetite, loss of body mass, dry mouth, and difficulty sleeping (Portenoy et al., 1994). These symptoms may be a result of the disease or treatment and can adversely affect health-related QOL (Portenoy et al., 1994).

The physical and emotional toll of caring for a partner with cancer may also negatively impact the caregiver. In a study examining sick leave usage, partners of lung cancer patients had the most sick leave episodes, which may be attributed to higher physical and emotional burdens of care (Sjövall et al., 2010). As cancer progresses, added caregiver stress may result in sleep disturbance, fatigue, and unhealthy behaviors. Studies have shown that caregivers' health behaviors may also be negatively impacted following a loved one's cancer diagnosis (Beesley et al., 2011). One reason for this is may be that caregivers prioritize the care of the patient over their own self-care.

Psychological Well-Being

An estimated 35% of people diagnosed with cancer experience clinically significant levels of psychological distress (Halford, Chambers, & Clutton, 2010). Risk for depression is higher in this population than in the general population. Being diagnosed at a younger age and being newly diagnosed are associated with elevated risk for distress (Hagedoorn, Sanderman, Bolks, Tuinstra, & Coyne, 2008).

The psychological distress associated with cancer has negative health and behavioral consequences, including nonadherence to medical regimens, increased emergency and inpatient service use, delayed return to work, and possibly elevated rates of suicidal ideation or suicide and mortality (Fang et al., 2012). A supportive partner can help to buffer the adverse impact of cancer on patient distress and QOL (Kayser & Scott, 2008). For example, in a study of women with breast cancer, vulnerability to anxiety was moderated by the degree of felt support from a partner (Borstelmann et al., 2015). In a study of head and neck cancer patients, partners who used positive social influence tactics were effective in boosting patient positive mood and encouraging patient self-care (Badr, Yeung, Lewis, Milbury, & Redd, 2015).

Despite the benefits of having a partner, research has shown that partners are often as distressed as patients and distressed partners may find it difficult to provide adequate support to the patient (Milbury, Badr, & Carmack, 2012). Anxiety and depression are the most commonly reported problems, with estimates for depression at 39% (Braun, Mikulincer, Rydall, Walsh, & Rodin, 2007) and for anxiety at 40% (Janda et al., 2007). Very little is known about the factors driving partner distress; however, the patient's functional decline and increasing distress coupled with the increased need for the partner to assist with symptom management and provide support are likely contributing factors. Partner anxiety levels, depression, and stress have all been shown to increase as the patient's functional status declines and the patient approaches death (Grov et al., 2005). Caregiver depression also appears to be sensitive to sleep deprivation; declines in the caregiver's physical health; the perceived burden of caregiving; changes in roles, responsibilities, and leisure activities; and social isolation. Two meta-analyses examined the relationship between the psychological distress levels of patients with cancer and their spousal caregivers and found their responses to cancer to be interdependent: each person affected the other's level of emotional well-being (Hagedoorn, Buunk, Kuijer, Wobbes, & Sanderman, 2000).

Social and Relationship Well-Being

At times, people with cancer may experience difficulties relating to others. Despite this, research has shown the protective value of social relationships and social support on patients' cancer-related stress (Helgeson & Cohen, 1996). Social support is also important for partners and accounts for a significant amount of variance in their QOL. Real or perceived lack of support from social network and family members is associated with high levels of physical and psychological exhaustion, and many caregivers report that their social support decreases over time (Fineberg & Bauer, 2011). Worsening illness can burden caregivers, who become fatigued and lack the time to continue normal social activities. This loss of a social network increases a sense of isolation and is associated with worse psychological well-being.

Despite the importance of network support, patients report that their spouses or partners are the first persons from whom they seek support after a diagnosis. Research on cancer patients suggests that support from family members and friends does not compensate for a lack of partner support (Manne, Alfieri, Taylor, & Dougherty, 1999). Although partners can be supportive, they can also engage in unsupportive, negative behaviors that include minimizing the problem, forced cheerfulness, and insensitive comments. In a qualitative study, partners' denial and avoidance of cancer-related discussions was distressing to patients, made them change how they interacted with their partners, and strained the marital relationship (Badr & Carmack Taylor, 2006). In another study, patients and partners were videotaped as they discussed cancer-related concerns, and researchers coded the exchanges for socially supportive and unsupportive behaviors (Manne et al., 2004). When patients made emotional disclosures and spouses responded in an unsupportive fashion, patients reported greater distress and lower levels of marital satisfaction.

Poor marital satisfaction is associated with greater psychological morbidity among cancer patients. In contrast, patients who report greater marital satisfaction and better marital functioning report lower levels of psychological morbidity (see Kayser, 2005). In lung cancer, Carmack Taylor et al. (2008) found that a cycle of distress develops whereby one partner's distress exacerbates the other partner's distress and that this association is weaker when patients and partners report higher levels of relationship functioning. One explanation is that good relationships promote positive supportive dyadic coping whereby one person recognizes the other's distress and assists him/her in coping. Another is that people in good relationships are more likely to act in the best interest of their partner and their relationship. In this case, patients/caregivers may believe that managing their own distress is in the best interest of their loved one. Indeed, in surveying 158 patients and their spousal caregivers, Badr and colleagues found that even though 34.6% of patients and 36.4% of the caregivers in their sample were distressed, *both* were distressed in only 17.6% dyads (Carmack Taylor et al., 2008). Thus, for about half of the distressed patients, their caregiver was not distressed, and for half of the distressed caregivers, the patient was not distressed. This is not to say that having a loved one who is distressed is not distressing for patients and caregivers with good relationships; rather, they may be better than those with poor relationships at managing their own distress so it does not reach a clinical level.

Cancer treatment can challenge established patterns of communication, control, and responsibility in a relationship. Some patients report greater conflict, decreased intimacy, and strained communication after diagnosis, whereas others report that the illness brought them closer together (Dorval et al., 2005). Each juncture of the cancer treatment process brings challenges to patients and partners' communication and joint coping. In the weeks following diagnosis, these include negotiating changes in roles and responsibilities, dealing with interference with life plans, and managing household and childcare responsibilities. Concerns about the impact of cancer treatment or the desire to undergo fertility preservation procedures can cause delays in cancer treatment. During treatment, declines in physical functioning may interfere with household responsibilities, and integrating cancer into the everyday routines of a couple can be demanding (Kayser & Scott, 2008). Increased caregiving responsibilities can also alter sexual expression and increase tension between partners. A survey study of men with prostate cancer and their wives found high rates of sexual dysfunction associated with cancer treatment. Greater sexual dissatisfaction was associated with poorer marital adjustment, particularly in the absence of constructive communication (Badr & Carmack Taylor, 2009).

Declining functional abilities may bring about the necessity for couples to discuss how care and assistance with daily activities will be provided to the ill partner. Couples also typically negotiate difficult choices regarding end-of-life treatments and care and cope with anticipatory grief (see McLean & Jones, 2007). For couples who enter the posttreatment survivorship phase, the primary challenge is negotiating the transition to "normal" life, including partners' respective pace preferences. For most, the main tasks include resuming a sexual relationship, discussing changes in life plans, discussing health behavior changes, dealing with disease and treatment-related late effects that may influence the patient's functioning, managing worry about disease recurrence, and discussing the meaning of the cancer experience for themselves and the relationship.

Research has consistently shown that open, supportive communication is vital to maintaining positive relationship experiences while coping with the side effects of treatment and progressive illness. From a couples' perspective, successful adaptation may be less dependent upon the circumstances of the illness than on how well the couple integrates cancer into their lives.

Effects of Couple-Based Interventions on Patient and Partner QOL Outcomes

Couple-based interventions acknowledge that both members of the couple and their relationship are profoundly affected by the cancer experience (see Hagedoorn et al., 2008; Manne & Badr, 2008). Badr and Krebs (2013) conducted a systematic review and meta-analysis of randomized controlled trials of interventions that aimed to improve the physical, psychological, and social well-being of cancer patients and their partners. Their systematic review featured 23 qualifying studies and a total of 2,645 participants. Studies had an average sample size of 115 participants each ($s = 77$). The average age of participants was around 55 years, and approximately 16% of study participants were non-White. Forty-seven percent of eligible patients declined to participate in the studies, and 25% of participants withdrew from the studies. The majority (60%) of these studies focused on either breast or prostate cancer. Meta-analysis of study outcomes found small but beneficial effects of the interventions on physical, psychological, and relationship outcomes for both patients and partners. Weighted mean effect sizes and 95% confidence intervals are summarized in Table 1.

Topics of intervention sessions varied with the theoretical model being used. Methods included techniques from cognitive behavioral therapy, psychoeducation, emotion-focused therapy, and

behavioral marital therapy. "Partner-assisted" interventions conceptualized the partner as a facilitator of skill learning for the patient. The other interventions more actively involved both partners, treating the couple as one unit. Most interventions were composed of six sessions. Most sessions were conducted in person, although some were conducted over the phone.

Badr and Krebs' (2013) review highlighted a number of methodological limitations in the couples' intervention literature. Often, researchers did not articulate a theoretical model. Few examined the mechanisms by which interventions affected outcomes, so there are questions as to whether the theoretical basis of the intervention was as hypothesized. Most studies had small sample sizes and thus were underpowered to examine changes in the multiple outcomes that were measured. Some did not include information on refusal or attrition rates, suggesting reporting standards could improve. One-quarter of the studies that were reviewed did not report outcomes for partners. A lack of patient improvement could be explained by negative but unexamined effects on the partner or the possibility that patients and partners respond to intervention at different rates. Thus, future studies should include both partners and ensure that the couple is the unit of analysis throughout the research process. Another limitation is that none of the studies evaluated the cost-effectiveness of couple-based interventions relative to interventions targeting the patient or caregiver alone. Studies evaluating the relative cost of different modes of administration (i.e., in person, over the phone, internet) are needed.

Future Directions

As our review suggests, significant empirical attention has been paid to the challenges facing cancer patients and their partners that impact their relationships and QOL. There are also a number of unexamined issues. Understanding why some patients do not get the support they desire or expect and why certain couples are at risk for poor psychosocial outcomes will help clarify the role of couple relationships in adaptation to cancer. We also still do not fully understand the mechanisms by which social relationships are beneficial for patient and partner psychosocial adaptation and QOL.

Researchers should recognize that relationships and relationship roles change over time. Most studies have evaluated outcomes shortly after diagnosis. Indeed, many couples report that cancer brought them closer together, but it remains unclear what happens over time as couples learn to deal with the long-term side effects of cancer. Greater attention to sociodemographic variables is also needed. Because the majority of couple-based studies have focused on single-gender cancers such as breast or prostate, it is difficult to disentangle gender and role (i.e., whether the individual is a patient or partner) effects. Thus, more studies should include both members of the couple and focus on cancers that affect men and women. In addition, couples at different stages of the life cycle or cancer trajectory (i.e., early-stage versus end-of-life versus the posttreatment survivorship phase) may experience different physical, psychological, and relationship stressors and therefore have different expectations regarding not only social support but also interaction with their partners. To date, very few studies have investigated the cancer experience of minority couples, despite the fact that a recent comparative analysis showed that cultural differences do exist—particularly around the dimensions of family boundaries, gender roles, conception of personal control, and interdependence (Kayser et al., 2014). Individuals with low socioeconomic status and those in same-sex relationships have also been underrepresented in this literature.

Pre-illness relationship factors may affect couples' motivations to use cancer as an opportunity to enhance their relationship. Individual factors such as attachment style and interpersonal skills may also influence relationship processes and adjustment. Few measures of cancer-related communication exist, and those that do involve self-reports that assess the quantity rather than the quality or nature of discussions. Finally, relationship quality may be an important moderator or proxy for social support. Individuals who are more satisfied in their relationships may perceive greater support, may be more likely to explain away partners' unsupportive behaviors, and may benefit more from the support that they do receive.

Future intervention studies should target lifestyle behavioral changes, since partners can engage in unhealthy behaviors (e.g., smoking) that can interfere with patient adherence to medical recommendations after a cancer diagnosis. Partners who model healthy behaviors for one another, acknowledge each other's successes, provide constructive feedback, and work together to overcome barriers may benefit in terms of increased self-efficacy and lasting behavioral change.

Although couple-based interventions have had many positive effects, they are seldom implemented in clinical practice setting. Several barriers need to be addressed in order for this to happen, including increasing the awareness of caregivers' and couples' issues in practice settings, training healthcare professionals on how to deal with caregiver and couples' issues, and demonstrating the impact of these interventions on healthcare utilization, patient satisfaction, and cost savings. Supporting partners and couples can benefit the patient's recovery and clinical outcomes. Improved patient outcomes, such as reduced postoperative complications resulting from early identification of problems, better management of adverse effects, increased adherence to oral medication, and early detection of adverse events, would result in reduced healthcare use and costs.

In conclusion, couple relationships exert a strong influence on both patients' and partners' psychosocial adaptation and QOL. Future research may benefit from an increased focus on couples' interactions to address ways that couples can adaptively cope together. In addition, there is a growing need for healthcare providers to view the couple as the unit of care and provide more information and support to partners so they can provide effective caregiving for the patient while also maintaining their own health and well-being.

Direct-to-Consumer Testing

Angela M. Legg and May Reinert
Department of Psychology, Pace University, New York, NY, USA

Soon after the sequencing of the human genome, healthcare professionals could order genomic profiling for their patients. These genetic tests provided predictive and diagnostic information about patients' health risks and carrier status for illnesses ranging from breast cancer to Huntington's disease. Interested patients needed to consult with a physician or genetic counselor prior to receiving testing. These healthcare professionals then initiated an order for the patient to take the genetic test, typically for only one disease. To improve patients' understanding of their genetic risks, some physicians also required their patients to attend genetic counseling or additional consultations upon receipt of their results. However, the landscape of genetic testing dramatically changed in 2006 with the creation of direct-to-consumer (DTC) genetic testing services such as 23andMe. Interested patients no longer needed to receive physician or counselor approval before getting a genetic test. Patients also were not required to seek consultations or counseling sessions after receiving their results (although they were provided with this option). Completing a genetic test was as simple as collecting a cheek swab, shipping the kit, and awaiting the results. People could receive genetic risk information on a host of conditions ranging from cystic fibrosis, Alzheimer's disease, Crohn's disease, ovarian cancer, and even baldness. It is no wonder, then, that *Time* magazine deemed the "Retail DNA Test" the Invention of the Year in 2008 (Hamilton, 2008).

Despite the enhanced accessibility to genetic information brought on by the DTC wave, some controversy surrounds the use of and distribution of genetic risk data through DTC means. In 2013, the Food and Drug Administration (FDA) sent warning letters to several DTC testing companies, including 23andMe, prompted by concerns over releasing false health information and possible misinterpretation of results. In response, 23andMe discontinued the disclosure of disease risk information. While the company still provides full ancestry data, they now release only raw genetic data. These raw genetic data cannot be interpreted by untrained consumers and require consultation with a healthcare professional.

Although the scope of this entry focuses predominantly on DTC genetic testing, the empirical literature base remains quite small, perhaps reflecting the dramatically and rapidly evolving nature

of the DTC genetic testing landscape. Thus, when appropriate, we reference a related literature on DTC advertising of prescription pills to draw relevant connections. Although DTC genetic testing and advertising of prescription pills are distinct, they both provide consumers with opportunities to make health decisions prior to consultation with a healthcare professional. We suspect that where the DTC genetic testing literature currently lacks evidence, research on DTC advertising of prescription pills can offer informative avenues for future research.

The nature of DTC testing raises a number of questions relevant to health psychology, two of which are important for the scope of this entry. First, what psychosocial variables influence people's interest in DTC genetic testing? Second, what outcomes and downstream effects result from getting a DTC genetic test?

Psychosocial Predictors of Interest in DTC Testing

The introduction of DTC genetic testing opened up new research avenues to examine psychological predictors of interest in (and uptake of) DTC tests. In contrast to the traditional, in-office genetic tests, DTC genetic tests offer a more private, less expensive (~$99), and more autonomous method for learning about health risks. However, the findings thus far do not paint a complete or clear picture regarding the psychosocial predictors of DTC testing, likely reflecting the nascent state of the literature.

Demographics

Before examining the subjective psychosocial variables that may influence the use of DTC testing, we first consider the role of demographics. Generally, people with the greatest interest in and use of DTC tests tend to identify as well educated, employed or retired, and Caucasian (Kaufman, Bollinger, Dvoskin, & Scott, 2012; Sweeny, Ghane, Legg, Andrews, & Huynh, 2014; Wilson et al., 2008). Although one study noted that older participants more frequently used an at-home test in the past, younger participants reported greater intentions to use a DTC test in the future (Wilson et al., 2008; but see Sweeny & Legg, 2011 for data showing no age differences).

A similarly inconsistent pattern emerges for gender. Some sources point to greater interest among women (Wilde, Meiser, Mitchell, Hadzi-Pavlovic, & Schofield, 2011), whereas other evidence suggests that men are more likely to use DTC testing (Wilson et al., 2008). Still other sources suggest no gender difference in DTC testing intentions (Sweeny & Legg, 2011).

Although no consistent link between income and DTC testing currently exists (Sweeny et al., 2014; but see Kaufman et al., 2012), some evidence from the DTC advertising literature suggests that people in lower income brackets are more persuaded by DTC advertising for prescription pills (Mathew, Spake, & Finney, 2008), a finding that may reflect lower health literacy levels in lower income individuals.

Self-Reported Reasons for and Against Testing

The most commonly reported reason for pursuing DTC genetic testing (or reporting intentions to do so) is that people are curious and desire detailed information about their genetic profiles (Goldsmith, Jackson, O'Connor, & Skirton, 2012; Roberts & Ostergren, 2013). Genetic counselors agree that DTC genetic testing can raise awareness and provide knowledge about risk factors (Hock, Christensen, Yashar, Gollust, & Uhlmann, 2011). They also report that DTC genetic testing is advantageous for people in rural locations who live far from trained genetic counselors (Hock et al., 2011). Further, in a review of the DTC genetic testing literature, Goldsmith et al. (2012) indicated that many people believe genetic test results will motivate future healthy behaviors, facilitate family planning and discussion for future health conditions, and could be used in conjunction with a physician's oversight to monitor health.

In contrast, people's reported reasons against testing tend to focus on fears of their emotional and psychological reactions if they learn they are at risk for a disease (Goldsmith et al., 2012). From clinicians' perspectives, the possibility of misinterpreting results is a commonly listed reason against testing, especially in the absence of a trained healthcare professional (Hock et al., 2011). Ninety percent of these genetic counselors also listed the risk of feeling a false sense of security if a person learns that he or she is not a carrier for a certain disease. Finally, the possible risks of inadequate security protections or abuse or misuse of private information are frequently provided reasons against testing (Critchley, Nicol, Otlowski, & Chalmers, 2015; Mathews, Wayne, & Carter, 2012).

Perceived Barriers and Benefits to Testing

The costs and benefits associated with taking a test can affect whether people pursue DTC testing. Perceived barriers, or the costs and disadvantages associated with testing, decrease people's intentions to obtain DTC genetic testing (Sweeny & Legg, 2011). Barriers include, but are not limited to, concerns about the unethical disclosure of genetic results, financial cost of testing, difficulty taking the test, and difficulty returning the test back to the company.

In contrast, believing that a genetic test will offer advantages and benefits consistently predicts interest in general genetic testing (Sweeny et al., 2014) and also for DTC genetic testing (Sweeny & Legg, 2011). Some of these benefits include the additional privacy afforded by DTC genetic testing, less embarrassment if seeking information about stigmatized diseases, lower cost compared with in-office genetic testing, motivation to adopt other healthy and preventive behaviors, and greater ability to prepare for and cope with a possible disease. Although people may also report the autonomy afforded by DTC genetic testing as a benefit, it remains to be seen whether perceived benefits related to autonomy and privacy have shifted in light of the 2013 FDA regulation. Further, now that DTC genetic testing companies such as 23andMe only provide raw genetic data, the research currently makes no comment regarding whether potential customers now perceive greater barriers due to the need to seek out healthcare professionals to interpret their genetic profiles.

Knowledge and Awareness

An interesting phenomenon captured in the literature is that some knowledge about and awareness of DTC genetic testing positively relates to intentions to pursue testing, but upon viewing additional or more complete information, people's intentions to pursue DTC testing tend to decline, and preference for obtaining genetic test results through a physician increases (Wilde et al., 2011). A similar pattern emerges when considering the valence of information people view. Participants who read both positive and negative information about DTC testing reported similar levels of interest to those who viewed only negative information (both were less interested than people who viewed only positive information), suggesting that people are particularly sensitive to the downsides of DTC testing (Sweeny & Legg, 2011). Perhaps naive curiosity is a more powerful predictor of intentions to test initially, but people become more cautious upon considering the possible barriers and disadvantages of testing.

