The Geography of Health

Arseny A. Ryazanov[1], Kirstie K. Russell[2], and
Nicholas J. S. Christenfeld[1]

Many factors contribute to, or subtract from, human health and longevity, from before conception to the moments before death, from what one eats and breathes, to what sports one enjoys, and what one drives and how one drives it. One factor that has received considerable attention is geography. Where you live predicts where, when, and why you die.

While there are myriad of ways that geography can be linked to health, they can be usefully, if roughly, divided into two broad categories. The first is that geographical location can be a proxy for differences in demographics, based on current and historical immigration patterns. That is, certain kinds of people, prone to particular sorts of ailments, are concentrated in particular geographic regions. We refer to this as an indirect geographical factor. The other is that geographical features have an impact on the health of residents. Living in a certain place can change the occupations, exposures, and habits of residents. We term this a direct geographical factor.

This distinction between geography as demography, through attracting different sorts of people, and geography impacting people after they live in a particular place is not as simple as the latter being an argument for geography being causal and the former being just a marker. It is instead that the relationship between region and health can differ. For example, a sunny region might attract retired people, who could be more likely to die from heart attacks and less likely to die from choking on a Lego brick. It would not be sun exposure per se that protects one from the dangers of toy asphyxiation. Nonetheless, making an area sunnier (we do not take a stand here on anthropogenic climate change, but just offer this as a hypothetical) could reduce that cause of death for its occupants over time. The causal pathway in this case would be changing immigration patterns. On the other hand, adding bike lanes to urban streets could lower heart attack mortality, with a causal impact on the cardiovascular health of current residents.

Both mechanisms clearly have public health implications, though those implications do differ in an important way. Promoting the health of residents is a central civic function. Attracting

healthy residents can also be useful locally, even if it does not make any overall difference at a larger scale because people are no healthier on the whole, just differently distributed. In the same way, attracting wealthy people to a particular state can enhance that state's tax revenues, even though that gain comes with a parallel loss in revenue to the state from which those people moved.

Causal Geography

Distinguishing between geography's influence on who lives in a particular place and how it changes those who live there is not a simple matter. It is certainly possible, for example, that a factor could have both effects. Adding bicycle lanes to a city could attract more fit bicyclists to that city and also make the people who live there more likely to become fit bicyclists. To further complicate matters, cities that add bicycle lanes might tend to be those whose residents are already keen on bicycling and so vote and lobby for such lanes. In this case, cardiovascular health would cause the change in geography.

There are several ways that geographic factors can be potent predictors of health outcomes without being causally involved. One is that geographic factors can be just markers. Cities with more bicycle thefts, for example, may be the ones with greater cardiovascular health of their residents. This would likely be just a reflection of the greater number of bicycles in use, and not a sign that encouraging thieves, perhaps by providing free bolt cutters, would be a useful public health program. Likewise, factors that may have been historically causal may no longer be so. Regional differences in climate or amenities that influenced ethnic migration patterns that are reflected in demography even today may no longer have any causal role, as, for example, those influenced by much immigration of a certain period passing through Ellis Island.

One way to increase confidence in a factor playing a causal role in health, short of experimental manipulation, is to show that its effect persists when controlling for the likely confounding variables. In this way, for example, one might explore whether caffeine intake still predicted negative health outcomes when controlling for smoking—which covaries with coffee drinking and is itself clearly causal. However, this approach carries a conceptual risk of controlling not just for confounds but also for possible mediators of the effect. In this case, one would potentially wrongly conclude that the variable of interest was not causal and was just a marker. To stick with our bicycle lane example, one might be interested in exploring heart disease risks of populations in cities with and without bicycle lanes. At the start of the study, concerned that cities could differ in other ways, one might statistically control for differences in reported diet and non-bicycle exercise habits. Should the association between health and bicycles lanes vanish in such an analysis, one could conclude that healthy populations like bicycle lanes, but that they are not causal, and so adding them would not enhance the population's health. However, it could be that the bicycle lanes are causally important and that their effect is through the impact they have on people's orientation toward diet and exercise. That is, bicycle lanes might encourage people to eat more healthily and generally to exercise more.

If one is interested in how resources should be allocated, questions of causality are not essential. It may also not be critical if the causal factor is not one over which one has control—such as the number of hours of daylight during the winter months or the suitability of the terrain for skiing. However, in designing interventions of controllable factors to promote public health, understanding and establishing the causal pathway becomes critical.

Indirect Geographical Factors: Regional Demographic Differences in Health

In reviewing some of the research on regional demography and health, we will confine ourselves to domestic findings, though clearly there are enormous differences between countries on important outcomes, from infant mortality to life expectancy. It is useful, when exploring the question of geography's connection to health, to consider how regions in the United States differ in terms of their demographic makeup. Demographic makeup of a population consists of several factors including age structure, race, and ethnicity. The following serve as examples of how the three are associated with varying health outcomes.

Disability and Age

Increased lifespans put larger demands on public health services, particularly in terms of chronic illnesses, injuries, and disabilities. As the US and world populations age, health problems shift to these focuses. Global trends aside, regions in which the population has a higher concentration of elderly people exhibit more age-related health problems than regions with younger populations. In Utah, for example, 32% of the population is between the age of 0 and 18, and 11% is over the age of 65. In Florida, on the other hand, an attractive destination for retirees, only 22% of the population is between 0 and 18, and 17% is over the age of 65 (Kaiser Family Foundation, 2013). Consistent with the demographic differences, Florida has a higher rate of disability than Utah (Erickson, Lee, & von Schrader, 2014a, 2014b). Thus, variation in age structure between regions can contribute to age-related health disparities.