Anticipated Regret

Before deciding to take a DTC genetic test, people often imagine how they will feel after they receive their results or how they will feel if they miss out on the chance to take the test. This anticipatory regret over testing and over not testing predicts intentions to test (Sweeny & Legg, 2011). In Sweeny and Legg's (2011) study, participants who viewed positive information about genetic testing reported greater anticipated regret over not testing (i.e., missing out on the chance to test), and participants who viewed only negative information or a combination of positive and negative information about DTC testing reported greater anticipated regret over testing. Both forms of anticipated regret mediated the relationship between information valence and intentions to pursue testing.

Advertising and Risk Framing

Advertising for DTC genetic tests plays a key role in converting curious parties into paying customers. As noted above, people report more positive attitudes toward DTC genetic testing after viewing positive information, but not after viewing a mix of positive and negative information (Sweeny & Legg, 2011). DTC genetic testing companies can also strategically frame their product in ways that garner customer support. An analysis of 22 DTC genetic testing companies documented the variety of risk-framing strategies such as emphasizing the commonality of certain diseases, the predominance of genetic components of disease at the exclusion of environment factors, and the need to know this genetic information to empower oneself (Einsiedel & Geransar, 2009). Other advertising techniques found in this analysis included emphasizing the simplicity of DTC genetic testing procedures, enhancing trust and credibility, and aligning the company with the scientific community. Similar patterns emerge in DTC advertising of prescription pills: overly simplified, overly positive, and overly emotional advertisements that emphasize the biological causes of illness and how prescription pills offer a way for consumers to gain control again (Frosch, Krueger, Hornik, Cronholm, & Barg, 2007).

Consequences of DTC Testing

Prospective studies examining people's intentions for testing and reactions to testing are limited. Of note, researchers affiliated with 23andMe conducted a longitudinal study to follow nearly 1,000 customers who received their genetic test results (Carere et al., 2014). Until more thorough research emerges, the current literature provides only limited evidence about people's subsequent actions, comprehension, and behavioral and psychological changes after receiving DTC genetic results.

Subsequent Consultations with Healthcare Professionals

Prior to the FDA regulating the distribution of health risk data, customers of DTC genetic tests received information about their carrier and risk status for a range of diseases and health issues ranging from Huntington's disease to baldness. After receiving these data, 43% of surveyed customers reported seeking additional information about one of their results, and 28% of the customers reported discussing their results with a healthcare professional (Kaufman et al., 2012; see Bloss, Schork, & Topol, 2011 for similar patterns). Similarly, nearly half of genetic counselors reported having a patient-initiated discussion about DTC genetic testing options, and 14% indicated that a patient had asked them to interpret DTC test results (Hock et al., 2011).

Comprehension of Results

Although many critics fear that consumers of DTC genetic testing will misinterpret their health risks, emerging evidence suggests the opposite effect. In their systematic review of the DTC testing literature, Roberts and Ostergren (2013) concluded that generally people can correctly recall and interpret their genetic risks. And despite advertising campaigns emphasizing the genetic causes of diseases, people receiving their genetic profiles understand environmental factors that contribute to illness above and beyond genetic predispositions (Kaphingst et al., 2012).

Changes in Health Behaviors

Receiving results from a DTC genetic test increases intentions to foster healthy behaviors such as dietary improvements and exercise, as reported by a third of Kaufman and colleagues' (2012) survey respondents. For example, a notable minority of respondents reported changing their medications or supplements or taking additional health tests after receipt of their genetic profiles (Kaufman et al., 2012). However, as is the case with many studies linking attitudes to behavior, people's intentions to increase their healthy habits after receiving DTC test results do not necessarily translate into actual behavior change. In fact, after receiving DTC genetic profiles, one study found no differences in people's dietary or exercise habits (Bloss et al., 2011).

Psychological Effects

After receiving results from DTC genetic tests, research points to changes in people's perceptions such that they tend to experience short-term increases in perceived risk for certain diseases, especially rare diseases (e.g., Graves' disease but not prostate cancer; James et al., 2011). However, this pattern no longer holds when people report their perceived risk a year after receiving their results. Contrary to what many people view as an important reason not to test, people do not seem to show increased levels of worry or anxiety after receiving their results (Bloss et al., 2011; James et al., 2011; Roberts & Ostergren, 2013).

In one of the first prospective studies on this topic, DTC genetic testing customers reported greater knowledge about genetics after receiving their test results but reported decreased genetics-related self-efficacy (Carere, Kraft, Kaphingst, Roberts, & Green, 2015). Regret over deciding to test negatively correlated with genetics self-efficacy. However, discussing results with a genetic counselor or other healthcare professional reversed this effect and predicted greater levels of genetics-related self-efficacy.

Opting Not to View Results

Finally, although it is interesting to consider the reactions of people who receive their results, what about the individuals who opt not to view their genetic profiles upon availability? Research on this topic is limited, but one study suggested that approximately 10% of participants choose not to view their test results when they became available (Bloss et al., 2011). Especially given that DTC genetic testing customers now receive only raw genetic data that must be interpreted by a healthcare professional, examination of the reasons and mechanisms behind people's reluctance to view their results seems a beneficial avenue for future lines of research.

Conclusion

Undoubtedly, the field of DTC genetic testing is rapidly changing. With this change comes new opportunities for research. We see four important avenues for exploration. First, given the new FDA regulations, how will people's interest in DTC genetic testing compare with traditional, in-office forms of genetic testing? Second, what individual differences predict testing uptake and seeking interpretation guidance for raw genetic data? Third, as more prospective studies emerge, what are the consequences and benefits associated with DTC genetic testing? Finally, as telemedicine and DTC opportunities continue to evolve, what tools and training initiatives do medical practitioners need to best equip them to serve their patients who use DTC genetic testing outlets? These questions and many others offer numerous research opportunities to continue unraveling the psychosocial correlates of DTC genetic testing.

What Is Worry?

Definitions of worry historically have been derived from research on "worriers." For example, Borkovec and colleagues defined worry as a chain of thoughts and images that are negatively affect laden and relatively uncontrollable (Borkovec, Robinson, Pruzinsky, & Dupree, 1983). Perceived lack of control may be the most important characteristic of trait worry, but we suggest that non-pathological worry need not involve uncontrollability. Instead, "normal" worry can be defined simply as a combination of negative *feelings* produced by unwanted, ruminative negative *thoughts*. Importantly, worry is neither exclusively an affective nor a cognitive experience; instead, it is a combination of the two. Although worry can occasionally persist over time, such as when one ruminates all night in bed about a forthcoming event, non-pathological worry is often short lived. McCaul, Branstetter, O'Donnell, Jacobson, and Quinlan (1998) called such experiences "emotional moments"—not full-blown emotional episodes represented by emotion descriptions such as fear or anger but rather the experience of relatively brief, negative feelings as one contemplates concerns having implications for the future.

We suggest that worry about disease can occur as a normal emotional moment and that normal worrying differs from two other related constructs: perceived risk and anxiety. Perceived risk is a cognitive construct, whereas we have defined worry as a combination of negative thoughts and negative affect. Moreover, the two constructs are potentially separable. One can, for example, perceive one's risk of contracting cancer as minimal but nonetheless worry greatly about the possibility; conversely, one can perceive one's risk of contracting cancer as likely but simply not worry about it, much as some cigarette smokers do. Research also suggests that worry about disease stemming from one's unhealthy behaviors predicts self-protective behaviors independently—and sometimes more strongly—than risk judgments (Magnan, Köblitz, Zielke, & McCaul, 2009).

Worry also differs from anxiety. Anxiety is accompanied by physical symptomology (e.g., arousal of the sympathetic system); worry does not necessarily involve symptoms. Worry has a particular target; anxiety can be general with no specific antecedent. Finally, as we shall see, worry often motivates problem solving; anxiety typically does not.

Do People Worry About Disease?

Worry can be directed toward many different life domains—one's family, job, finances, and friendships, for example. Interestingly, health concerns do *not* top the list of worries people report; indeed, a commonly used worry tool—the Worry Domains Questionnaire—does not include health or disease as a possible worry target. Survey data confirm the conclusion that disease does not head the list of worry domains. For example, young adult, healthy German women were interviewed about their worries (Becker, Goodwin, Hölting, Hoyer, & Margraf, 2003). The most common worries concerned work issues, closely followed by concerns about the health of others and then worry about their families. Lindesay et al. (2006) assessed worry among both men and women across the lifespan. They found that 30–40% of participants worried about relationships, finances, and work. Older adults reported having these concerns less frequently. Health-related worry was reported less often overall but remained consistent throughout the lifespan. In contrast, in a review of 21 studies assessing older adults, Hunt, Wisocki, and Roger (2009) noted that although few worries were reported, health concerns were prominent in their older samples.

Regardless of whether health concerns are the most intense or frequent worries people have, when people *do* worry about health and disease, some diseases attract more concern than others. In a sample of US adults, Wang et al. (2009) assessed worry about six different diseases: heart disease, diabetes, stroke, colon cancer, breast cancer, and ovarian cancer. Women worried most about breast cancer, followed by heart disease and diabetes. In contrast, men worried most about heart disease, reporting somewhat lower levels of worry for diabetes, stroke, and colon cancer. Senay, Alford, and Kaphingst (2012) conducted a similar survey study, assessing worry about 8 diseases among nearly 2,000 healthy adults. Both men and women reported worrying most about cardiovascular diseases (heart disease, high blood pressure, high cholesterol) followed by diabetes, colon cancer, lung cancer, skin cancer, and osteoporosis, and other survey studies reveal similar results.

Worry clearly depends on the specific disease assessed, with research suggesting that cardiovascular disease—the most common ailment affecting American adults—also attracts the most worry. However, it is also important to consider the *overall* degree of worry about disease. In the Wang et al. (2009) study, for example, participants rated their degree of worry during the last 4 weeks on a 1 (not at all worried) to 5 (worried almost all the time) scale. Overall, the frequency of worry was fairly low: only women describing worry about breast cancer reported a mean worry over 2. Such data suggest that many participants worry not at all about a particular disease. The mean level of worry described in Senay et al. (2012) was greater—perhaps because respondents were asked about (a) the intensity rather than the frequency of worry and (b) a different timeframe, lifetime versus the prior month. Specifically, participants were asked on a 1 (not worried at all) to 7 (very worried) scale how much they worried about developing each particular disease *throughout their lifetime*. Heart disease had a reported mean of 4.62, high blood pressure 4.59, high cholesterol 4.33, and diabetes 4.26. Colon cancer, skin cancer, lung cancer, and osteoporosis all had means below 4.

We were unable to uncover studies reporting absolute frequencies of worrying data across diseases, that is, studies addressing the proportion of a sample reporting *any or no* worry about different diseases. Some data from individual disease studies, however, suggest that the overall proportion of persons worrying a great deal could be relatively low. For example, Moser, McCaul, Peters, Nelson, and Marcus (2007) used nationally representative data from interviews with over 6,000 adults. The survey questions assessed worry for several cancer types. Approximately 2/3 of the respondents said they "never" or "rarely" worried about getting colon cancer, and a similar proportion of men said the same about prostate cancer. Over half of the women surveyed said they rarely or never worried about breast cancer. Moving forward, it would be important to obtain these sorts of data across many different diseases and to report categorical frequencies as well as scale means.

Research suggests the following in terms of how much we worry about disease: (a) overall levels are relatively low in comparison to worries about other aspects of life; (b) older people are more likely than younger adults to worry about their health, although worry is modest even among the former group; (c) worry about particular diseases ties in some way to disease likelihood because people worry more about diseases they are more likely to experience; and (d) many people worry minimally or even not at all about disease.

What Determines the Degree of Worry About Disease?

Many factors influencing the degree to which one experiences worry are associated with perceived disease risk. Perceived risk is composed of susceptibility judgments (the degree to which one feels they are likely to develop a disease) and severity judgments (how bad the disease consequences would be). Both of these risk components predict worry about developing a disease such that stronger perceptions of personal likelihood or severity are associated with more worry. However, worry's associations with susceptibility judgments are stronger than its associations with severity (Cameron, Sherman, Marteau, & Brown, 2009). It could be that the difference in association strength between perceived likelihood and severity may be due to self-relevance. Worry about a disease and perception of personal likelihood of a disease are self-relevant in that one must look to the self to judge each. In contrast, severity judgments can be made without referencing the self. That is, one can perceive the outcomes as severe without necessarily thinking they are susceptible to experiencing such consequences.

The commonsense model (CSM) of illness representation (Leventhal, Brissette, & Leventhal, 2003) provides a general framework for how different disease-related variables influence risk and worry. This model posits that how people think about ("represent") illness may elicit affective reactions such as worry. Illness representations include five content domains: identity (illness label and symptoms of illness), illness cause (e.g., heredity, behavior), illness timeline (time to onset, duration), illness consequences, and illness control (personal or medical control of progression or cure). These domains should differentially influence likelihood and severity judgments, such that beliefs about illness identity, cause, and timeline should affect likelihood estimates and beliefs about consequences and controllability should affect severity judgments. Importantly, all five illness representations should also influence worry about the disease.

Linked to the issue of likelihood estimates, Cameron (2008) found that illness identity (e.g., skin burns easily, dark moles), cause (e.g., hereditary, behavioral choices such as skin exposure), and timeline (e.g., developing skin cancer "at this age") each predicted worry about developing skin cancer. An important component of identifying an illness is beliefs about symptoms that indicate illness, such as shortness of breath indicating heart disease or a discolored mole indicating skin cancer. Illness symptoms should typically increase worry, although they could also reduce worry in some special circumstances. Moye et al. (2015) compared worry about developing melanoma before and after total-body digital photography among individuals with atypical mole syndrome. This approach creates high-resolution images that can identify changes in the skin surface. Worry scores were lower after the photography session than before but only among individuals with a history of melanoma. Assuming that individuals with a previous history of melanoma generally have heightened susceptibility perceptions, when viewing images that show no visual evidence of melanoma (suggesting that melanoma is not present), these individuals reported reduced worry.

"Cause" is another CSM component that influences susceptibility judgments and worry. Most prominently, individuals with a family history of disease report more frequent and more intense worry about developing a disease than individuals without a family history (Vassy & Meigs, 2011). A family history is likely to encourage beliefs that a disease has a genetic cause, thereby increasing susceptibility judgments. Another "cause" factor is the extent to which individuals believe that specific risky behaviors lead to illness or that health-protective behaviors prevent illness. Thus, individuals who engage in risky behaviors may perceive themselves at greater risk and be more worried about illness. Finney Rutton, Blake, Hesse, Augustson, and Evans (2011) found that compared with former and nonsmokers, current smokers were more likely to report their likelihood of developing lung cancer as "very high" and to report worrying about cancer "often or all of the time." Cameron (2008) also showed that one facet of "timeline"—time to onset of a disease—was related to likelihood judgments and worry. Specifically, timeline beliefs ("People of my age are likely to develop skin cancer now—at this age") were associated with personal likelihood of developing skin cancer and worry about contracting skin cancer.

The CSM also provides a framework for factors contributing to severity judgments. In particular, the CSM includes an "illness consequences" domain. The potential consequences of a disease are many. They could be medical (e.g., long-term disability), social (e.g., social life, money), and psychological (e.g., changes to one's identity). This category would also include perceptions of the consequences of the disease treatment. Cameron (2008), for example, found that perceptions of more intense pain from treatment predicted greater worry about developing skin cancer. Similarly, women undergoing a genetic test for breast cancer reported more worry when they also thought that the consequences of a positive finding would be devastating (Cameron & Reeve, 2006).

Illness timeline perceptions are theoretically associated with likelihood and not severity judgments within the CSM framework, but they have been positively associated with severity judgments nonetheless (Cameron, 2008). Additionally, we were unable to find empirical evidence that control over disease outcomes (the other illness representation thought to be associated with severity judgments; Cameron, 2008) is associated with severity judgments, although it has been connected with worry. Specifically, Gibbons and Groarke (2015) found that stronger perceptions of control (personal and treatment) over breast cancer were associated with less worry about getting cancer in one's lifetime. Importantly, severity judgments are less commonly assessed than likelihood judgments in the extant literature, and thus it is difficult to determine the extent to which these constructs factor into severity judgments—a task left for future research.

In the CSM, symptoms of illness are incorporated as a component of perceived likelihood. Yet, visibility of symptoms of disease may also be a contributing factor to severity as it is one way that disease severity can be interpreted (e.g., consequences of mouth cancer could be a less severe sore on the lip or more severe tooth decay). Further, imagery of symptoms may promote greater worry about developing the disease because it keeps the consequences of the disease more salient or enhances concern of social consequences such as embarrassment or stigmatization. For example, messages about the consequences of smoking elicit greater worry when they are presented in graphic format (showing images of smoking consequences) compared with text-only formats (Magnan & Cameron, 2015).

The CSM describes a dynamic process in which illness representations, feelings about illness, and behavior change over time. As one has new experiences or acquires new information from one's own experiences, social network, physicians, or news/educational materials, representations of the various components may change. To this end, experiences such as familiarity with individuals who have experienced the disease and personal history of the disease, each of which is typically associated with greater worry about (re)developing the specific disease (Moye et al., 2015), may affect *all* illness representations. For example, a person with little knowledge regarding breast cancer may gain more insight into the symptoms (i.e., illness identity), cause, and timeline of breast cancer from helping a friend who is currently undergoing treatment. A person having previously experienced breast cancer may worry about recurrence because of firsthand knowledge of the disease consequences.

Representations of illness risk clearly influence the degree to which one worries about illness. Indeed, communicating risk information can increase worry about developing an illness (Magnan et al., 2009). Although factors linked to perceived risk may influence the degree of worry experienced, enhancing knowledge about health risks in and of itself does not always increase worry. Personal perceptions of risk are not necessarily rational estimates, but rather they can sometimes be subjective estimates derived from various characteristics one associates with risks in addition to aspects of feelings of risk. For example, in the case of a rare but serious disease, the actual risk of developing the disease is low, but dread associated with the disease may increase worry about the disease. Ultimately, although various representations of illness may contribute to perceived risk, they may also directly influence worry *without* influencing perceptions of risk. That is, one may worry about a disease without necessarily feeling "at risk." In short, risk and worry are not the same thing.

Worry Consequences

Worry can have both negative and positive consequences. One can worry "too much," and we would expect extremes of worry about disease to be accompanied by a lowered quality of life. Data confirming this possibility have been reported primarily among individuals who are already suffering from a particular disease. Worry about cancer recurrence among survivors, for example, is associated with a lower quality of life (Tewari & Chagpar, 2014). Extremes of worry could also promote avoidance of screening because of worries about finding the disease (Cameron, 2003). An interesting dichotomy appears here: Worry about the outcomes of a screening test motivates avoidance whereas worry about the disease itself motivates one to obtain a screening in the first place.

The consequences of worry need not always be negative. Worry about disease is related to problem solving and can facilitate active coping. In this regard, worry about disease promotes self-protective behaviors. For example, smokers who worry about disease think more about quitting (Magnan et al., 2009). People who worry more about cancer are more likely to have regular mammography screening and to have had a colon cancer screening test (Moser et al., 2007). And, among women with an inherited risk of breast and ovarian cancer, those who worry more are more likely to adopt risk-reducing surgery (Portnoy, Loud, Han, Mai, & Greene, 2015).

We have previously proposed three reasons why worry might motivate self-protective behaviors. Worry can provide an additional, *rational* thought about taking health-protective action. One might reason, "If I'm this worried about having a heart attack, I should probably do something about it." Second, worrying by definition involves intrusive thoughts. Thinking frequently about potentially suffering from disease keeps the issue "in mind," serving as a persistent reminder that something needs to be done. Third, worry may motivate problem solving simply to end the negative feelings accompanying worry itself. Regardless of why, the point is clear: Worry can motivate planning and produce self-protective behaviors.

Conclusions

People worry about many aspects of their lives, only one of which is their health. Many people worry about specific diseases, although most individuals do not report a great deal of worry. People are more likely to worry about a particular disease if they feel at risk—especially if they feel susceptible, but also if they see the disease consequences as severe. Other variables that enhance worry in part through risk judgments include experiencing symptoms, a family history of the disease, perceptions of distressing disease treatments, a perceived lack of control over the disease, and negative images arising from thinking about the disease. Finally, some variables will increase worry separately from judgments of risk, such as feelings of dread about the disease. When people *do* worry, it can have either or both positive and negative consequences. Worrying a great deal about disease can lead to a lower quality of life, but it is important to also recognize that worrying about disease motivates many individuals to adopt behaviors that will effectively stave off disease and its consequences.

Author Biographies

Kevin D. McCaul is a professor of psychology at North Dakota State University. A social psychologist, Dr. McCaul's most recent research has addressed relationships between cognitions, feelings, and self-protective health behaviors. In particular, he has connected thoughts about risk and feelings about worry in the context of cancer screening and smoking prevention and cessation. His empirical findings clearly suggest that worry is an important motivator of self-protective behaviors such as mammography screening and smoking cessation.

Renee E. Magnan is an assistant professor in the Psychology Department at Washington State University Vancouver. Her research uses social psychological theory to address issues in disease prevention and health promotion. A general focus of her work addresses how affect influences perceptions of health communications and health decisions and motivates self-protective health behaviors (e.g., smoking cessation, exercise, alcohol use).

Michael P. Mead completed his undergraduate work at Grand Valley State University and is presently a graduate student in the Health/Social Psychology PhD program at North Dakota State University, where he works in the SLEEP laboratory under the supervision of Dr. Leah Irish. His research interests include relationships between marital interactions and sleep quality, sleep hygiene behaviors, and mechanisms linking sleep and diet.

Measuring behaviors and subjective experiences via self-report is ubiquitous in health psychology and behavioral medicine. Traditional approaches to self-report have typically asked individuals to recall and summarize their experiences over a specific span of time (e.g., weeks or months). Assessments with briefer recall periods have also been used in laboratory or clinic settings in conjunction with study designs that maximize experimental control and facilitate standardized data collection. Over the past several decades, however, the use of momentary assessments has gained momentum and has moved the study of psychosocial factors and health behaviors from the clinic and laboratory into people's real-life environments. These momentary approaches fall under the framework of ecological momentary assessment (EMA; e.g., Shiffman, Stone, & Hufford, 2008; Stone, Shiffman, Atienza, & Nebeling, 2007). Here, we provide an overview of the concept and characteristics of EMA methods followed by current examples of EMA applications for the psychosocial study of health. We conclude this chapter with an outline of promising new future platforms for EMA applications in health psychology.

Defining Characteristics of EMA

The four defining features of EMA are (a) assessments of individuals' current states and behaviors to reduce bias in recall and memory construction, (b) data collection in people's natural habitat to maximize ecological validity, (c) careful attention paid to the timing (schedule) of assessments, and (d) collection of multiple assessments over time to capture the dynamic

interplay between various states and contexts that shape people's experience (Shiffman et al., 2008; Stone et al., 2007). It is important to note that EMA is not a single methodology but consists of a variety of measurement techniques that arose from diverse traditions. These traditions include written diaries, self-monitoring, experience sampling, behavioral/activity monitoring, and physiological ambulatory monitoring; the first three are being more central to the refinement of current EMA methods (Shiffman et al., 2008; Stone et al., 2007).

Written diaries are probably the oldest historical root for the development of EMA methods (Verbrugge, 1980) with formats ranging from open-ended narratives to standardized daily assessments. At times, diary assessments were also combined with measurement of physiological indices, such as heart rate or blood pressure. Self-monitoring approaches to subjective states and behaviors have also been influential in the development of EMA. Due to their focus on specific events, self-monitoring approaches did not concentrate on aspects of sampling or data capture outside of the specified target area (Shiffman et al., 2008).

The experience sampling method (ESM) is another term that describes momentary data collection of experiences, and it predated the development of EMA. The term was originally coined by Csikszentmihalyi and Larson (1987), who pioneered the real-time assessment of individuals' subjective states and experiences. ESM was developed to obtain a characteristic set of current experiences by random, signal-contingent assessments as participants went about their daily lives (Hektner, Schmidt, & Csikszentmihalyi, 2007). This was done by having participants' complete diary assessments repeatedly throughout the day.

EMA expanded the scope and more thoroughly defined the tenets of the sampling approaches for within-day monitoring (the four features mentioned above). Furthermore, the principles of EMA are not limited to self-reports of experiences, but may be applied to all manner of ambulatory monitoring tasks, for example, the assessment of ambulatory blood pressure and heart rate. Thus, in some respects EMA is a broader concept than ESM, and it has been widely adopted in the behavioral and medical sciences. Furthermore, there are "guidelines" for presenting the results of EMA studies (Stone & Shiffman, 2002), which serve as a useful evaluation standard; for example, the guidelines suggest considerable details be presented about the sampling schedules and compliance rates.

Advantages of EMA Over Traditional Recall Assessments

In this section, we describe some of the most prominent advantages EMA methods offer over traditional retrospective assessments.

A key feature of EMA is the collection of data from participants in their natural environment. Many, if not most, behaviors and experiences are context dependent, and there is growing concern that findings obtained in laboratory or clinic settings do not adequately capture people's real-world experiences. According to Brunswik (1956), data collection in people's natural habitats increases the ecological validity of assessments and generalizability of study findings. In other words, in order to achieve representativeness of individuals' experiences or behaviors, one has to carefully sample them in their everyday or natural contexts (Shiffman et al., 2008). In addition, studying participants in daily life can reveal important contextual information, which is usually not available in many traditional self-report instruments or interview assessments, and this information can help with the interpretation of subjective experiences and behaviors.

EMA methods advanced, in part, to circumvent the limitations inherent in retrospective recall. For many decades, research has relied heavily on recall to glean information about people's psychosocial states and behaviors. It has been widely shown that retrospective reporting, however, is susceptible to a variety of biases and heuristics that can compromise its accuracy. Several possible sources of recall bias are noteworthy. For example, people are more likely to remember experiences that occurred closest in proximity (recency effect) and experiences that are in line with their current affective state (mood-congruency effect; see Stone et al., 2007).

The longitudinal nature of EMA methodology is particularly suited for the study of temporal sequences and dynamic processes as they unfold over time. Many content areas in health psychology are concerned with change in people's subjective experiences, naturally occurring or resulting from treatment. Understanding the dynamic interplay between affective, cognitive, and behavioral factors over a short period of time is, therefore, particularly relevant. Cross-sectional and prospective designs can only provide one or a limited number of snapshots, whereas EMA's dense sampling formats can enable a fine-grained and nuanced perspective (Shiffman et al., 2008).

Analyses of contextual relations are frequently of a cross-sectional nature because they examine the co-occurrence of situations and experiences, and not their sequential relationship, even in longitudinal data collection designs (Shiffman et al., 2008). Moreover, many traditional symptom questionnaires or clinical interviews do not assess context directly. For example, affective symptoms are usually assessed in terms of their frequency or intensity over a certain timeframe, but not with regard to specific contexts (Ebner-Priemer & Trull, 2009). EMA studies allow not only the establishment of a linkage between experiences and situations but also the disentangling of context-specific antecedents and consequences of individuals' experiences.

Another important consideration with regard to situational factors is the fact that context does not only exclusively refer to a specific situation or environment but may also embody another individual (e.g., a spouse or family member). Most EMA designs focus on a single person; however, it is possible to conduct dyadic sampling when it is of interest to determine how one person's feelings and actions impact the other (Laurenceau & Bolger, 2005).

Measurement Considerations in EMA

There are two key measurement concerns for the implementation of EMA: reactivity and compliance.

Reactivity can be defined as the potential for experience and behavior to be altered by the act of assessing it (Shiffman et al., 2008). In EMA, it is plausible that the intensive sampling methodology (along with auditory or visual prompts to complete assessments) could alter people's natural environment and their experiences by shifting their focus to the phenomena under study. To date, however, empirical evidence provides little support for measurement reactivity in EMA (e.g., Hufford & Shiffman, 2002).

Although the intensive sampling methods of EMA approaches offer the opportunity to obtain a fine-grained perspective of people's experiences and natural contexts, the completion of repeated assessments in daily life places a burden on study participants. Compliance with EMA assessments has, therefore, been a much-debated topic in the literature. Earlier approaches using written diaries have highlighted the issue that repeated sampling alone may not automatically guarantee momentary or real-world data collection. For instance, studies using paper diaries usually inferred compliance based on participants' date and time entries that were written on the diaries. However, studies have found that forward and backfilling of diary entries is quite common (Shiffman et al., 2008). In other words, participants may note that they completed a report at a given time but may have actually completed their ratings after the fact or in advance of the specified time (Stone, Shiffman, Schwartz, Broderick, & Hufford, 2003). Another important piece of evidence concerning the authenticity of people's accounts pertains to treatment adherence, such as medication taking. Research has shown that compliance with a medical regimen as indicated by participants in written diaries does not necessarily correspond with adherence tracking performed by electronic devices. In fact, participants overstated their compliance compared with what was objectively recorded by the devices (Hufford, 2007). Current EMA data collection modalities enable the verification of when assessments were completed through electronic date and time stamping of entries.

Limitations of EMA Studies

Given the intensity of many EMA sampling schedules, it is not surprising that EMA studies are very demanding, both on participants and investigators. Participants must be willing to have their daily activities interrupted to complete assessments that can be disruptive and annoying (though many studies report excellent compliance). This raises the concern that only certain sorts of people will volunteer for and be able to complete EMA studies; moreover, it is likely that some professions (e.g., surgeons, bus drivers) are simply not capable of participating in real-time sampling. Thus, the demands of EMA may raise a threat to the generalizability of the findings, raising the possibility of selection bias. End-of-day diaries and day reconstruction methods (Kahneman, Krueger, Schkade, Schwarz, & Stone, 2004) provide alternatives that are less demanding; however, they also yield much less information about the day and are prone to some recall bias.

EMA Sampling Approaches

EMA sampling protocols can be broadly characterized as event contingent or time contingent, the latter including random assessment scheduling strategies and schedules with regularly spaced or fixed assessment intervals (Shiffman, 2007). The selection of a particular sampling scheme depends on what is being studied.

Event-contingent EMA methods are usually employed when the construct of interest is a concrete episode or behavior. Examples of these types of episodes in health psychology are physical activities like exercise, medication taking, pain flares, panic episodes, smoking, stressful events, and interpersonal interactions. Assessments are completed in response to a specific event, and it is usually the research participant who reports on the occurrence that may then trigger subsequent questions regarding the experience. When choosing an event-based approach, there are several considerations. First, what constitutes a specific event or episode needs to be clearly defined and communicated between researcher and participant. Second, the researcher needs to decide when a specific event will be recorded. Third, the usual frequency of an event should be taken into account when designing a sampling protocol. If the frequency of an event is very high, it may be too burdensome and unrealistic for participants to record an episode. If the frequency is very low, sampling needs to be conducted over a larger time span, and participants need to remember the recording protocol. Finally, verification of the authenticity of the event occurrence is difficult to establish since this approach often relies upon the participant reporting an episode (see Shiffman, 2007).

Time-based EMA sampling approaches are frequently implemented when researching phenomena that vary continuously over time and cannot be compartmentalized into discrete episodes, such as mood states and symptomatology (Shiffman et al., 2008). Time-based schedules vary in frequency and timing (Delespaul, 1995) but can broadly be divided into random and fixed interval assessments. The frequency of assessments should be based on the research questions. Random schedules usually deliver assessments at variable times throughout the day. These are the most commonly used schedules in EMA because they can provide a representative picture of respondents' environments, symptoms, and experiences, whereas all other schedules may not be truly representative of everyday life. Assessments can be programmed completely at random or randomized within strata of the day. In the latter, assessments can be randomly administered within certain predefined blocks of the day, such as in the morning and in the evening. For certain purposes, it may be advantageous to use a combination of random and fixed interval sampling. For example, if one is interested in studying the antecedents of panic attacks or the mood benefits of exercising, a combination of the two schedules may be preferable.

Success and Current Applications of EMA

The prominence and success of EMA is evident in numerous reviews and books that have appeared on the topic across the years. At this point, EMA has become a stand-alone acronym that is recognized in the fields of health psychology and psychosomatic and behavioral medicine. In addition to several books and chapters (e.g., see Hektner et al., 2007; Stone et al., 2007), reviews focus on the promise and challenges of EMA methods (Scollon, Kim-Prieto, & Diener, 2003) and applications of EMA to behavioral medicine (Robbins & Kubiak, 2014). We refer the reader to these sources for more detail than can be discussed in this chapter. In the following sections, we review recent examples of EMA applications that are of particular relevance for health psychology.

The ability of EMA methods to capture people's daily life as it unfolds has opened the door to the study of social behavior and interpersonal processes from the perspective of a real-time dyadic system. Social support, marital satisfaction, and dyadic adjustment, which have a long-standing tradition in health psychology due to their potent associations with health and illness, can be studied within this framework. Up until recently, research has often relied on patients' retrospective accounts about their interpersonal environment and relationship characteristics. This has provided an important yet incomplete glimpse into the complex dynamics of a person's social network for several reasons. First, studying interpersonal dynamics through the lens of an individual may not reflect how other dyad members view them and their behavior. This is of particular relevance when studying social support and behavioral responses toward the patient. Second, perceptions and behaviors of dyad and social network members mutually influence each other, and marital and family relationship experiences may change over time. In order to reveal an accurate and complete picture of social dynamics, it is therefore essential to study all network members of interest and examine how interpersonal processes unfold over time as couples or dyads go about their daily lives.

In clinical assessment, patients' medical progress has traditionally been assessed on a weekly or monthly basis, which requires patients to recall their symptoms and medical progress. However, as noted above, retrospective self-report measures are strongly influenced by current states and salient events. In addition, assessments conducted in the clinic setting limit the ecological validity of patients' self-reported symptoms. The successful integration of EMA methodology into routine care is still in its infancy. However, real-time symptom assessments and patient tracking offer promising avenues to augment clinical assessment and can be suited to fit the needs of medical practice.

A logical extension to EMA data collection approaches has been the development of Ecological Momentary Intervention (EMI; for review see Heron & Smyth, 2010). Early implementations of EMA in clinical practice were primarily geared toward its use as an assessment tool. Bridging the gap between therapeutic consultations in the medical office and patients' experiences in their natural settings has not been an easy task in psychological treatment (Shiffman et al., 2008). However, clinicians have long aimed to effectively integrate treatment into patients' daily lives to facilitate practice and maintenance of skills between sessions (Heron & Smyth, 2010). EMI encompasses a variety of treatment approaches that mirror EMA methodology—delivery of treatments to people in real time in their natural environments (see Heron & Smyth, 2010).

The opportunities and benefits of introducing EMA methods into treatment delivery are vast. For one, the reach of EMI extends into patients' everyday lives. This means that the benefits of treatment are likely to be optimized. Second, the availability of treatment delivery in patients' natural contexts makes it possible for patients to integrate new skills and tools in their personally relevant contexts and settings. Third, practice and maintenance of new skills and behaviors is more readily achieved (Heron & Smyth, 2010).

Patient-reported outcomes (PROs) serve an increasingly important role in treatment evaluation and ultimately in health economics and health policy (Robbins & Kubiak, 2014). PROs refer to a variety of self-reported symptoms and behaviors pertaining to health and well-being, including pain, fatigue, psychological distress, and quality of life. The major US regulatory agency for medicine and devices, the Food and Drug Administration (FDA), issued "preliminary" guidance to the pharmaceutical industry emphasizing that real-time data collection, including EMA and end-of-day diaries, is preferable because PROs based on retrospective self-reports over long periods may have compromised validity due to retrospective reporting biases (FDA, 2009). To date, interventions in health psychology and behavioral medicine are slowly beginning to adopt EMA methods for the measurement of PROs. A recent example is a randomized controlled trial on mindfulness training in adults vulnerable to depression (Geschwind, Peeters, Drukker, van Os, & Wichers, 2011). Momentary sampling of positive emotions and of appraisal of pleasant daily activities 6 days before and after the intervention was conducted. The authors found that mindfulness-based cognitive therapy was associated with enhanced experience of positive emotions as well as greater appreciation and responsiveness to pleasant daily activities. Although studies like these are making their inroads into the clinical setting, much more progress needs to be made to fully integrate EMA methods into the standard toolkit for evaluating PROs in health psychology interventions.

Future Directions for EMA Methods

The versatility and richness of EMA methods have found their way into numerous settings and content areas. Technological advances are enabling new and flexible platforms for expanding the reach of EMA data collection. In particular, mobile phone applications for EMA have grown very rapidly. There are several new smartphone-linked capabilities that may be the future of EMA applications—combining self-report with socio-contextual, physical, and physiological momentary assessment (frequently referred to as mHealth methodologies).

Clearly, the future of EMA methods seems bright. Pending the appropriate implementation and validation of these new technologies, we believe that the effective and evidence-based integration of EMA technology into research and clinical practice will successfully propel the psychosocial study of health into the future.

Author Biographies

Dr. Doerte U. Junghaenel received her doctoral degree in social and health psychology from Stony Brook University. She is a research scientist at the USC Dornsife Centers for Self-Report Science and for Economic and Social Research at the University of Southern California. Her research focuses on the multimodal measurement of patient-reported outcomes, the examination of individual differences in symptom experience, and the study of interpersonal dynamics and how they may relate to favorable adaptation in chronic pain.

Dr. Arthur A. Stone is professor of psychology and director of the USC Dornsife Center for Self-Report Science at the University of Southern California. He was distinguished professor of psychiatry and psychology at Stony Brook University. Dr. Stone has been involved with the development of self-reports to measure end-of-day and within-day phenomena that led to EMA. More recently, he has been involved with the development of alternative methods for capturing daily experience, including the Day Reconstruction Method.

The Effects of Health-Related Policy

Robert García and Steve Sussman

Keck School of Medicine, University of Southern California, Los Angeles, CA, USA

The role of policy often is to prevent an event from occurring that could do harm. This is especially clear when looking at health policy. The twentieth century saw many advances in the health status of much of the world's population due to the increased understanding of what effects health. We can think of many examples of how health policy improved health: tobacco product regulation, workplace safety, clean-air regulations, seat belt laws, child safety, sanitation, food handling, and removal of lead-based paints, as examples. While these policies have been effective at improving our health status, there are still other areas that need to be addressed (e.g., Should sales of unsafe tobacco products be permitted at all? Is the cost-effectiveness of removing toxins from the workplace too low?). Further, with ever changing technology it is important to adapt our policies in a similar rapid and effective fashion. We can learn important lessons from the successful history of tobacco policy to confront the new challenges to our health. In this chapter, we will examine how tobacco policy led to the change in societal norms and eventually the population's health.

A Brief History on the Growth of Big Tobacco

Many people have heard of the role of tobacco in the growth of the American colonies, both the English and Spanish domains. However, few know that up until around the mid-nineteenth century, those who smoked tobacco would not inhale (Proctor, 2011). The curing process that allowed tobacco to become milder and therefore inhaled was discovered by accident, when the fire being used to cure tobacco leaves died out and the workers quickly threw on charcoal to reignite the fire (Kluger, 1997; Proctor, 2011). The charcoal burned hotter and therefore provided a different curing process and mildness allowing users to inhale (Proctor, 2011). Along with creating a milder product, it also decreased costs as this method used a small fraction of fuel compared with the traditional wood fires (Kluger, 1997). Another major innovation that helped to spread the use of tobacco is automation. Specifically, the Bonsack

(cigarette rolling) machine invented in 1880 allowed for manufacturers to produce 210 cigarettes per minute (Kluger, 1997; Proctor, 2011). This invention could replace 500 individual employees (Proctor, 2011). Modern machines can produce nearly 20,000 cigarettes per minute (Proctor, 2011). The mechanization process allowed cigarette manufacturers to sell them cheaply further spreading nicotine addiction for pennies while making large profits.

Perhaps the largest contributor to the proliferation of tobacco use was its industry's agile and effective application of marketing. Over the decades, the tobacco companies have been able to respond accordingly to a changing world. One example often cited is how tobacco companies were able to capitalize on war. During the World Wars, the tobacco companies were able to use the war and home front to increase consumption of cigarettes. After World War 1 the consumption of cigarettes tripled (Brandt, 2007). During the Second World War, the tobacco companies were required to turnover a portion of their profits toward the war effort. They would use this to their advantage and market their products as a patriotic duty for American society. Cigarette consumption after that war doubled (Proctor, 2011). Tobacco companies continued to use current events in society to increase their reach. Other examples include the suffrage and civil rights movements in which cigarettes were marketed as an equalizer for marginalized populations (Brandt, 2007; Proctor, 2011). With the increasing use of cigarettes, the evidence of their detrimental effects on health became clearer that would eventually lead to more regulation of the industry. As cigarettes fell out of favor and became more regulated in most developed countries, the industry turned its attention to lower- and middle-income countries who welcomed the manufacturing jobs (Kluger, 1997; Proctor, 2011).

The Changing Tide: The Beginning of Tobacco Regulation

Two publications helped to start the regulation of tobacco products in the United States. First was an article in the December 1952 issue of *Reader's Digest* by Roy Norr titled "Cancer by the Carton" that was one of the first main stream, lay publications to link smoking to cancer (Brandt, 2007; Norr, 1952; Proctor, 2011). A little over a decade after this, the US Surgeon General released their first report about smoking and its effects on health in 1964. At that time 43% of the US adult population were smokers (U.S. Department of Health and Human Services, Public Health Service, Office of the Surgeon General, 2014). Most of the policies that arose after the initial report focused solely on providing the consumers information on tobacco products and their consequences (U.S. Department of Health and Human Services, Public Health Service, Office of the Surgeon General, 2014). To government officials at that time, it was up to the public to change their behavior, and the government was responsible to provide information about their behaviors and related consequences (Dinno & Glantz, 2009; Glantz, Barnes, Bero, Hanauer, & Slade, 1995; U.S. Department of Health and Human Services, Public Health Service, Office of the Surgeon General, 2014). The tobacco companies strongly refuted these claims (e.g., of lung cancer and cardiovascular smoking-related diseases) and conducted their own "science" to contradict the growing scientific consensus (U.S. Department of Health and Human Services, Public Health Service, Office of the Surgeon General, 2014).

The tobacco industry turned to marketing again, this time to maintain their consumers. While more people became aware of the risks carried with smoking, there was still a lag in behavior change due to the marketing campaigns that created doubt in the US public (Proctor, 2011; U.S. Department of Health and Human Services, Public Health Service, Office of the Surgeon General, 2014). Two years after the initial 1964 report, only 40% of the US public considered smoking a major cause of cancer compared with 90% in 1990 (U.S. Department of

Health and Human Services, Public Health Service, Office of the Surgeon General, 2014). Over the next few decades, the information provided by governmental health agencies was associated with change in tobacco use prevalence. To combat declining prevalence the tobacco companies changed their advertising to start including terms that gave consumers a perception of health (Brandt, 2007; Glantz et al., 1995). Such terms included “light” and “mild” and were meant to help combat the negative health effects of cigarette ingredients such as tar (Grier & Kumanyika, 2010; Iglesias-Rios & Parascandola, 2013). The government’s approach to only providing information was limited. More policy action was needed to address the increasing rates of consumption in populations such as racial/ethnic minorities.

Marketing Regulation

With the increasing awareness of the health risks of tobacco products, there was an increase in the regulation of tobacco advertising. Consequently, the industry over the next decades would dramatically increase their advertising expenditures in unregulated media (U.S. Department of Health and Human Services, Public Health Service, Office of the Surgeon General, 2014). For example, after the banning of television ads, the tobacco industry increased their advertising in magazines. While the ban on broadcast marketing did lead to a decrease in smoking behaviors, research has shown that limited marketing bans have limited impacts (Wakefield et al., 2002). Expenditures on magazine advertising increased from $62 to $152 million after the television ban (Proctor, 2011; U.S. Department of Health and Human Services, Public Health Service, Office of the Surgeon General, 2014). Further, tobacco companies used more imagery that promoted perceptions of healthier and cooler products, which were effective among youth and racial/ethnic minorities (Dauphinee, Doxey, Schleicher, Fortmann, & Henriksen, 2013; Ribisl et al., 2017; Siahpush, Jones, Singh, Timsina, & Martin, 2010). The lack of a complete policy on tobacco marketing assisted in the creation of large disparities in smoking behaviors among different racial/ethnic groups. African Americans and Native Americans consistently have a higher prevalence of smoking compared with non-Hispanic Whites (Centers for Disease Control and Prevention [CDC], 2005, 2014). As regulation continued to evolve, so did the tobacco industry’s effort to maintain their profits and market share.

In 1998, there were further advertising and promotional bans applied to the tobacco industry with the implementation of the Master Settlement Agreement (MSA). The MSA bans on advertising included the use of cartoon characters, billboards, public transit placements, product giveaways, and the branding of merchandize (Loomis, Farrelly, Nonnemaker, & Mann, 2006; Wakefield et al., 2002). In the decade after the MSA, tobacco companies retail environment advertising expenditures increased from $6.7 to $9.9 billion (Widome, Brock, Noble, & Forster, 2013). However, the tobacco industry advanced exposure to marketing and promotional materials in the retail environment, including convenience stores, which are frequented by youth. The ability to further control youth uptake in smoking was hampered by marketing in the retail environment and, likely, accounts in part to a plateau in the reduction of cigarette smoking since the late 1990s (U.S. Department of Health and Human Services, Public Health Service, Office of the Surgeon General, 2014). The bans on marketing, however, did help to denormalize smoking in US society and brand it as unacceptable behavior (U.S. Department of Health and Human Services, Public Health Service, Office of the Surgeon General, 2014). This denormalization of smoking helped governmental agencies in the implementation of other policies that dramatically decreased smoking and other tobacco use in the United States. Another benefit from the MSA was that it funded tobacco control programs at the state level.

Taxation: Beyond Increasing Costs

The most dramatic decrease in smoking behavior happened after the doubling of the federal tax on cigarettes in the early 1980s (Chaloupka, Cummings, Morley, & Horan, 2002; U.S. Department of Health and Human Services, Public Health Service, Office of the Surgeon General, 2014). Further, states with higher tax rates for cigarettes also demonstrated lower smoking rates (Carpenter & Cook, 2008; Meier & Licari, 1997). The decrease of smoking behavior, however, cannot be attributed solely to higher taxes but also to the funding those taxes provided to create new and effective tobacco control programs at all levels of government (Sutfin, Szykman, & Moore, 2008; U.S. Department of Health and Human Services, Public Health Service, Office of the Surgeon General, 2014).

The revenue from the taxes made it possible to create effective anti-tobacco use advertisements and other programming relevant to different populations (Sutfin et al., 2008). Many of these campaigns targeted youth since the vast majority of smokers begin before the age of 26 (CDC, 2014). The youth-smoking prevalence has continued to decrease in recent years with 10.8% of youth reporting being current smokers in 2016 compared with 34.8% in 1999 (CDC, 2016). While financial investments in anti-tobacco marketing still are not at the same level as tobacco industry marketing, this infusion of revenue to state and local programs helped these and other grassroots programs gain strong footing to combat tobacco's influence on our youth.

The New Federal Mandate on Tobacco Regulation

By the time of the 50th anniversary report in 2014 the overall smoking rate in the United States had decreased to 19% (U.S. Department of Health and Human Services, Public Health Service, Office of the Surgeon General, 2014). The prevalence of smoking is at historical lows, and with new regulatory authority of the Food and Drug Administration (FDA) under the Family Smoking and Prevention Tobacco Control Act, there is promise that there can be further decreases in smoking and the burden of tobacco-related disease among the whole population. Efforts to give the FDA regulatory authority occurred as early as 1965, but they did not receive this authority until 2009 (U.S. Department of Health and Human Services, Public Health Service, Office of the Surgeon General, 2014).

The federal FDA recently released its final "deeming rule," which extends the agency's regulatory authority to all tobacco products, including electronic smoking devices, cigars, pipe tobacco, and hookah tobacco. The deeming rule extends several provisions of the federal Tobacco Control Act to these new tobacco products. For example, these products are now subject to the federal prohibition on sales to minors, the federal prohibition on free sampling, federal warning label requirements, and the requirement that tobacco manufacturers register with the FDA and seek the agency's review of new tobacco products.

Moving Forward: What Can We Learn From the Fight Against Tobacco

With the growing prevalence of chronic disease and the burdens of such diseases falling more on vulnerable populations such as racial/ethnic minorities, lower SES communities, and youth, it is important that we apply the lessons from tobacco policies and apply these to other areas. For example, one such area includes policies addressing sugar consumption. Many initiatives have been undertaken to levy a tax on sugar-sweetened beverages, but the sugar/food industry has been able to use marketing, just as with tobacco, to defeat these measures. Passage of such measures could have the similar effect of tobacco taxes in providing funds to create campaigns to combat the influence of that industry on youth.

There is also a recognition of the effect of advertising on the consumption of unhealthy food among children and adults (Harris, Haraghey, Lodolce, & Semenza, 2018; The Federal Trade Commission, 2012).Similar to tobacco there is evidence on the need to reign in the manipulative marketing tactics such as depicting healthy activities (e.g., playing sports) in the promotion of unhealthy foods and beverages (Harris et al., 2018). Recent literature also shows the existence of disparities between racial/ethnic groups. Children of Hispanic/Latino descent, for instance, report lower usage of the Internet but have higher exposure to websites promoting food and beverages (Hyary & Harris, 2017). After the Federal Trade Commission's (FTC) initial report on the advertising of unhealthy food to children, the industry created the self-regulated Children's Food and Beverage Advertising Initiative (Powell, Harris, & Fox, 2013). The promotion of healthy lifestyle messaging is the goal of this industry-led initiative. The tobacco industry had similar approaches in an effort to prevent further regulation, which in the end did little to prevent youth uptake of tobacco products but did help in their public image (Proctor, 2011). Eventually research and programs like the Truth Initiative countered these efforts by the tobacco industry and helped to decrease the uptake in tobacco use behaviors.

It is important for public health professionals to look at how the government and scientific efforts to address smoking were responded to by the tobacco industry—and how to limit such unhealthy counter-responses. Some research has attempted to counter unhealthy food and beverage marketing by creating similar promotions of healthy food, but the results do not show increased interest or consumption among youth (Harris et al., 2018). Another approach will be necessary to counter unhealthy food and beverage marketing, perhaps one similar to the Truth Initiative and similar counter tobacco campaigns, where the campaigns address how consumption of unhealthy foods and beverages cannot only effect your health but also other aspects of a youth's life (e.g. social, sports, health). It may be possible to more effectively advance healthy lifestyles and decrease disease burden through policy advances such as stopping misleading advertisements, taxation of unhealthy products, and widening the net on attempts to sidestep policy.

Embodied Health

Ariel J. Mosley, Trevor James Swanson,
and Mark J. Landau

Department of Psychology, University of Kansas, Lawrence, KS, USA

Embodied health refers broadly to the study of health outcomes within the theoretical framework offered by perspectives on *embodied* or *grounded* cognition, which are increasingly influential in the cognitive sciences (e.g., Barsalou, 2008; Blascovich & Seery, 2007; Niedenthal, Barsalou, Winkielman, Krauth-Gruber, & Ric, 2005). These perspectives challenge the traditional assumption that mental representation and cognition can be understood in terms of abstract, symbolic information processing independent of having the particular types of bodies that we have. Instead, they propose the meanings people give to abstractions are intimately connected with their bodily (sensorimotor) states and routine interactions with the physical environment.

Because bodily states and experiences intersect with health outcomes in many diverse ways, the study of *embodied health* encompasses several interesting questions regarding the psychological processes underlying mental and physical well-being. For example, how do people "read" their bodily states to assess their health status? How do health-relevant behaviors like smoking and flossing become habitual motor routines?

This entry focuses on just one embodied process: using knowledge of bodily experiences to conceptualize health-relevant concepts. Many of these concepts are abstract because they refer to outcomes and causal relations that we cannot directly observe or experience, that are remote from our daily lives, or that we imagine occurring in the distant future, if at all. Few non-experts have a detailed mental model of, say, the biochemical processes by which ultraviolet radiation triggers malignant melanoma, or the effects of antidepressants on brain functioning. Consequently, these concepts can be difficult to understand in their own terms.

According to conceptual metaphor theory (Lakoff & Johnson, 1980), metaphor is a cognitive tool that people can use to understand (not just talk about) abstract concepts in terms of dissimilar concepts that are relatively more concrete. Metaphor supports understanding by creating a set of mental associations, called a *mapping*, between aspects of the abstract concept and corresponding aspects of the concrete concept. When people employ a metaphor to think,

the mapping enables them to draw on knowledge of the concrete concept as a framework for construing the abstract concept, even though the two concepts are unrelated at a surface level. In some (but not all) metaphors, the concrete concept is a sensorimotor state (e.g., increase in body temperature) or a familiar bodily activity (e.g., manipulating objects and containers). Researchers call these *bodily metaphors.*

Let's illustrate how bodily metaphors might shape mental models of health concepts. "I've *come a long way*," Claire says of a nasty cold, "but I'm not *out of the woods* yet." Of course, a cold is not a trip or journey in any literal sense, so why does Claire talk this way? She has difficulty grasping what a cold is and how it works. Employing the metaphor *cold recovery is a journey*, she maps colds onto an easily visualized schema for moving along a path. Now she can represent recovery as a *destination*, her persistent cough as an *obstacle*, and medication as *moving* her in the right *direction*. Colds and journeys both involve bodily experiences, but they are obviously concepts of a very different kind. That is the point: Claire capitalizes on a coherent *journey* schema to make sense of vague, complex, and occasionally threatening ideas about health.

But do people, in fact, use bodily metaphors to grasp health concepts?

Qualitative Evidence

Some evidence for the use of bodily metaphors comes from qualitative analyses of the language used by health practitioners and the general public to talk about those concepts. Susan Sontag's (1978) seminal book *Illness as Metaphor* revealed that metaphors pervaded discourse on cancer in the nineteenth and twentieth centuries. She showed that medical experts used a personification metaphor that attributes cancer agency and malevolent motives, referring to it as a growing, eating parasite, a demonic pregnancy, and an invasion of alien cells. Other metaphors portrayed cancer as a corrupting, corroding, and consuming force. Complementing Sontag's broad historical analysis, Penson, Schapira, Daniels, Chabner, and Lynch (2004) analyzed cancer patients' narratives and found that they, too, rely on concrete metaphors to communicate with doctors about the experience of having and treating cancer. Particularly common is a military metaphor that compares various aspects of cancer to analogous aspects of physical combat with a personified enemy, as reflected in phrases like "cancer *hit me hard*" and "I'm *battling* cancer."

Bodily metaphors also appear in narratives of substance addiction. Akers, Gordon, Reyna, and Severson (2013) analyzed over 2,000 online forum posts in a web-based cessation program for smokeless tobacco. They found that respondents frequently used metaphors to talk about tobacco, nicotine addiction, and substance cessation. Many of these metaphors were based on bodily experiences. For example, cessation was described as a journey to be completed, a physical battle to be won, and an escape from being physically restrained against one's will.[1]

One other example will suffice this one from the domain of mental illness. Clients diagnosed with depression frequently compare depression to being spatially *down*, *low*, and *sinking* (McMullen & Conway, 2002). Other conventional metaphors compare depression to a physical weight holding one down and therapy as *easing* or *removing* that burden, or to a state of darkness (McMullen & Conway, 2002).

Qualitative evidence that linguistic metaphors pervade health discourse suggests that people use metaphors at a deeper conceptual level to represent and reason about health concepts. Yet an alternative interpretation of these findings is that people talk using conventional metaphoric idioms, but they think about health concepts without the aid of metaphor. Therefore, we need to "peek under the hood" of language and examine whether bodily metaphors actively shape online health cognition.

Experimental Evidence

Toward this end, researchers in social and cognitive psychology have recently developed empirical strategies that can be used to test metaphor's causal impact on information processing (Landau, Robinson, & Meier, 2014). One strategy is to expose people to a message that uses metaphoric phrases or imagery to compare an abstract concept to a superficially unrelated concrete concept—what researchers call a *metaphoric framing*. The reasoning is that if exposure to a metaphoric framing activates a metaphor in observers' minds, it should trigger a cascade of associations entailed by that metaphor's mapping. As a result, people should transfer emotions and cognitions associated with the framing's concrete concept to interpret analogous aspects of the abstract concept.

A quick illustration: Jennifer hears on TV that a cold medication gives people a "bold step forward," activating the bodily metaphor *cold recovery is a journey*. If that metaphor operates as a systematic mapping, as conceptual metaphor theory posits, then it should prompt Jennifer to pull from her knowledge of journeys to reason about corresponding aspects of colds, even those aspects of colds that are not mentioned explicitly in the original TV message (e.g., what causes colds). If the message had compared cold recovery to another concrete concept, such as evicting an annoying houseguest, or described it without metaphor, then we would not expect Jennifer's understanding of colds to be colored by her knowledge of journeys.

Supporting studies show that even brief exposure to bodily metaphoric framings leads people to transfer emotions and cognitions associated with the relevant bodily states to interpret abstract health risks. In one representative study, Scherer, Scherer, and Fagerlin (2015) showed that exposure to various bodily metaphoric framings of the flu led participants to report stronger intentions to get vaccinated. Specifically, college students reported stronger intentions to get the flu vaccine if they read messages framing the flu as an *enemy combatant* ("an army attacking the body"), a *wild beast* attacking the body, or a *riot that revolts against the body*. What is the mechanism behind this effect? In line with our theoretical reasoning, exposure to these metaphoric framings prompted participants to transfer *emotional worry* associated with protecting their bodies from concrete hazards (getting assaulted by an enemy, dangerous animal, or angry mob) to assess how much the flu threatens their well-being. This heightened worry energized participants to take action to protect themselves.

In addition to motivating prevention behavior, bodily metaphoric framings influence decisions about which course of action to take to address health concerns. Hauser and Schwarz (2015) reasoned that in an actual state of war or physical combat, more active and aggressive actions (e.g., throwing punches) are generally seen as more appropriate than passive responses. Hence, they predicted that exposure to a war metaphoric framing of cancer (versus a non-metaphoric framing) would reduce people's intentions to engage in so-called self-limiting cancer prevention behaviors—that is, those focused on restricting one's own behavior (e.g., reducing consumption of red meat and alcohol)—especially when compared with more active prevention behaviors (selecting high-fiber foods). This is exactly what they found. Put another way, self-limiting behaviors are not typically associated with an aggressive battle setting, so the war metaphor portrays them as less appropriate for properly fighting the "war on cancer."

Of course, in reality, these behaviors might be quite effective. Metaphor use may support understanding, but it does not guarantee accurate or healthy decisions (a point we return to in the next section).

Going further, our analysis suggests a more complex interaction between the metaphoric framing of an abstract disease and the metaphoric framing of a candidate treatment. To illustrate, imagine that Nader understands depression metaphorically as being *down* or *low*. He may infer that a medicine or therapeutic technique designed to treat depression needs to *lift him up* to be effective. Objectively speaking, depression is an abstract cognitive–affective condition, not a drop in vertical position, meaning that a treatment's associations with upward movement have no bearing on its efficacy. Still, it is possible that Nader thinks about depression by analogy to his experience of upward and downward movement and, as a result, he relies on that embodied knowledge to interpret a treatment's efficacy.

This phenomenon was demonstrated in a series of studies by Keefer, Landau, Sullivan, and Rothschild (2014). Participants who had been exposed a metaphoric framing subtly comparing depression to being *down* positively evaluated the effectiveness of a purportedly new antidepressant medication, named "Liftix," advertised as an "uplifting" treatment for people experiencing depression. Participants seem to have reasoned that the medication works if it "solves" the bodily problem of being down. In contrast, when depression was framed without a provided metaphor, participants were not especially attracted to Liftix. For them, the medicine's advertised *up*-ness was irrelevant.

In fact, participants actively denigrated a treatment if it was framed metaphorically as solving a *different* bodily problem than the one used to frame depression. When depression was framed as a problem of being *darkened*, participants rated Liftix as less effective than Effectrix, an equivalent medicine framed in non-metaphoric terms. If you're trapped in the dark, a drug that "lifts" your mood is not particularly effective.

Summing up our selective literature review, qualitative linguistic analyses show that bodily metaphors are commonly used in medical and lay discourse to communicate about a range of abstract health-relevant concepts. Converging experimental research provides stronger evidence that bodily metaphors operate at a conceptual level, shaping outcomes like health risk assessment, health behavior intentions, and treatment evaluations. Specifically, studies show that even incidental exposure to bodily metaphoric framings of health concepts leads people to make judgments and decisions about those health concepts that parallel their schematic knowledge of the bodily concepts to which they are compared. Even though those bodily concepts are unrelated and even irrelevant to the health concept at hand, they are nevertheless useful for gaining a confident grasp of the otherwise abstract, complex, and uncertain processes underlying health. This is one way in which health is embodied.

Practical Implications

Why does all this matter? Although health complications are partly determined by factors that are difficult for individuals to fully anticipate or control, ultimately their choices make a big difference. For example, it is estimated that 43% of all cancers could be prevented by changing high-risk behaviors and reducing exposure to environmental risk factors (Parkin, Boyd, & Walker, 2011). That is why health communicators have for many years publicized messages about health risks through various media outlets like public service announcements and consumer product labels. These messages are designed to motivate recipients to adopt and maintain lifestyle behaviors that reduce their risk of disease. Yet, despite the current health messages in the media, people continue to engage in unhealthy practices, indicating that there is considerable potential to improve the power of these messages.

One way to accomplish this is to enhance these messages with bodily metaphors. The theory and research summarized above suggest that such metaphors are interpreted by observers not simply as colorful figures of speech; instead, they can systematically influence how people think about risk, treatment efficacy, and other operative constructs. Hence, developing communication strategies that guide the design of bodily metaphoric health messages can be a low-cost, theoretically grounded, and potentially powerful means of improving health message efficacy.

With this promise, however, come potential pitfalls. Metaphor usage is not guaranteed to help people *accurately* construe a health concept or motivate them along the path to lifestyle behavior change. That's why it is important to consider when bodily metaphors help and when they mislead or squelch motivation to make healthier choices.

When Bodily Metaphors Help

When a health risk seems abstract or removed from the practicalities of daily life, people may not feel particularly worried about the threat it poses, and hence they are not energized to change their current behavior. Metaphor can be used to compare that risk to a more concrete, easily visualized hazard, which might elicit the worry necessary to energize preventative behavior. This process was demonstrated in the aforementioned studies by Scherer et al. (2015): comparing the elusive and invisible flu virus to an aggressive army intent on attacking one's body raised observers' worry to energizing levels, prompting them to take action to get inoculated.

We can derive a more specific hypothesis from conceptual metaphor theory. If exposure to a metaphoric framing leads observers to recruit *their* knowledge of the concrete bodily experience to interpret the target health risk, then it should motivate action particularly among those individuals who, by disposition, are highly fearful of that bodily hazard. If, in contrast, observers are not especially disturbed by that hazard, then the metaphoric message will not elicit the worry necessary to motivate prevention. Landau, Arndt, and Cameron (2015) put this idea to the test. They built on Scherer et al.'s procedure but added an individual difference moderator: How much does the observer fear physical confrontations with aggressive others?

For individuals who strongly fear confrontations, exposure to metaphoric phrases and imagery comparing invisible ultraviolet radiation to an aggressive person pummeling one's skin increased worry about skin cancer risk and, furthermore, strengthened intentions to use sunscreen when going outside. But among participants who previously reported that they are not particularly disturbed by the idea of an aggressive person trying to hurt them, this metaphor had no effect on worry or motivation to apply sunscreen.

In addition to increasing energizing levels of worry, a metaphor can bolster so-called *response efficacy*. That is, it can bolster people's confidence that a recommended treatment behavior is effective at reducing their risk. Imagine that a doctor prescribes a new medication to help a patient falls asleep. If the patient lacks an intuitive understanding of how that medication works, he may not be sufficiently motivated to use it. A metaphor can compare the treatment's effect to a familiar aspect of the patient's ordinarily bodily experience. The sleep medication can be framed, for example, as "loosening the grip" of a nerve-wracked consciousness, thereby permitting sleep. The patient already has a familiar, confident sense of how manual gripping and "letting go" work, and a metaphor can transfer that schema to bolster confidence that a treatment works.

Similarly, metaphor has the potential to bolster *self-efficacy*, or confidence in one's ability to perform a behavior required to produce desired outcomes—in this case, reducing risk for health complications. Metaphors can reinforce feelings of self-efficacy by likening an abstract treatment or prevention behavior (e.g., "control your anxiety") to something that is more concrete (e.g., "When that inner ball of anxiety starts shaking, turn your mind's gaze away to something pleasant"). More generally, metaphors help the person make meaningful sense of health-related concepts and situations that might otherwise seem overwhelming in their ambiguity and unpredictability (Teucher, 2003).

Additionally, because metaphors provide a stock of familiar images and schemas for how things work, they can facilitate communication between medical health professionals and the lay public (Krieger, Parrott, & Nussbaum, 2011; Penson et al. 2004; Reisfeld & Wilson, 2004). When treatment metaphors such as "fighting the war on cancer" are used in patient–practitioner communication, they can reduce perceptions of ambiguity and allow for increased understanding. This is important because an emerging and controversial topic is patient-based decision making, a practice that puts patients in the driver's seat and makes them more active in the decision making process (Mazur, 2015). However, endorsing this practice can be a double-edged sword. It can empower patients, but it can also expect them to make important decisions without sufficient background information. Without having an educated understanding of the choices available for treatment, these patients may feel confused. Metaphors can help to provide information about the disease and treatment options without subjecting patients to a long process of deliberation, questioning, and uncertainty.

Furthermore, although we saw in Hauser and Schwarz's (2015) work that understanding cancer as an enemy to be "fought" can reduce people's intentions to engage in self-limiting treatments (e.g., restricting one's diet), this was only true when the treatments were framed in exclusively non-metaphoric terms. "Restricting one's diet" in and of itself may seem like a rather ineffective weapon for "fighting the war on cancer," but when told that this technique was *apt for fighting enemies*, participants viewed it as a useful and desirable strategy for treatment. This finding highlights the point that consistency between metaphorically framed health problems and their solutions not only increases motivation to seek treatment but also guides the individual to seek interventions that are easier to understand. By clearing the uncertainty that obscures our understanding of abstract health risks, metaphors can help us take responsibility and confidently address the issues that threaten our personal health and overall wellness.

When Bodily Metaphors Hurt

As alluded to earlier, a metaphor's utility for understanding is no guarantee of its accuracy, and in some cases the use of bodily metaphors can be misleading. By basing models of a health concept on concepts of a different kind, without due consideration of the health concept's unique properties, metaphors can perpetuate myths and negative stereotypes of individuals affected by disease.

Consider that, historically, the most pervasive metaphor for cancer is that of a military battle. Cancer discourse is replete with the vocabulary of war: *combatants*, *weapons*, *battles*, *soldiers*, *the wounded*, *warriors*, *survivors*, and *victories* (Mukherjee, 2011). However, a metaphor's mapping is partial and selective, meaning that it highlights certain aspects of the target concept (making them salient guides to thought and behavior) while at the same time playing down other aspects of the relevant ideas, pushing them to the periphery of consciousness.

Metaphors can mislead about the nature of a given health risk and a treatment's efficacy. For example, in a typical war, there is a single, clearly defined enemy. This may explain why oncologists in the 1960s narrowly tailored their efforts to find a "universal cure" for all forms of cancer. They imagined cancer to be *one* disease—a single, monolithic entity. The *war* metaphor may have underpinned the belief in the underlying singularity of cancer. Now, with scientific advancement, we are learning that cancer is a shape-shifting disease of immense diversity, and the same treatment cannot indiscriminately be applied to all forms.

The broader point is that studying how metaphors shape mental models of health concepts can not only improve health message efficacy but also shed light on unacknowledged sources of persistent misconceptions about health. The converse is that there may be a treatment or intervention that is, in actuality, quite effective, but if it is framed in a way that does not appeal to people's metaphorical conception of the health risk, it will not be endorsed.

Metaphors can foster misconceptions about not only a health risk or treatment but also those individuals who are affected by it. Sontag discusses this harmful consequence of metaphoric language, noticing the negative influences that cultural myths surrounding cancer had on her as a patient. She suggests that culture can potentially turn diseases into mythologies by perpetuating negative stereotypes and attributing stigma to both the disease and the afflicted individual. Sontag extends her critique of metaphors, purporting that AIDS has become the disease that is most demonized by society. Widely promulgated metaphors portray AIDS as pollution or decay, implying that afflicted individuals possess tainted moral values (reflecting the more general metaphor *immorality is dirt*; Lakoff & Johnson, 1980). Comparing this disease to a "plague" highlights not only the infectiousness of the physical virus itself but also the transmission of immorality. The diagnosed patient is perceived to be responsible for indulging in delinquency, and the illness is viewed as a punishment for social deviancy. This perception not only contributes to patients viewing themselves as socially devalued members of society but also may hinder them from seeking necessary treatment. Furthermore, it may disincline public policy officials from supporting funding for research and interventions.

Additionally, metaphors can mislead about the individual's role in terms of having the agency or responsibility necessary for action and consequently may place the burden on the patient. Patients may begin to construct their own subjective experiences with the framework provided by the chosen metaphor, which in turn may promote feelings of shame, guilt, or hopelessness. Sontag suggests that as long as cancer is viewed as an evil enemy rather than a biological disease, victims of cancer will be demoralized upon learning that they have such a disease. Moreover, she asserts that the metaphor may actually distract from effectively treating the disease, leading to a greater number of fatalities by inducing paralyzing fear.

Although too much fear can be problematic, it is important to keep in mind that arousing a certain amount of fear can be beneficial for patients when making decisions about health behaviors. In particular, research on fear appeals in the health literature shows that inducing a moderate level of fear is the most effective way to motivate health behavior change. High levels of fear can backfire because people just shut down and repress awareness of the problem (Glanz, Rimer, & Lewis, 2002). Therefore, if metaphors transfer emotional worry from concrete hazards to evaluations of the target health risk, and that fear is very high, it may paralyze people from taking action. For example, envisioning how cancer cells "invade the body" and describing chemotherapy as "chemical warfare" can induce confusion and cause cancer patients to be overwhelmed by the threatening nature of the disease.

Similarly, doctors and health researchers can get caught in a web of beguiling metaphors that may lead to miscommunication. Aside from the public's response to metaphors, medical professionals and researchers may have their scholarly efforts guided by a superordinate metaphor that is appealing for the sake of clear comprehension, but which leads them to overlook the unique properties of the target health concern and inject it with properties that it does not have. The implication is that interventions designed to reduce misconceptions and motivate behavior should pay particular attention to *which* metaphors are used in ordinary and medical discourse to frame health concepts.

Looking Ahead

The use of bodily states and physical experiences to inform health-related cognition and behavior is, most likely, not a single phenomenon produced by bodily metaphor or any other single mechanism. Instead, much like other complex social cognitive processes, it is likely to be produced by an underlying battery of interacting mechanisms. If this is true, the question then becomes, what are those mechanisms?

Besides bodily metaphor, candidate mechanisms are featured in influential views on embodied cognition (see relevant references at the outset of this entry). Consider Barsalou's (1999, 2008) perceptual symbols systems model. This model posits that concepts contain representations of bodily states (e.g., sensations) that customarily occur during interactions with relevant stimuli and contexts. To illustrate, people's *influenza* concept may contain, in addition to abstract knowledge of viruses and treatments, sensorimotor representations of bodily symptoms (e.g., fever) that routinely occur during experience with the flu. As a result, thinking about those concepts triggers the simulation, or neural reactivation, of associated bodily states, even when the individual is not currently interacting with the relevant stimuli (i.e., thinking about flu activates the bodily experience of nausea).[2]

The important point for now is that there is a large body of theory and research on embodied or grounded cognition that can be used to guide further work on embodied health. Developments in this area promise to shift us away from a narrow view of minds as disembodied information processors and reveal the vitally important roles that embodied experience plays in health-relevant cognition and lifestyle behaviors.

Notes

1 Other common metaphors, less directly tied to bodily states, compared cessation to a job or the breakup of a dysfunctional friendship with tobacco. This variability illustrates that not all conceptual metaphors are embodied; rather, some capitalize on cultural schemas of social interactions.

2 Embodied simulation mechanism and metaphoric conceptualization are distinct mechanisms. Distinguishing them is not relevant for the purposes of this entry. For a detailed comparison (see Landau et al., 2014).

Emotion Regulation

Emily W. Shih and Elizabeth L. Davis

Department of Psychology, University of California, Riverside, CA, USA

Emotions are adaptive because they provide information that usually carries consequences for people's health-related goals. For example, feeling a rush of fear in response to a rustling sound in the bushes signals the possibility of an adverse situation (e.g., a snake in the underbrush) and prompts a reaction (e.g., freeze, flee, fight) designed to enable survival. Our emotional experiences, whether generated by the small-scale hassles of daily life or true life-and-death situations, can impact our overall health and well-being by triggering a cascade of stress responses. These responses are extremely useful under conditions of objective threat (there really is a snake in the underbrush) but can be corrosive in situations in which the emotional response and resulting behaviors are poorly matched to the situation (a person feels extreme fear, but the rustling sound was caused by the wind; even worse, a person feels no fear, but the rustling sound was actually caused by a snake ready to strike). Thus, our ability to regulate our emotions once they are evoked—to downplay, calibrate, or otherwise modulate them—can weigh heavily in how we experience and respond to stress and, in turn, our susceptibility to poor physical health.

This entry is organized into two parts. The first describes and defines emotion regulation as a construct and highlights the known links between emotion regulation and physical health. Given the conceptual similarities between experiencing negative emotions and experiencing stress and distress, we discuss emotion regulation in relation to stress responding, focusing on why and how emotion regulation abilities are vital to promoting, sustaining, and enhancing our health. The second section moves beyond the direct association between emotion regulation and health, highlighting sources of the inherent variability in people's emotion regulation skills and how this maps on to susceptibility to illness and disease—we consider individual and developmental variability in skill and the importance of context, as moderators of the emotion regulation-health link that are ripe for future work to examine. Though research on these boundary conditions and constraints is growing, this is a relatively new area of focus, and we conclude with recommendations for health psychologists who wish to further understanding of emotion regulation's role in promoting or undermining people's health.

Emotion Regulation

The emotions we experience not only can influence our behavior in the short term but also can carry long-term consequences for how we understand and process our experiences, which in turn influences our future decisions. This process can apply not only to basic, daily life tasks like deciding which movie to see (avoiding one that looks likely to be scary, if the last scary movie you saw scared you so much, you jumped in your seat and spilled your drink all over your date) but also to life decisions that are much more consequential. For example, feeling upset about an awkward interaction with a new doctor can lead to negative emotions in the moment and, more damagingly, can preclude someone from seeking medical attention for later ailments. Poorly regulated emotion can interfere with successful health at the behavioral level, reflected in the decisions people make and the habits in which they engage, and at the physiological level, as reflected by dysfunction in stress response systems. We consider both behavioral and biological levels of analysis as crucially important to a complete understanding of emotion regulatory processes implicated in health.

Among the most robust findings in health psychology are those documenting the role that negative emotions and distress (or negative affect) play in the onset, maintenance, and exacerbation of health problems. Negative emotions appear to be associated with these health-relevant outcomes due to their potential to trigger a cascade of behavioral (e.g., self-medicating with substances) and physiological (e.g., allostatic load) responses that often result in enhanced susceptibility to certain illnesses. A classic example is work conducted by Cohen and colleagues (1995), in which researchers experimentally induced physical health reactions by systematically exposing participants to a respiratory virus. Measures collected during the trial included samples of nasal secretions for detection of infection, facial tissues for assessing mucus secretion weights, and daily self-reports of negative affect states and upper respiratory symptoms. All measures were also gathered before exposure to the virus to allow a baseline comparison. Most people got sick because of the virus exposure, but one of the most intriguing findings was that people ultimately developed a more severe form of the illness if they had reported more negative affect at the time of the exposure.

Despite the role that negative emotions may play in worsening experiences in some contexts, they can be extremely adaptive in others. For example, experiencing negative emotion signals a status change in a goal that a person holds, and detecting this change in one's goals prompts certain responses (behavioral, cognitive, physiological, motivational) in line with the specific emotion at hand. Consider a parent who reprimands a child for impulsively darting into a busy street. In the moment, the scolded child might burst into tears and feel that the parent's reaction is overly harsh, but to the extent that this reprimand slows or stops the child's future urges to run into traffic, it has ultimately served as an excellent deterrent (and health-promoting behavior).

Generally speaking, positive emotions are viewed as being protective—to one's well-being, mental health, or even physical health. People with more positive dispositions (e.g., those who experience positive affect more often or more intensely) tend to have stronger immune systems and cardiovascular function. Positive emotions are not always beneficial, however—context is crucial. Displays of positive emotion in certain (usually social) contexts can be highly inappropriate or offensive to others and thus confer substantial costs for the person who misjudged or miscalibrated the emotional response. For example, laughing uproariously during a somber funeral eulogy would probably introduce considerable tension to multiple relationships, costing the person social support resources and potentially introducing negative emotional states.

Thus, both positive and negative emotions may be adaptive or maladaptive, depending on the particular context. Context is critical for identifying, expressing, and regulating one's emotions in ways that promote adaptive functioning (social, behavioral, physiological). Emotions are informative (about the status of our goals) or protective (as in the case of a positive emotional disposition), but they can also be detrimental if they are miscalibrated for the context—of the wrong form, at the wrong time, or with the wrong intensity. In these cases, emotions must be regulated to promote adaptive or successful functioning. How people go about doing this, however, carries a separate set of consequences for functioning.

Broadly, emotion regulation encompasses any process that significantly influences the quality, intensity, timing, or dynamic features of an emotional experience (or response). According to this definition, emotion regulation refers to a wide range of biological, social, and behavioral regulatory processes (Gross, 2001). The way people regulate emotions depends on many factors, including the emotion at hand, the individual's point in the lifespan (e.g., infancy versus childhood versus adulthood), and the sum of one's experiences with emotion and regulation up to that point (e.g., experience or input from the environment). Though emotion regulation is often conceptualized as a means of "managing" one's emotions (i.e., the regulation *of* emotion), it can alternatively be viewed as the process by which one's emotions regulate behavior (i.e., regulation *by* emotion). Regardless of which view one takes, the relation between emotion and regulation is bidirectional, dynamic, and transactional over time—though emotion processes are often studied experimentally by inviting participants to the lab and evoking a target emotional state, in reality people rarely find themselves feeling "neutral" in their daily lives. People may feel mildly pleased about some good news they received this morning, or mildly anxious about an impending deadline, but regardless of whether emotions are intense enough to require active attempts at regulation, people are experiencing and modifying their feelings all the time. Often, emotion-related behavior (and motivation for regulating certain affective states) is driven by display rules, or sociocultural norms and standards for behavior. These norms vary across cultural groups and provide prescriptions for which emotional responses are appropriate in which contexts. Unsurprisingly, these standards for emotion expression have clear consequences for the way people regulate their emotions in the service of these superordinate sociocultural goals.

From this view, the incredible complexity of emotion regulation processes becomes clearer—for any individual person, effective regulatory behavior will depend on a host of factors, be constrained by multiple aspects of the context, and vary within person over developmental or historical time. Thus, no one way of regulating emotion is likely to be effective across all of these gradients of variability, so it is important for people to cultivate regulatory flexibility—in other words, to engage in regulatory processes that are readily adaptive, situationally responsive, and socioculturally specific. Effective emotion regulation predicts all manner of adaptive outcomes, including better social strategies when engaging with peers (e.g., Lopes, Salovey, Côté, Beers, & Petty, 2005) and greater success in cognitive delay tasks (e.g., Carlson & Wang, 2007), indicating the importance of considering emotion regulation processes for general well-being and healthy functioning.

Emotion Regulation Predicts Health and Well-Being

Emotions and the ability to effectively regulate one's emotions (e.g., change or modify emotional experience as desired or required) have been linked to physical health. For example, the chronic tendency to experience a particular emotional state (e.g., negative affectivity) predicts illness symptoms (Watson, 2000). Thus, mood states that are longer lasting have clear implications for people's health. One explanation for the link between negative emotions and poor health outcomes centers on stress regulation as a mechanism by which unchecked (unwanted) negative emotions become overwhelming. Stress can be thought of as a process (e.g., noticing that you have been progressively feeling more "stressed" before a big exam), an outcome (e.g., a measurable biomarker that changes under conditions of challenge), or an experienced event (e.g., stressors, life events, or daily hassles). Here we consider stress as the process of reacting to input from the environment, in light of how this process physically taxes the body. Thus, stress typically arises when individuals perceive that they cannot effectively cope with the demands being made on them, or with threats to their well-being.

Stress reactivity can be defined as biological reactivity to environmental stressors, and individual differences in this response are thought to partially account for the broad between-person variability in susceptibility to stress-related illnesses. Generally, exaggerated stress reactivity is viewed as maladaptive and potentially toxic to one's overall well-being, placing individuals at heightened risk for mental and physical health problems. A common approach to describing the damaging effects of accumulating stress is to use an allostatic load framework, an approach that quantifies the "wear and tear" on the physiological systems of the body that are responsible for maintaining homeostatic function as well as supporting stress responses under conditions of challenge. Generally, the activation of the stress response system (the sympathetic branch of the peripheral nervous system, the system responsible for "fight-or-flight" responses) and return to pre-challenge levels and homeostasis after a challenge has ended or been handled (the parasympathetic branch of the peripheral nervous system, the "rest and digest" calming response to threat) is an extremely adaptive dynamic response. Under certain conditions like chronic stress or repeated exposure to intense stress, however, the system wears down. Prolonged or repeated activation of these allostatic systems results in the breakdown of their optimal functioning, providing evidence of allostatic load on the system, which brings a host of physiological and health-related problems.

Stress arises and persists under conditions of challenge and influences the physical functioning of the body. The more intense, chronic, or prolonged the experience of stress, the more consequences for the stress response systems and the greater likelihood of experiencing physical health decrements. Stress has been linked to all leading physical causes of death, including heart disease, cancer, and stroke (Cohen, Janicki-Deverts, & Miller, 2007). It is also commonly associated with development of major mental health issues such as depression, post-traumatic stress disorder, and pathologic aging (Marin et al., 2011). By logical extension, one can think of negative emotions as a potential source of intense, chronic, or prolonged distress that may ultimately have similar effects on physical health. Coupled with ineffective emotion regulation, distressing negative emotions can be especially damaging.

Many studies addressing the relation between emotion regulation and physical health have focused on how emotion regulation affects immune system functioning. People who regain or maintain positive emotional states through means of laughter or coping with humor when faced with stressful life experiences can show improvements in immune functioning (e.g., Tugade, Fredrickson, & Feldman Barrett, 2004). Reported positive and negative emotions have been linked with the release of secretory immunoglobulin A (S-IgA). S-IgA is considered the antibody first on defense against the common cold. Some research suggests that positive moods appear to enhance immune system responding, but this effect is compromised by negative moods. Emotion regulation, to the extent that it decreases negative emotion or enhances positive emotion, can thus arguably influence S-IgA levels.

Ineffective emotion regulation can also influence long-term health by increasing the risks of mental health problems like depression and anxiety. Dysregulated negative emotions like anxiety, fear, and sadness are implicated in many clinical symptoms and predict later disorders. For example, O'Leary (1990) found that when grief and sadness were not effectively regulated, these affective states often forecasted severe unipolar depression, which can result in immunosuppression. For example, Pisani et al. (2013) surveyed approximately 8,000 students about aspects of their lives including maladaptive emotion-related functioning: suicide attempts, difficulties in emotion regulation, lack of emotional clarity, limited access to emotion regulation strategies, and depressive symptoms. Difficulty regulating one's emotions (lack of clarity about feelings and limited access to useful strategies) related to increased depressive symptoms and likelihood of suicide attempts. Even after controlling for the presence of depressive symptoms, students who had difficulty with regulating their emotions showed elevated likelihood of a suicide attempt. Thus, ineffective emotion regulation is often implicated in affective psychopathologies like depression and anxiety disorders and can also affect this component of healthy functioning.

Additionally, stress, distress, and dysregulated emotion can interfere with behaviors that would enable someone to ameliorate physical health concerns. Abele and Hermer (1993) demonstrated that emotional states influenced people's beliefs about both their desire and their ability to engage in health-promoting behaviors. Individuals who were happier perceived themselves as better able to carry out health-promoting behaviors and had greater confidence that these behaviors would effectively treat their illness symptoms. On the other hand, individuals who were sad had less self-efficacy in relieving their illnesses, believing that they were limited in their ability to make themselves feel better, which interfered with subsequent seeking of or adherence to treatment.

Stress can also increase the likelihood of engaging in maladaptive behaviors (e.g., abusing substances, remaining in unhealthy relationships), which can have negative effects on physical health. These behaviors may represent maladaptive ways of regulating emotion. For example, considerable evidence suggests that people use and abuse alcohol as a result of their expectations of how it will influence their emotional states, as people tend to overdrink in attempts to regulate their negative feelings or to increase and heighten positive feelings (e.g., Sher & Grekin, 2007). Additionally, negative emotional experiences are an important antecedent to tobacco use (e.g., Shiffman & Waters, 2004). Smoking rates are considerably higher among individuals who have been diagnosed as clinically depressed, and people report that the desire to change how they feel is a primary reason for smoking.

Other behavioral evidence suggests that the consistent use of certain emotion regulation and coping strategies is also associated with health outcomes, even when introduced as part of an experimental intervention. Emotional disclosure is a form of emotion regulation, as it allows someone to revisit an upsetting experience as a way of processing the event or to enable the person to seek social support from others. Pennebaker (1997) found that even the simple act of disclosing emotional experiences in writing improves individuals' subsequent physical health. Students assigned to write about a traumatic emotional experience made fewer health center visits compared with students assigned to write about a neutral or mundane topic. Enhanced immunological functioning has also been observed as a result of emotional disclosure, in conjunction with decreases in self-reported physical symptoms and depression. In related work, Emmons and McCullough (2003) assigned participants to one of three groups: (a) a "count your blessings" group, (b) a "list your daily hassles" group, and (c) a control group. Individuals who counted their blessings weekly for ten weeks reported the best subjective health outcomes (e.g., fewer physical complaints, increased exercise and sleep, better sleep quality), supporting the idea that cultivating better regulatory abilities can promote health.

Individual and Developmental Variability in Emotion Regulation Skill

The benefits of effective stress reduction and emotion regulation for adaptive functioning are hard to overstate. Stress reduction and emotion regulation skill leads to enhanced concentration, improved communication and relationships, more stable moods, and ultimately better physical health. Of course, there is considerable variation in how people regulate their emotions effectively and what constitutes "effective" regulation will necessarily change with time and across contexts. Here, we consider some of the external constraints and individual differences in effective emotion regulation that represent promising directions for future research into the effects of emotion regulation on physical health and functioning as the field moves toward identifying more precise targets for intervention. Specifically, we consider moderators of the relationship between emotion regulation and health. Clarifying the direct links between emotion dysregulation, distress, and health outcomes is an important first step, but we encourage scientists in this area to begin to examine the putative moderators of the associations (e.g., for which individuals, under which circumstances, are a particular way of regulating emotion "effective"?) to advance knowledge in the field.

People vary in what they can do to regulate negative emotions and stress. Adults in particular have a diverse set of options from which to choose when regulating negative emotions and dealing with stress. Two strategies that have been shown to be effective across a variety of contexts are reappraisal and problem solving. Gross (1998) first highlighted the efficacy of reappraisal by showing that it results in positive emotional and physical responses to emotion-eliciting stimuli. Both reappraisal and problem solving are a common component of cognitive behavioral therapies for psychopathological disorders (e.g., Stewart & Chambless, 2009). In contrast, expressive suppression and emotional avoidance have been shown to be relatively maladaptive responses to stressors and are associated with risk for psychopathological disorders, including anxiety (e.g., Campbell-Sills, Barlow, Brown, & Hofmann, 2006).

In daily life, people encounter multiple opportunities to engage in context-appropriate regulation. For example, it is often necessary to actively regulate emotions in professional or social settings because the workplace requires sustained attention, and successful social interactions are governed by display rules. Work or school contexts may be sources of different amounts and types of stress at different developmental stages, and effective implementation of specific strategies will thus vary according to contextual demands. There has been growing interest in the importance of flexibility in implementing strategies to match contextual demands because some strategies have been shown to be more costly under certain circumstances. For example, in social contexts, suppressing the expression of one's true feelings can interfere with establishing rapport or closeness to the extent that the suppressor appears disengaged and avoidant (rather than benignly neutral, perhaps, Butler et al., 2003, but see Butler, Lee, & Gross, 2007, for evidence that this negative effect of emotion suppression is qualified by culture). In contrast, expressive flexibility, which is the ability to flexibly enhance or suppress emotional expression across different contexts, protects against detrimental effects of cumulative life stress (Westphal, Seivert, & Bonanno, 2010). Considering the constraints that context can impose on individuals' responses to stress and regulation of negative emotions represents an important direction for future work.

Differences in the effects of specific emotion regulation strategies are also important to acknowledge because an understanding of individual differences in emotion regulation abilities involves examination of the emotion regulation strategies that people acquire and use in their own lives. The way people choose to regulate their emotions and deal with stress and negative events is variable, and what may be successful for one individual may not be for another person, or for the same person in a different context. Stress levels, how people react to stress, and the effects of stress on well-being all represent sources of heterogeneity that must be unpacked to understand the effectiveness of different emotion regulation strategies. Identifying differences in the process of acquiring particularly adaptive and functional emotion regulation strategies across the lifespan can help us isolate the developmental origins of dysregulated behaviors that could put individuals at risk for illnesses and negative health-related outcomes. Such an approach would be useful for informing future intervention work by identifying children at increased risk for later physical health problems and allowing intervention efforts to target improvement of emotion and stress regulation.

Intrinsic and extrinsic factors contribute to individual differences in emotion regulation skill, and many of these originate very early in life. Intrinsic differences in biological stress response systems and temperament (biologically based individual differences in emotional reactivity and self-regulatory ability) can put children on a particular developmental trajectory toward (or away from) emotional, mental, and physical health. These intrinsic factors emerge early in infancy and are influenced by the infant's reactivity to environmental stimulation, as well as ability to self-soothe and regulate distress. These early temperamental factors influence later development of more explicit attentional and inhibitory skills that may be applied to regulating reactions. Of course, the development of emotion regulation skill and flexible strategy use in early life is shaped by dynamic transactions between the child and environment, including other people. Children's families, neighborhoods, schools, peers, and culture all play a role in emotional development, as do aspects of the individual child (e.g., in eliciting and seeking out certain kinds of input from the social world). Most research to date has focused primarily on caregiver and parental influences. For instance, a child's ability to effectively manage negative emotions or distress hinges on both the child's capacity for self-soothing and the sensitivity and responsiveness of a caregiver to meeting the emotional needs of the child. The developmental transactions and individual factors that contribute to the attainment of competent emotion regulation abilities will fluctuate as a function of the child's capabilities and resources during periods of skill acquisition. The inherent variation in these transactions thus contributes to individual differences in emotion regulation in childhood, adolescence, and into adulthood, with implications for physical health throughout development.

Conclusion

Emotions have enormous influence over a wide range of health outcomes. Effectively managing negative emotions in a way that mitigates their negative effects is vital for adaptive functioning. Effective emotion regulation abilities can play a crucial role in promoting improved physical health outcomes (e.g., stronger immune systems) and guarding against health-damaging behaviors (e.g., alcohol abuse, smoking). Thus, it is important for people to develop competent emotion regulation abilities to promote healthy outcomes. It is not possible to narrow the cause of competent emotion regulation abilities to a single determinant source. Instead, we can attempt to understand which emotion regulation strategies work for which people in which contexts to begin to more fully understand the links between competent emotion regulation abilities and people's overall health and well-being.

Her research uses a biopsychosocial framework to clarify emotion processes that predict adaptive (e.g., academic success, social competence) and maladaptive (e.g., psychopathology, physical health problems) outcomes.

Everyday Coping Behaviors

Coping takes place over the course of daily life, yet measures of coping have not always reflected this context. This entry discusses how methodology has shaped what we know about coping and what we have learned so far about everyday coping behavior, beyond coping styles and strategies.

Traditional Conceptualization and Measurement of Coping

Initially, coping research focused on strategies and dispositions that influence the impact of a negative event on well-being. This research yielded important insights about different types of coping strategies (e.g., active versus passive coping, emotion versus problem-focused coping) and when these types of strategies are most adaptive. For example, active coping—taking direct, intentional action to alleviate a stressor or its impact (Carver, Scheier, & Weintraub, 1989)—is generally an adaptive strategy when faced with a problem that is possible to remedy or reappraise. In the face of a stressor that is uncontrollable and not persistent (e.g., a temporary positive result for a diagnostic test), disengagement from the situation can be adaptive immediately following the event (Taylor & Stanton, 2007).

These distinctions made great strides toward understanding adaptive and maladaptive ways of handling major stressful experiences, but researchers noticed that an important piece was missing from coping research: the role of everyday behavior and experiences. For example, we know that active coping is often a helpful strategy, yet we do not know the specific daily behaviors enacted during the active coping process. Past research has also yielded limited knowledge about the changes active coping produces in everyday life. Further, questions remain about the role of active coping in the face of minor stressors throughout the day. Researchers noticed that these limitations were largely due to the methods used to assess coping. Exclusive use of retrospective self-reports unduly restricts what we can learn about coping because they are

limited to what people can remember—often what was most salient or recent—and exclude less memorable behavior and contextual information (Stone & Neale, 1984). Further, general endorsement of a particular item on a coping questionnaire is more appropriate for assessing coping styles as an individual difference, but not in-the-moment coping behavior (Stone et al., 1998; Stone, Greenberg, Kennedy-Moore, & Newman, 1991). Empirical evidence for this notion came 20 years later, when one study found that "concordance between global and daily reports was weak" (Todd, Tennen, Carney, Armeli, & Affleck, 2004, p. 310). Thus, coping researchers moved away from solely using global coping reports and began to use methods that get closer to behaviors linked to coping with daily diaries and ecological momentary assessments (EMA).

Daily Diaries and Ecological Momentary Assessment of Coping

Daily diary methods are daily reports, typically completed at the end of each day, in which participants can record their use of coping-relevant constructs such as coping strategies, mood, and support received. Using daily diaries, coping research gained insight into the role that minor events play in the coping process, as well as how daily fluctuations in coping, mood, and other behaviors influence coping outcomes such as psychological adjustment. Early diary research sought to understand the role of everyday stressors (e.g., arguments, deadlines, minor illnesses) rather than solely major events (e.g., divorce, loss of a job, death of a loved one). For example, one study used daily diaries to assess everyday stressors and their impact on mental health (Bolger, DeLongis, Kessler, & Schilling, 1989). This study focused on married couples' daily stressors and mood over 6 weeks. They found that mood was better explained by day-to-day stress than researchers previously thought and that interpersonal conflicts best predicted day-to-day mood compared with other daily events. Daily diaries, then, provided a more accurate picture of what accounts for everyday mood than global reports alone could provide.

One of the biggest benefits derived from daily diary methodologies within coping research was the ability to conduct within-person investigations throughout a variety of stressful experiences. A study by Bolger et al. (1989) found that interpersonal conflicts explained 20% of the within-person variance in mood when facing everyday stressors. Other diary studies have also revealed the associations between use of specific coping strategies and well-being. One study revealed that using catharsis—emotion expression to reduce negative feelings about the stressor—and social support seeking were related to increased negative affect among a sample of men coping with daily stressors (Stone, Kennedy-Moore, & Neale, 1995).

Daily measurement of coping also facilitates more in-depth examination of individual differences in between-person studies. For example, rheumatoid arthritis patients completed daily diaries about their pain, coping, and mood for 75 consecutive days (Affleck, Urrows, Tennen, & Higgins, 1992). This study revealed vast differences in coping strategies used by the participants beyond what past retrospective accounts had depicted. Specifically, some people went weeks without using any coping strategies for their pain, while others used multiple strategies each day. Further, the study found that some participants reported using only one type of coping strategy throughout the study, whereas others reported a vast array of strategies. These previously unidentified individual differences in coping styles were discovered due to the unique methodological advantages of daily diaries.

EMA further improved our knowledge of daily events and coping by extending to the momentary level with multiple daily assessments. Multiple studies have found that such momentary reporting significantly increased the precision of measurement of daily coping by relying even less on memory than diary methods. Notably, one study investigated the difference between coping reported immediately and two days after a stressful event by using an event-contingent method, which instructs participants to complete reports each time a stressful event (or other event of interest) occurs (Stone et al., 1998). The researchers found only 30% agreement between the momentary report and the retrospective reports of coping, even though the retrospection extended back only 2 days. This study was the first to show the advantage of EMA to study coping over even very brief periods of retrospection.

EMA has been useful in uncovering in-the-moment coping strategies that are helpful for specific stressors, like asthma symptoms. In one study, participants with asthma reported coping style, symptoms, and peak expiratory flow rate multiple times a day using a signal-contingent EMA, in which participants respond immediately after being prompted. Researchers found that use of avoidant coping strategies was associated with worse-than-normal asthma-related symptoms (Nazarian, Smyth, & Sliwinski, 2006). Thus, the introduction of EMA to coping research further improved the fidelity of self-reports of coping.

Though daily diaries and EMA vastly improved upon retrospective measures of coping, researchers have noted that they only provide information about coping that participants can readily report (Todd et al., 2004). The participant's perspective on coping is undoubtedly important, but no single measure can provide every piece of relevant information about coping in everyday life. Even as early as 1984, Stone and Neale noted the limitation of their daily self-report measure of coping, stating that they "do not claim to have developed a fully valid measure of coping; the potential weakness of the measure—that it relies on self-report—is all too obvious" (p. 905). Like retrospective reports, EMA is still subject to some of the same biases (e.g., social desirability) and limited to what people notice about their coping. Though it seemed obvious to coping researchers in 1984, the field did not begin to shift beyond self-reports until much later, when technology made it more feasible to compare self-reports to behavioral measures.

Naturalistic Observation of Coping

By sampling participants' social environments, researchers gain access to coping-relevant behaviors that go unnoticed by participants. For example, two studies employing the electronically activated recorder (EAR) (Mehl, Robbins, & Deters, 2012), a naturalistic observation method that consists of participants wearing a device that records ambient sound, have revealed links between expressive behavior and coping outcomes. First, a small sample of women with rheumatoid arthritis wore the EAR over 2 weekends, revealing preliminary evidence that sighing is more an indicator of depression than pain (Robbins, Mehl, Holleran, & Kasle, 2011). Another study of women with either rheumatoid arthritis or breast cancer uncovered the potential interpersonal cost of swearing in the coping context. Analyses revealed evidence that swearing in the presence of others may repel support networks at the expense of psychological adjustment (Robbins, Focella, et al., 2011). These findings shed light on the importance of mundane behaviors enacted in everyday coping, beyond reported strategies.

Naturalistic observation also remedies the problem with exclusive reliance on participants' reports of their social environments (e.g., how often specific topics arise in conversation). Questionnaire methods inherently assume what is most impactful in the coping process because they limit responses to the topics researchers have deemed most important (Hagedoorn, Sanderman, Bolks, Tuinstra, & Coyne, 2008). It is possible that over the years, coping researchers have developed questionnaire measures that capture the most important facets of coping; however, this claim has yet to be empirically tested using other types of data collection for comparison. Naturalistic observation can complement self-reports of coping by providing an unfiltered account of everyday coping behaviors.

In one study, couples coping with breast cancer wore the EAR for 1 weekend and completed health and adjustment measures while the patient was undergoing active treatment. This approach provided unique insight into couples' daily interactions while enduring a highly sensitive and stressful experience. Interestingly, this study revealed that on average, cancer came up in less than 5% of couples' conversations (Robbins, López, Weihs, & Mehl, 2014). This discovery contributes a fundamental, if simple insight that has been missing throughout decades of cancer coping research. Past studies of the interactions of couples coping with cancer have focused almost exclusively on cancer-related conversations. However, consistent with relational regulation theory (Lakey & Orehek, 2011), which underscores the importance of ordinary social interactions, these findings highlight that an exclusive focus on cancer conversations overlooks 95% of couples' interactions. A focus on mundane, daily interactions may help resolve a long-standing conundrum in the cancer coping literature: studies consistently find that the quality of social relationships is greatly important for adjustment, but social support interventions based on this knowledge are relatively ineffective (Coyne, Stefanek, & Palmer, 2007). It is possible that a focus on mundane topics and behaviors not historically deemed important to coping research would improve the efficacy of coping interventions—perhaps by uncovering coping strategies that people can more readily incorporate into their daily lives.

Examining the coping-relevant facets of mundane rather than problem-focused conversations is thus a critical next step in the study of everyday coping. So far, one study has revealed that word use within non-cancer conversations is linked to dyadic adjustment, a multifaceted measure of marital quality, among couples coping with breast cancer (Karan, Wright, & Robbins, in press). Specifically, patients' and spouses' positive and negative emotion words were indicative of their partners' better and worse dyadic adjustment, respectively. Further, conversational focus on the spouse, as indexed by patients' use of "you" and spouses' use of "I," was linked to better adjustment in both partners. This finding emphasizes the importance of balance in the marital relationship—paying attention to the spouse in everyday conversation—while facing a major stressor like breast cancer. Such findings would remain concealed without the use of naturalistic observation methods like the EAR.

Summary

The study of everyday coping is still in its infancy, and more questions than answers remain about how facets of daily life contribute to coping. So far, we have learned that daily stressors greatly influence mood, people differ in their utilization of coping strategies, and expressive behaviors untapped by self-report methods may be important to the coping process. Developments in coping methodology have added more complete representations of coping in everyday life to what we already knew about coping styles and general coping tendencies.

Each research method has contributed a unique piece of information about how people cope in everyday life. Retrospective reports inform us about general coping styles and perception of how people feel they cope, whereas daily and momentary reports contribute the experience and perception of coping as it unfolds in daily life. Naturalistic observation fills in the coping-relevant behaviors and aspects of social environments that are difficult or impossible to report. Methodological plurality in coping research has led to greater understanding of how people respond to both major and minor stressors in everyday life.

Future Directions

Theory Building

Many questions remain, including how knowledge about everyday coping will be incorporated into existing overarching coping theories, as well as contribute to new ones. There are almost no unifying theories on everyday coping to date. One notable exception is relational regulation theory, which posits that most of the variance in social support is accounted for by mundane social interactions (Lakey & Orehek, 2011). More theories like this one, based on the existing body of research on everyday coping, are needed.

Multiple Perspectives on Coping

Greater use of EMA, naturalistic observation, and other methods in coping research is warranted, chiefly for adding diversified perspectives to gain a more comprehensive understanding of everyday coping. In addition, ambulatory physiological measures could facilitate knowledge of the pathways between everyday coping behavior and health. Passive telemetrics—automated sensors that participants can wear—give insight into fluctuations in emotion throughout the course of a day. While most passive telemetrics have not yet been used to study coping, it is now possible to begin incorporating them into studies to automate assessment in daily life. One cellphone app, the frequent electrodermal activity and event logging (FEEL) system, labels social interactions such as phone calls or emails as low, medium, or high stress using skin sensors and information already available from the phone (Ayzenberg & Picard, 2014). This work has aided in the recall of stressful events and can be utilized in combination with EMA and naturalistic observation to fine-tune advice on the types of support that are beneficial at various points throughout the day. For example, a study could passively sense stress levels, observe supportive behavior, and collect momentary reports of satisfaction with support. Multimethod approaches that harness technological advances hold promise for contributing to a more thorough understanding of coping.

Coping Behaviors

In addition to unpacking specific daily coping processes, new methodologies can also aid in the consideration of broader issues. For example, the field has not yet agreed upon which everyday behaviors should be considered “coping.” Researchers debate whether the definition of coping should be limited to what people do to effortfully alleviate the impact of a stressor, or whether the definition should include more automatized, habitual behaviors (e.g., Coyne & Gottlieb, 1996). Mapping observations of everyday behaviors onto reported coping strategies can identify behavioral manifestations of well-established coping constructs and thus provide a clearer sense of what people view as “coping” in their own lives. As technology advances methodological opportunities, research on coping can increasingly include facets of everyday life that contribute to a more complete picture of how people cope as they go about their days.

Expressive Writing

An Introduction to Expressive Writing

Both conventional wisdom and empirical evidence support the benefit of disclosing strong emotions. One approach to emotional disclosure is writing; emotional writing has of course long existed in creative and expressive arenas, has been used in conjunction with psychological and behavioral therapies, and occurs naturally in many contexts (Smyth & Greenberg, 2000). Over the last three decades, however, there has been specific and continued interest in a particular technique of expressive writing (EW). In this approach, individuals are asked to write about their deepest thoughts and feelings surrounding a stressful or traumatic experience. Writing typically takes place over several sessions spanning days or weeks, usually confidentially and privately. One aspect of this approach that differentiates it from other disclosure processes—especially sharing with other people—is that privately writing about personal thoughts and feelings removes socially driven feedback that may arise when talking about them with someone else (for better or worse, helpful or unhelpful advice, feeling supported or being rejected or judged, etc.). Remarkably, engaging in just 15–20 min of EW at each of three or four time points often produces psychological and physical benefit. Given the relative ease and access to EW (it essentially can be done by anyone, anywhere, and anytime), it holds potential for individual use and as an adjuvant psychosocial treatment. We discuss these points below, along with a representative summary of the EW literature.

Early Work

The Early Years of EW Research

EW was first introduced in an experimental framework by James Pennebaker and Sandra Beall (in 1986) and was seen as a means for individuals to safely express and work through their

thoughts and feelings. In their initial study, college students assigned to the experimental condition wrote about their emotions and facts related to a prior trauma; those in the control group wrote about a different, emotionally neutral topic at each writing session (e.g., time management, daily activities). Results showed that those in the experimental condition experienced better subsequent health outcomes (e.g., fewer health center visits during the 6 months following the writing task) compared with those in the control group. This seminal study began a line of research that now includes over 300 studies and introduced several procedures and practices that still impact EW work today.

First, Pennebaker and Beall (1986) established initial "guidelines" for administering EW as an intervention: participants are randomized to either an experimental condition in which they write about personally emotional topics, or to a control condition in which they write about topics that are not associated with strong emotions (e.g., daily activities). Across 3–5 days, both conditions complete writing sessions for about 15–30 min in a private room without receiving any feedback about the content of their writing. These procedures were largely used in subsequent studies for years; more recently, the specific EW methods used in research and practice have become increasingly more variable as researchers and clinicians have begun testing EW's effectiveness in different contexts. For example, whether the specifics of the writing instructions, or the way the intervention was administered, could be altered to increase effectiveness (i.e., have stronger effects on health outcomes) or efficiency (i.e., improve health with shorter writing times or fewer writing sessions). As such, there is now tremendous variation in how EW is administered in research and clinical settings (a topic reviewed later).

Second, Pennebaker and Beall (1986) were the first to provide empirical evidence for EW's ability to improve writers' long-term health (in this case, several months later). As such, this study put EW "on the map," inspiring other researchers and clinicians to use it in their work. Indeed, in the decade following the initial study, EW was tested as a means to improve a wide range of health and well-being outcomes in a variety of contexts other than college students; these included prior life trauma in adults and in adolescents, recent job loss, workplace performance and absenteeism, and psychotherapeutic and healthcare settings (Frattaroli, 2006; Smyth & Greenberg, 2000).

The number of these studies grew into a sizable literature that allowed for the use of meta-analysis, a statistical method that combines data from all available studies on a given topic to estimate an effect size, in this case, testing the effect sizes for EW improving different outcomes. The first meta-analysis of a small number of early studies suggested that overall EW had a medium effect size, which is on par with effects found for psychotherapy and other psychological interventions (Smyth, 1998). More specifically, the meta-analysis found that EW's benefits were the strongest for physiological outcomes (e.g., immune system antibodies, liver enzyme functioning) and psychological well-being (e.g., mood, depressive symptoms) with medium to large effect sizes. Similar medium to large effects were found for self-reported health outcomes (e.g., frequency of healthcare utilization, physical symptoms) and improvements in academic/workplace settings (e.g., workplace absenteeism, reemployment, academic performance, grade point average), respectively. Finally, contrary to expectations at the time, there was no evidence that EW positively impacted a (heterogeneous) group of health-relevant behaviors (e.g., exercise activity, diet, alcohol/drug use), finding a small and nonsignificant effect size for these behaviors.

One aspect of this early meta-analysis was noteworthy—positive effects were observed not only on self-reported outcomes (e.g., how well someone said that they were feeling) but also on objectively measured outcomes (e.g., being reemployed, various biological measures, such as liver enzyme function or indicators of the immune system). Some concern had existed that much of the effect of EW may be due to “demand characteristics” or similar reporting biases; finding positive impacts on objective outcomes greatly reduced concerns that such biases were (at least largely) driving observed effects. More generally, the positive initial studies and early meta-analytic support provided a sufficient evidentiary base to spur a large number of (often quite ingenious) studies from an array of researchers, which tested the range and limits of EW.

This first decade of EW studies had another significant implication. The growing number of studies on EW suggested that people were willing and able to write about deeply emotional and highly personal topics when participating in research studies. Even among those individuals who might be expected to shy away from fully confronting past trauma in their writing, for example, persons with posttraumatic stress disorder (PTSD), EW appears to be a feasible and acceptable treatment method. One common and expected side effect of EW is a short-term increase in distress immediately after a writing session is completed, particularly when participants write about a prior traumatic event (as opposed to EW variants, such as writing about positive experiences or benefit finding, some of the range of alterations in writing instructions are discussed later). There do not, however, appear to be long-lasting negative side effects. In fact, most participants generally describe the activity as helpful, rewarding, and enjoyable. As such, EW is seen as a feasible and safe approach to use in controlled research environments, in medical or therapeutic settings, and perhaps even in private settings (e.g., participants’ homes). Of course, as with any form of treatment or intervention tool, care needs to be taken when applying EW to sensitive samples or individuals whose health or safety may be at risk as a result of confronting their deeply personal emotions and thoughts during writing (e.g., individuals who are acutely and severely depressed or suicidal).

A New Direction: EW and Physical Health

The exciting early work in EW often studied relatively healthy, typically well-adjusted samples (with some notable exceptions, such as maximum security prisoners). Given the findings that EW could impact some biological processes, as well as subjective well-being, researchers and clinicians began to apply EW to patients with medical/health conditions. The first explicit test of EW as an adjuvant treatment in patients with medical disorders was conducted in community volunteers with mild to moderately severe asthma or rheumatoid arthritis (RA; Smyth, Stone, Hurewitz, & Kaell, 1999). Participants were randomly assigned to an EW condition or a neutral writing task. Objective disease-specific health indicators were assessed at baseline and 2 weeks, 2, and 4 months after the writing intervention; spirometry measured pulmonary functioning in asthmatic patients and clinical examinations by a rheumatologist measured RA patients’ disease status. For each of these outcomes, EW led to clinically significant improvement in a greater proportion of the sample than did control writing.

Smyth and colleagues thus found that EW was a beneficial adjuvant psychosocial treatment for improving clinical health outcomes among patients with chronic illness. This study led to a number of additional questions about the use of EW as an intervention in medical patients. In particular, could EW be useful for improving clinical outcomes in other medical conditions and contexts? Could EW help patients adjust to the diagnosis of a serious illness? Are there specific contexts in which, or individuals for whom, EW works best? How does EW lead to benefits—what are the specific mechanistic pathways (e.g., cognitive or emotional processes)? These and other questions have led to continued interest in EW as a research and clinical topic and generated a large number of studies that tested EW as a treatment for improving clinical outcomes in additional patient populations and for helping healthy individuals better adjust to life stress.

To date, the EW literature is replete with empirical studies and a growing number of systematic and meta-analytic reviews on EW. Overall, this literature shows that EW can produce fairly reliable, although modest, improvements in psychological and physical well-being. These improvements appear to exist among both healthy individuals and those suffering from physical or mental illness. It is essential to note, however, that not all studies find significant improvements in psychological and clinical outcomes. Researchers continue with efforts to identify the exact conditions under which (and the individuals for whom) EW is effective.

Given the vast scope of the EW literature, we provide below a representative (rather than exhaustive) summary of the major topic areas based on recent work and seminal studies, along with some recommendations for future research directions that may help us better understand the potential uses and limitations of EW.

Health Benefits

Medical Outcomes and Physical Functioning

As noted, evidence for EW's positive impact on medically relevant and objectively verifiable disease indicators has been found in a handful of high-quality studies. For example, several researchers found significant improvements in immune function among healthy participants and other patient samples (e.g., patients with HIV; Frattaroli, 2006). Newer findings also have replicated the benefit of EW among asthma patients (Smith et al., 2015) and have shown faster wound healing after EW (e.g., Weinman, Ebrecht, Scott, Walburn, & Dyson, 2008). More prevalent are studies showing EW's positive effects on patients' subjective physical health and functioning (rather than core indicators of disease status). These include self-reported improvements in physical mobility, functioning, and symptoms (e.g., pain, fatigue, sleep quality) and decreases in medical visits (Faller et al., 2013; Frattaroli, 2006; Harris, 2006).

Other work, however, has not found support for EW improving medical outcomes or more general physical functioning. As an example, EW has been widely administered to patients with different types of cancer as it was hoped that these patients would show health benefits similar to those found in other patients. This work has produced a large literature, with studies demonstrating some capacity for EW to improve aspects of cancer patients' self-reported health (e.g., sleep quality, pain intensity, general health); however, many other studies have not observed such improvements (Merz, Fox, & Malcarne, 2014). In part, this may be attributable to the fact that there is tremendous variability across these studies (discussed further below); for instance, different types of cancer have disparate underlying disease processes that may be differentially impacted by EW, and the way in which EW is administered in these different studies (e.g., having patients write about positive aspects of their lives since their cancer diagnosis vs. a past traumatic event, having patients carry out EW shortly after their diagnosis vs. several months later) may alter its effectiveness in improving health outcomes.

This literature on EW in cancer patients is not unique; rather, it highlights the complexity and uncertainty of trying to make sense of a complex literature testing the capacity of EW to improve health outcomes. Indeed, similar to the literature on EW in cancer, we see inconsistent findings in many other domains, including physical symptoms and general physical functioning and health behaviors (e.g., substance use; Frattaroli, 2006; Niles, Haltom, Mulvenna, Lieberman, & Stanton, 2014). In sum, the exact underlying features and mechanisms that make EW an effective intervention for improving health are not yet fully known (Smyth &

Pennebaker, 2008); as such, many reviews of its benefits on physical health are limited to conclusions along the lines of "it appears to be helpful in many cases, but not always and not for all people."

Psychological Functioning and Well-Being

As we noted in the introduction, emotional expression more broadly defined is often associated with a range of psychological benefits, and early EW studies showed improvements in self-reported mood states (e.g., depression and anxiety levels). Since that time, EW has shown effects on various aspects of psychological functioning in healthy individuals, including reducing rumination (i.e., repeated intrusive negative thought patterns), clinical depression, and psychological distress (e.g., anxiety). One major area of exploring EW's ability improve psychological health has been conducted among individuals with chronic disease as patients often suffer from psychological comorbidities (e.g., depressive symptoms). And as the majority of approaches to EW focus on expressing thoughts and feelings about a stressful or traumatic event, there has been keen interest in its effect on posttraumatic stress (PTS) symptoms; an emerging literature tests EW as a form of treatment for military veterans who experienced combat trauma, other trauma victims (e.g., rape, vehicle accidents), and dyads coping with shared trauma (e.g., couples dealing with extramarital affairs). As is seen in the previously mentioned literature on medical outcomes and processes, evidence that EW leads to positive psychological outcomes among clinical samples and healthy populations is not uniform. That is, some work has failed to show that EW produces any benefit on aspects of psychological health and well-being among patients with chronic illness, individuals with mental disorders, and healthy persons. Further research is needed to help identify what factors determine EW's ability to help individuals better their psychological adjustment in general life or in response to a severely stressful or traumatic experience.

Interim Summary

Emerging evidence indicates that EW has some restorative physical and psychological health effects among patients with illness and among healthy individuals. Some studies, however, find benefits in areas that are not specific to one disease process (e.g., sleep, pain) or do not find positive effects for EW on health outcomes at all (or only for some subset of participants in a given study). Thus, EW is clearly not a panacea for improving disease status in medical patients, or for improving health in general. The reason(s) for the inconsistency in these findings is unclear, although moderating factors (discussed next) may play a role.

Further research on whether EW is an effective tool for improving physical and psychological health, in the general population and among individuals with physical or mental health conditions, is needed to determine the utility and parameters of incorporating EW into routine healthcare services. Ongoing research and clinical efforts will further develop our understanding of EW and how it may best be used to improve health.

Moderating Factors

Given some of the aforementioned inconsistencies in the results of EW studies, researchers have attempted to identify factors that may influence *for whom* and *under what conditions* the intervention is effective. If certain characteristics influence whether or how much EW improves health (i.e., if moderators are identified), the intervention could be refined and targeted toward specific subgroups who may experience the greatest benefit.

Individual Differences

Theoretical and clinical perspectives regarding disclosure, emotional processing, and cognitive processes (e.g., thoughts/beliefs) pointed researchers to a wide range of individual difference factors that may influence response to EW. Indeed, evidence suggests that EW's effects are often moderated by individuals' personal characteristics, such that benefits are stronger among individuals with different characteristics (e.g., gender), dispositional traits (e.g., tendencies to engage in expressing one's emotions to others), or levels of psychological distress or disease status at time of study entry.

In addition, several studies show that participants' social environments appear to moderate EW's effects on psychological outcomes. For instance, a number of studies in cancer patients have found that individuals with higher social constraints—perceived social hindrances for disclosing thoughts and emotions—are shown to benefit more from EW than those individuals with lower social constraints (Merz et al., 2014). Findings such as these suggest that EW may be more effective for individuals who lack a supportive social environment, but questions about the exact social conditions under which EW may be most effective remain.

Other possible moderators are just emerging in the literature. For example, the early work by Smyth and colleagues (1999) found that EW was effective in patients with asthma or RA but that sample was composed of patients with mild–moderate illness severity. A recent study by Smith and colleagues (2015) conceptually replicated the earlier work in asthma patients; they found that patients with moderate illness severity obtained benefits from EW, whereas patients with very mild or very severe disease severity did not. Although clearly preliminary, such findings suggest that EW may not be helpful for improving disease status when an illness is so severe that it can no longer respond to EW, or if it is so mild that there is little room for improvement. Future studies should continue to test EW's impact on clinical health outcomes to further substantiate illness severity as a moderator and to determine whether there are other moderating illness characteristics.

Features of the Intervention: Differences in Writing Instructions as an Example

The benefits of EW are also shown to vary depending on specific features of the intervention. Although there are many details to consider, here, we cover differences in writing instructions as many studies manipulate this aspect of the intervention; through this example, we hope to demonstrate the complexity inherent to EW and the intricate details that need to be considered when administering it in a therapeutic context.

The majority of studies that have altered the writing instructions have participants write about positive aspects of past traumatic experiences, such as new things that they have come to appreciate more and that they have learned about themselves (e.g., posttraumatic growth), or new friendships that have developed (e.g., "benefit finding" or "meaning making"). Much of this work has yielded beneficial outcomes (e.g., fewer physician visits, lower psychological distress, and depressive symptoms), but it is unclear whether the mere act of writing about something "positive" means that it is personally meaningful to the participant. That is, it could be that simply writing about emotive topics, whether they are positive or otherwise, is what confers the observed health benefits. Moreover, altering the writing instructions to be about something positive may also produce processes that can influence participants' emotions, cognitions, and/or physiology; this makes it difficult to pull apart the influence of the positive instructions versus the intervention itself.

Interim Summary

Overall, individual differences such as personality traits and medical characteristics appear to moderate EW's effects, but findings are (once again) not consistent. It is possible that EW works best for a subgroup of individuals (e.g., those with moderately severe illness, those without supportive social environments). Given the wide range of outcomes and populations in which moderation effects have been observed, much work is needed to determine which personal characteristics influence EW's effects consistently in specific contexts (e.g., past trauma vs. current trauma, chronic physical illness vs. mental health diagnosis vs. no health problems).

Moreover, the manner in which the EW is carried out procedurally may also play a role in its effectiveness. In addition to the example of highly variable writing instructions presented above, there are many other differences in how EW is administered (e.g., timing after [traumatic] event, location where the writing takes place, characteristics of the person administering the intervention, length of follow-up to when health outcomes are assessed) that likely play a role in how effective the intervention is in improving health outcomes. Ongoing and future research and clinical efforts will further develop our understanding of EW and how it may best be used to improve health.

How EW Improves Health: Potential Mechanisms

We still do not fully understand precisely how EW leads to beneficial outcomes, although many potential accounts of mechanisms exist in the literature. There are dozens of potential explanations that have been offered in the literature, and evidence that is broadly consistent with each explanation has been observed. What is considerably more difficult, however, is finding ways to show that a particular mechanism or process is uniquely important, or that EW is targeting some processes but not others.

Given that the initial EW paradigm was centered on writing about a past traumatic experience, many theories about its underlying mechanism(s) stem from various perspectives on stress and coping. One theory that emphasizes integration of cognitive and emotional processes proposed that EW helps convert trauma-related memories into language and facilitates meaning making and processing. Engaging in EW was thought to help create coherent narratives about a prior traumatic experience that would help assimilate the trauma-related memories with other memories, which, in turn, would reduce unwanted reexperiencing of the trauma and physiological arousal associated with trauma-related memories (in other words, facilitate coping), thus, improving health. A related but distinct theory focused more directly on the aspect of trauma exposure. It proposed that EW helps individuals cope with past exposures to traumatic experiences by helping them habituate to them. That is, completing multiple writing sessions about an emotionally distressing or traumatic experience repeatedly exposes participants to their negative thoughts and emotions associated with that experience, allowing negative emotions associated with that experience (and, perhaps, associated thoughts, physiology, and behaviors as well) to dissipate over time.

Other theoretical models for how EW improve health have been centered on aspects of the writing itself, specifically, in the act of translating emotional experiences into words. For example, one perspective proposed that translating deeply personal thoughts and emotions related to a specific experience would increase people's self-awareness. Self-awareness, in turn, could then improve people's ability to regulate or stabilize their cognitive, behavioral, and especially affective responses to emotionally charged situations. Another model purported that translating abstract thoughts and emotions into written words with a linguistic structure allows individuals to better understand their past experiences in a way that could help them integrate those experiences into their understanding of the world and of themselves. Related explanations suggested that translating experiences into written language could help individuals build a narrative framework for their trauma over the course of the writing. Such a narrative framework would lead to insights and help redefine and reconceptualize traumas in a more coherent manner that allow for "letting go" of past negative experiences.

There are clearly many other explanations as well, some drawn more directly from clinical literatures addressing therapeutic approaches (e.g., cognitive behavioral-based approaches, self-regulation), and yet others that rely on more specific mediational pathways (e.g., affect labeling and neural encoding, sleep processes). Although beyond the capacity of this brief summary to review them all, this brief and selective summary is meant to demonstrate that there are numerous theoretical models for the plausible mechanisms of how EW may lead to positive health outcomes. It is also worth noting that these models are difficult to tease apart as many share a common basis (e.g., cognitive and emotional processes, translating experiences or thoughts into words). As such, evidence offered in support of one mechanism or pathway (e.g., changes in emotional responding over time) is consistent with several (even most) theoretical explanations. Finally, although there is often a desire to identify a single (parsimonious) mechanism that can explain an intervention's effects, it is likely that EW operates by activating multiple pathways. There may be a cumulative benefit through the engagement of multiple mechanisms of change (e.g., self-regulation and cognitive integration) and/or with EW producing benefits via different mechanisms for individuals in different contexts (see Smyth & Pennebaker, 2008).

Future Directions

There are certainly many remaining research questions about EW. Perhaps most notably and as is likely clear from this review, further work is needed to better understand the circumstances under which EW will be helpful. How can we be sure to get EW to the right people, in the right context, at the right time, and in the right way to optimally promote positive health and well-being?

Given the considerable variability in writing instructions and intervention parameters (e.g., length and number of sessions, timing of follow-up), it is absolutely essential that all published research studies systematically and comprehensively report methods and analytic strategies. This would allow for more accurate evaluation of whether (and how) procedural variations in EW interventions that exist between studies (e.g., location of writing, contact with and characteristics of research staff, etc.) may influence the efficacy of EW as an intervention. Future research may also consider testing EW in combination and in comparison with other more laborious, time-intensive, and costly interventions, determining the added value and relative efficacy of EW in clinical settings (see Cummings, Hayes, Saint, & Park, 2014, for review).

Future mechanisms research might consider adopting a pluralistic approach that assesses multiple mechanisms. This would allow examining important questions—for instance, moderated mediation: does EW lead to health benefits via different pathways among some individuals or contexts versus others (e.g., men vs. women, different types of trauma, healthy persons and patients)? Similarly, there may be unique combinations of processes that lead to positive outcomes or dynamic feedback systems that unfold over time (perhaps even over different timeframes). These are all tremendously important and exciting areas for future EW research.

Summary

Expressive writing (EW) allows individuals to freely disclose their personal thoughts and emotions about a strongly emotional experience (typically, but not always, one that is stressful or traumatic); this is usually done in a private, "safe" environment that removes the risk of negative or socially stigmatizing feedback. Researchers have used EW to facilitate positive health outcomes in college students, healthy community residents (sometimes with particular challenges, such as unemployment), and patients with medical illnesses (e.g., asthma, PTSD, and cancer, among others).

In general, existing empirical evidence suggests that EW produces modest but fairly reliable, physical, and psychological health benefits. There is also, however, evidence that EW is more or less effective in some contexts and is more beneficial for some people than others. A challenge for future research is to systematically test moderating factors that may help optimize EW's benefits. Although the underlying processes by which EW confers its health benefits are not yet fully clear, multiple theoretical models provide a basis for testing plausible mechanisms, some of which may act simultaneously or sequentially. EW thus remains an area of theoretical and clinical interest, and further examination of its potential as an adjuvant treatment in medical and therapeutic settings is warranted.

Failed Control of Health Behavior

Melissa V. Auerbach and Marci Lobel

Department of Psychology, Stony Brook University, Stony Brook, NY, USA

Addiction Risk

Health behaviors provide a potent context for examining self-control failure, as many health-relevant behaviors, including food consumption, sleep, substance use, and sexual behaviors, affect critical outcomes such as physical health, longevity, and even survival. Cigarette smoking is a particularly common topic when studying self-control failure. Millions of Americans try to quit each year, yet a large majority of these attempts fail within the first month (Dube, Asman, Malarcher, & Carabollo, 2009). These high rates of failed smoking cessation are due not only to the physiological addiction to nicotine but also to the emotionally and behaviorally addictive properties of cigarette smoking. Overconsumption of food and alcohol are also considerable domains of self-control failure, as over time and with repeated failures of self-control, such behaviors may become chronic and evolve into addictions (Bland, Melton, Welle, & Bigham, 2012) especially when a person's motives for these behaviors change or intensify (Hustad, Carey, Carey, & Maisto, 2009). For example, it has been shown that moderate drinkers who consume alcohol for social reasons are at risk for addiction if they start drinking in order to cope with stress.

However, there has been little attention toward understanding why people who are not addicted fail at controlling their health behavior. College students are a particularly important group to examine, as behaviors such as drinking and overeating are considered socially normative in college (Bland et al., 2012) but can become chronic and impair health and well-being. This entry examines behavioral control among nonaddicted people to further our understanding of the origins of addiction risk.

Social Cognitive Theories

Health behavior theories such as the health belief model and the theory of planned behavior are often used to investigate health behavior among nonaddicted individuals. These approaches

are especially valuable in describing the uptake of health-promoting behaviors such as exercise and eating healthfully. Many health behavior theories emphasize goal setting as an instrumental first step in implementing self-control processes (Legault, Gutsell, & Inzlicht, 2011). Cybernetics is an approach that has been used to model self-control processes in humans, reducing control to three components: goal setting, behavioral monitoring, and behavior implementation. For example, according to cybernetic principles of self-control, dieters first set a specific goal for the kinds of food they want to eat. Next, they monitor their eating behavior for instances when it is discrepant from their goals. If any discrepancies are detected, they change their behavior (e.g., "Put down the chips and grab the broccoli!"; Legault et al., 2011). Goal setting creates a discrepancy between what one wants to do and what one is currently doing, and this discrepancy is what sets self-control in motion.

Health behavior theories generally do not explain the adoption of health-impairing behaviors such as smoking or binge drinking. Furthermore, by focusing on future outcomes of health behavior, prevailing theories tend to underestimate the role of the present moment as a factor that influences behavior (Darlow & Lobel, 2012; de Ridder & de Witt, 2006). Healthy intentions can be overruled by acute reactions to challenging situations. For example, even for individuals who regularly exercise and eat healthfully, vulnerability during periods of stress may lead them to succumb to vices such as unhealthy snacking. Furthermore, because most people are involved in multiple goal pursuits and engaged in many roles concurrently, they often need to divide their resources. Focusing on health behavior in isolation is a limited approach, as other life responsibilities compete for time, energy, effort, and other resources. Therefore, it is important to take into account the influence of situational factors (e.g., stress and fatigue) involved in the immediate context when examining control of health behavior.

Self-Control Theories

Self-control theories are applicable when considering the influence of situational factors involved with health-impairing behavior. For example, studies show that self-control is influenced by previous attempts at self-control, by mood, and by working memory capacity. Therefore, health behavior can be compromised when other contextual factors, such as stress and fatigue, impede efforts at self-control.

A widely accepted perspective on self-control is that it can be characterized by two systems of behavior (e.g., Dvorak & Simons, 2009). One system involves control over goal-oriented behaviors, such as eating nutritiously or abstaining from smoking to promote good health. This control of goal-oriented behavior tends to focus on long-term outcomes such as improvements in health. The second system involves appetitive or hedonistic behaviors that serve more immediate and contextually related goals, often to alleviate stress, improve mood, or derive pleasure (Vohs & Heatherton, 2000). This immediate system includes responses to temptations and cravings, such as consuming highly palatable and easily available foods (de Ridder & de Witt, 2006). Dual-process theories tend to separate cognitive and emotional processes: the immediate system is more emotionally reactive to context (e.g., smoking a cigarette in response to distress), and the goal-oriented one is more cognitively effortful (e.g., exercising to promote longevity). Therefore, according to this perspective, when people experience self-control failure, they are unable to override dominant, hedonistic response tendencies despite their desire to regulate behavior or maintain health goals.

The "hot/cool system" theory (Metcalfe & Mischel, 1999) is one relevant example of a dual-process theory of self-control. This theory suggests that the "hot system" pertains to resisting temptation or impulses. The "cool system" pertains to acting on planned and premeditated actions. The cool system relies on long-term executive function resources, such as reasoning and strategizing, and is therefore considered a cognitively based system, whereas the hot system is emotionally based as it deals with immediate reactions to the context. This theory suggests that the cool system functions less when individuals are confronted with impulses requiring immediate control and that the hot system is used to pursue short-term, immediate goals (de Ridder & de Witt, 2006).

Strack and Deutsch (2004) suggested a similar dual-process theory of self-control. One mode, termed "effortful," tends to rely heavily on information processing and regulatory control. The other mode, termed "impulsive," is reactive and responds to emotional situations. Dual-process approaches thus suggest that when individuals struggle with self-control, they experience conflict between competing behavioral tendencies, one being more emotionally reactive (e.g., smoking a cigarette during a time of stress) and the other being more cognitively effortful and goal oriented (e.g., smoking cessation).

Objectives

Below we extend existing theories of self-control to examine why people fail at controlling their health behavior. *We define failed control of health behavior as compromising distal health goals for more proximal, immediately rewarding outcomes.* We theorize that failed behavioral control is composed of cognitive and emotional factors that are unique and somewhat independent of one another but also interrelated. First, we expand upon the role of the immediate context involved in contemporary theories of self-control failure. Recent self-control theories explain that failure to act in accordance with one's long-term goals is the result of emotional impulses taking precedence over cognitive, effortful considerations (de Witt Huberts, Evers, & de Ridder, 2014). Although emotionally reactive impulses are often a leading predictor of failed behavioral control, we posit that people may sometimes abandon their long-term goals by employing cognitive strategies that invoke the present moment (e.g., "The future is uncertain. Eat dessert first."). We will thus explore cognitive strategies involved with immediate fulfillment that have received little attention in prior work. Second, we aim to integrate cognitive and emotional factors that have previously been underemphasized in research on failed health behavioral control. Further research is needed to understand how these two systems (emotional and cognitive) operate together, particularly to understand failed control of health behavior.

Cognitive Factors that Lead to Immediate Fulfillment

Dual-process theories posit that emotionally driven and/or impulsive factors are the primary explanation for why people opt for an immediate reward rather than adhering to their long-term goals. However, we argue that the dual-process approach is limited, as both the emotional and cognitive systems may both be independently involved with immediate reward fulfillment. We posit that there are two unique cognitive systems involved with health behavioral control: one that is effortful and aimed at providing attentional awareness toward long-term health goals, as discussed in existing dual-process theories, and a second that is less well studied according to the dual-process perspective, which consists of moment-salient behaviors that tend to involve less effort or deliberation than goal-oriented cognition. Below we discuss cognitively driven moment-salient behavior.

Theory of Discounting

The theory of discounting (Rachlin, Raineri, & Cross, 1991) is one cognitive approach that suggests people may perceive the moment as more important than the future, which is distant and uncertain. The more an individual discounts the future, the more likely they will be to choose a short-term option over a long-term one (Rachlin et al., 1991). Therefore, this theory helps to explain why the moment may be prioritized over long-term health goals. Stritzke, Breiner, Curtin, and Lang (2004) found that smokers tend to hold conflicting beliefs: they believe it is foolish to risk their health by continuing to smoke, yet they also believe life is uncertain so they might as well enjoy the moment. This study indicated that some people believe that it is highly uncertain that they will collect a long-term reward, so they might as well choose the more immediate reward. Thus, people may temporarily suspend their long-term goals when faced with certain contextual demands.

Automatic Decisions

Quick and automatic decisions may also compel someone to abandon their long-term goals and to adhere to the moment. It is unlikely that all the choices people make necessitate the active involvement of the self. Many choices that are made, especially those that are quick and effortless, may not be deliberate. For example, skipping breakfast in the morning is considered to be an unhealthful behavior as it increases one's appetite throughout the day, deregulates glucose levels, and often leads to subsequent overeating and weight gain. However, the behavioral effects of skipping breakfast are often overlooked by individuals, especially young adults. Although automatic behaviors such as skipping breakfast are typically easy and effortless, the impact of such behaviors can jeopardize long-term health goals.

Habits are another pertinent aspect of automatized behaviors. In general, people tend to behave in routinized, repetitive, and mindless ways (Langer & Moldoveanu, 2000), which may lead to the development of poor health habits. Unconscious habits, or mindless behaviors repeated over and over, may lead one to rely heavily on established patterns (Langer & Moldoveanu, 2000). For example, it has been shown that many smokers who relapse are not experiencing negative affect but are smoking outside of their awareness (e.g., Tiffany, 1990). Poor health habits are also likely to persist if one is unaware of the long-term costs associated with these behaviors. For example, research indicates that heavy drinkers do not pay attention to the "warning signs" of previous alcohol consequences, such as poor judgment or alcohol-related accidents, and do not adjust their drinking patterns to avoid them further (Hustad et al., 2009). Such poor health habits can thus be outside of awareness and may be antithetical toward health goals.

Integrating Cognitive and Emotional Perspectives

Dual-process approaches suggest that the cognitive, effortful system is invoked less when individuals are confronted with impulses requiring immediate control and that the emotionally reactive system is used to deal with short-term, immediate goals (de Ridder & de Witt, 2006). Thus, these theories separate cognitive and emotional processes. However, this distinction is a limitation because there is considerable evidence that cognitive and emotional processes work in concert to influence behavior (Dvorak & Simons, 2009). According to contemporary theorists, emotion and cognition are fully integrated and without clear demarcation in the human brain (e.g., Inzlicht, Bartholow, & Hirsh, 2015). Individuals confronted with an emotional impulse may experience two simultaneously occurring cognitive processes: a declined functioning of the goal-oriented cognitive system and a cognitive appraisal process. Cognitive appraisals help determine emotional responses, and the full experience of emotion typically includes thought and action impulses (Lazarus, 1982). Thus, health behavioral control is likely to elicit simultaneous occurrence of emotional and cognitive processes.

Cravings and Temptations

Momentary cravings and desires can trigger both emotional and cognitive processes involved with failed control. Cravings, or intense desires for a particular substance, are highly salient psychological phenomena that influence behaviors like snacking and lead to weakened self-control. Individuals with a goal to lose weight may at first be cognitively effortful as they inhibit their cravings for fatty snacks. However, after multiple occurrences of controlled and healthful eating, this inhibitory system may eventually break down either due to an overpowering stressor or due to cognitive overload. Cravings can be so powerful that they may temporarily alter attitudes or perceptions toward a substance. In one study (Sayette & Hufford, 1997), cigarette smokers assigned to a "high urge" condition abstained from cigarettes for a few hours; "low urge" participants had recently smoked a cigarette. Then all were instructed to list as many positive characteristics of smoking as they could within 90 s, followed by a 90-s period in which they listed negative characteristics. More positive items were generated by high urge smokers than by low urge smokers. Thus, cravings can influence attitudes toward a desired substance, at least in the short term. Selective accessing of positive information related to an unhealthful behavior such as cigarette use may increase the likelihood of that behavior (Sayette & Hufford, 1997).

Environmental cues may also integrate cognitive and emotional processing in ways that lead to failed control. Temptations toward unhealthful behavior are ubiquitous in modern society and include frequent exposure to environmental cues such as fast food advertising. Such temptations, particularly if they are continuous, can undermine attempts to refrain from unhealthful behavior such as overeating. When people are in a "hot" visceral or emotional state, the presence of temptation directs their cognition toward an impulsive action. Yet people are often unaware that the stimuli in their environment may be spontaneously activating these cognitive processes that determine their behavior. Additionally, the restraint involved in day-to-day temptations one experiences can deplete self-control. Other environmental cues, including the observed actions of companions or outright social influence by them, can trigger failure in controlling one's health behavior in the current moment and also undermine long-term goals such as weight loss, physical fitness, and low cholesterol because these often require consistent adherence across time.

Intrapersonal Resources

Mental fatigue is another powerful contributor to failed self-control that has been found to be associated with cognitive processes. Mental fatigue refers to feelings that people may experience during or after prolonged periods of cognitive activity. These feelings are very common in everyday modern life and generally involve tiredness or even exhaustion, an aversion to continuing with the present activity, and a decrease in the level of commitment to the task at hand. Although considered to be a negative affective state, mental fatigue is often discrepant with an overarching goal and may be regulated by engaging with sources of immediate gratification. One of the more influential theories to come from research on fatigue is the limited strength model, which suggests that all of the resources available for self-control are in a single domain (Vohs & Heatherton, 2000). In other words, the resources required for behavior like attentional control are the same as those that are used for unhealthful behavior like overeating. This model posits that self-regulatory strength is a finite, renewable resource that is drained when people attempt to regulate their emotions, thoughts, or behaviors. For example, stressful situations can be depleting and lead individuals to poorly regulate during subsequent attempts of self-control. Thus, the emotional and cognitive processes driven by fatigue are highly integrated as they pool from the same domain-general source.

Similar to fatigue, stress has shown to be an emotionally potent factor in failed behavioral control that can exhaust an individual's personal resources. Situational factors like stress may make individuals more responsive to cognitive appraisal and less responsive to goal-oriented processes. In particular, acute stress due to an emotionally demanding event may diminish the importance of long-term goals while increasing the salience of the immediate context. This process can explain why acute stress often leads to relapses of smoking and drinking as well as to diet breaking (Baumeister, Heatherton, & Tice, 1994). Baumeister et al. (1994) suggested that affectively charged moments focus attention on immediate stimuli, decreasing the resources needed to attend to higher-level goals. In other words, it may be difficult for people to be aware of their goal-oriented behavior when emotionally charged situations demand a focus on immediate stimuli.

Although some instances of self-control failure are emotionally driven and not cognitive or deliberate, there are also instances of stress-related failed control that involve deliberate decisions influenced by cognitive appraisal. For example, if a man is on a diet and makes a conscious decision to eat an unhealthy dessert everyday by thinking he "deserves" it for all the stress he has endured, this reasoning indicates that his appraisal processes may have overpowered his long-term diet goals. Similarly, if a woman with the goal of reducing alcohol consumption has successfully regulated her alcohol intake for a week, she might "reward" herself by having a drink. Therefore, certain cognitive appraisal processes may lead individuals to fail at self-control by justifying a break from healthy goal pursuits.

Threatening emotional states can also produce a bias toward short-term thinking. This bias may be considered adaptive, as responding to the present context is sometimes more important for immediate survival than its long-term, accumulated consequences. Research on emotion-focused coping offers insight as to why people may prioritize substances that help ameliorate the immediate context. Alcohol is thought to serve as a form of immediate self-medication, reducing negative emotional states for some individuals. Similarly, cigarette smokers often cite anxiety reduction as a primary reason for smoking, and escape from negative affect has been found to be an essential motive for drug use.

Similarly, improving a negative mood may also be triggered by a cognitive appraisal process that makes contextual demands particularly salient. Negative mood signals a need for action, often leading one to search for strategies that will improve the mood or one's environment. Although unhealthful, mood-improving behavior tends to be motivated by an emotionally impulsive system, it also may occur due to a conscious choice to suspend one's long-term health goals. Unlike bouts of quick intense emotion, negative moods can last for several hours or days.

A continuous, persisting negative mood can also lead to negative social and work-related consequences, as it impairs emotional inhibition and concentration. Therefore, unhealthful behavior may be a deliberate solution to relieve a persistent negative state. Research on "negative state relief" and tension reduction illustrates that people are more willing to participate in risky unhealthy behavior when attempting to ameliorate or avoid experiencing negative mood.

The perceived duration of one's mood can also determine whether or not to engage in unhealthful behavior. Tice, Bratslavsky, and Baumeister (2001) found that after inducing a negative mood, those who believed their mood was modifiable engaged in impulsive behaviors such as eating fattening snacks. However, when participants believed that their affective state was more permanent or long-lasting, the desire for impulsive behaviors diminished. Thus, people's perceptions of the duration of their negative moods can determine whether or not they should indulge in immediate forms of gratification to make themselves feel better.

Conclusion

There is growing interest in self-control failure as a risk factor for addictive behaviors such as alcohol abuse and overeating in individuals who are not currently addicted. Over time and with repeated failures of self-control, unhealthful behavior may become chronic and evolve into addiction. Self-control failure has previously been theorized as a dual-process phenomenon in which cognitive and emotional processes are separate. However, these theories are simplistic and have been poorly integrated. Considerable evidence suggests that emotional and cognitive processes are mutually causative and work in concert with social and situational factors to influence behavior. Together with the cognitive, emotional, and social processes that enable or inhibit self-control, a variety of relevant psychological factors including momentary cravings, mental fatigue, and stress also help to explain why people fail at controlling their health behavior.

Melissa V. Auerbach, MA, is a doctoral candidate in social and health psychology at Stony Brook University. Her research has focused on psychosocial aspects of health behaviors among a variety of populations, including college students and pregnant women. A recent study demonstrated the conceptual and empirical value of differentiating health-promoting and health-impairing behavior in pregnant women. An ongoing project will test the model of failed self-control that is articulated in this entry.

Marci Lobel, PhD, is professor of psychology and director of the Doctoral Program in Social and Health Psychology at Stony Brook University. Her research investigates social psychological factors such as stress, coping, and perceived control that influence physical health and well-being. She is currently conducting studies of the health effects of discrimination experienced by pregnant women of color and the ways that women cope with discrimination and other types of stress during pregnancy.