Sickle Cell Disease and African Americans

African Americans of sub-Saharan descent are particularly vulnerable to a genetic condition known as sickle cell disease: 1 out of every 500 African Americans is born with the condition (Centers for Disease Control and Prevention [CDC], 2015). This disorder can result in cerebrovascular disease, cognitive impairment, and even death in affected children. African Americans represent larger portions of the population in the southeast United States (CDC, 2015), and this region reports larger estimated populations of individuals affected by the condition than other areas. Concentrations of demographic groups with genetic predispositions to particular diseases can thus contribute to regional health disparities as well.

Liver Cancer and Asians

Asian Americans are almost three times more likely to develop liver cancer than Caucasians (Lin, Chang, & So, 2007). While liver cancer is not a particularly common cause of mortality in the United States in general, it is the second leading cause of mortality among Asian American men (Lin et al., 2007). Asian Americans are most heavily concentrated in the American West, in states such as California and Hawaii. Consistent with the demographic distribution, these regions experience elevated liver cancer mortality. As with the regional differences in sickle cell disease, the combination of Asian American men's predisposition to liver cancer and their geographic concentration leads to varied health outcomes between regions.

Tay–Sachs and Ashkenazi Jews

Tay–Sachs disease, a genetic lipid storage disorder caused by the lack of a vital enzyme, causes children to lose motor skills and mental functions. Although children afflicted by Tay–Sachs disease usually appear healthy at birth, by about 6 months of age, they generally start to show signs of slowed development. This genetic disease is most common among individuals of Eastern European Jewish (Ashkenazi) descent (National Human Genome Research Institute [NHGRI] 2011). Other Jewish groups and non-Jewish groups are a hundred times less likely to be afflicted by this disease. While 1 in 27 Jews is a carrier of the Tay–Sachs gene, only 1 in 250 people in the general population is a carrier. Since both parents must be carriers for the offspring to be affected, the 10-fold carrier rate produces a 100-fold incidence rate. Therefore, regions such as New York City, where many Ashkenazi Jews reside, exhibit elevated occurrence of the disease. Other demographic groups that show similarly elevated rates of Tay–Sachs include a French Canadian population living near the Saint Lawrence River and a Cajun community in Louisiana (NHGRI, 2011). Once more, concentration of at-risk populations in a particular geographic area, such as New York, can create regional health disparities.

Asthma and Puerto Ricans

A disproportionate number of Hispanic children are affected by asthma, a disease that affects the lungs, often manifesting itself in repeated episodes of breathlessness, coughing, and wheezing (CDC, 2015). A 1996 study of East Coast families found that 25% of Hispanic families had at least one asthmatic child, while this was true for 18% of non-Hispanic Black families and only 10% of non-Hispanic White families (Beckett, Belanger, Gent, Holford, & Leaderer, 1996). Two-thirds of the Hispanic children with asthma are Puerto Rican: Puerto Rican children are more vulnerable to developing asthma than any other ethnic or racial group in the United States. As a result, regions with large Puerto Rican populations show elevated asthma rates. New York City, which contains the largest concentration of Puerto Ricans in the mainland United States, had an asthma mortality rate three times the national rate from 1981 to 1985 (Weiss & Wagener, 1990). Part of this geographic concentration may be attributed to the susceptibility of the Puerto Rican population to asthma.

Suicide and American Indians

Suicide rates between 2005 and 2009 were highest among American Indian/Alaskan Native males (25.96 suicides per 100,000) compared with other racial and ethnic groups and women (CDC, 2015). In 2013, Montana and Alaska had the highest state suicide rates of 23.9 and 23.3 per 100,000, respectively (Drapeau & McIntosh, 2015). Montana and Alaska have notable American Indian and Alaska Native populations, respectively. The highest rate of suicide in Montana is among American Indians (27.2 per 100,000; Rosston, 2012). The average annual rate of suicide among Alaska Native people during 2003–2008 was double the rate for Alaska non-Native peoples. These American Indian and Alaskan Native populations thus influence overall regional suicide rates.

Direct Physical Geographical Factors

The particulars of a region's geography certainly influence the patterns of immigration, from proximity to Ellis Island for various waves of European immigration and proximity to the

Pacific for waves of Asian immigration, to familiarity of terrain for Scandinavian immigrants, to proximity to steep trails for immigration of the young and athletic. Geography can also have an impact on health patterns more directly by altering the behavior and exposure of people once they are there. We will offer various examples of such effects.

Latitude

Seasonal affective disorder (SAD) is a pattern of depressive or bipolar episodes. Winter SAD has been found to correlate with latitude, occurring more often at higher latitudes in North America. However, the relationship between latitude and SAD appears much stronger in North America than in Europe, suggesting that social context and genetic factors may moderate this effect (Mersch, Middendorp, Bouhuys, Beersma, & van den Hoofdakker, 1999). Warm regions can have other health concerns: regions of the United States such as parts of Arizona and Texas have increasingly become home to Africanized honey bees, which results in an increased risk of people experiencing systemic anaphylaxis from bee stings, as these bees are more aggressive than non-Africanized bees. Weather itself can have acute implications for public health as well: heat waves increase heat-related mortality, and increased temperature has been found to correlate with increased all-cause mortality as well (Stafoggia et al., 2006).

Natural Disasters

Natural disasters can influence health immediately and dramatically, and they can also impact outcomes beyond the immediate effects of the disaster. Experiencing an earthquake in the first trimester is associated with shorter gestation in pregnant women. Increases in communicable diseases follow in the wake of natural disasters such as a tsunamis or earthquakes. A review of posttraumatic stress disorder following natural (and other) disasters found substantial evidence for resulting posttraumatic stress disorder (Neria, Nandi, & Galea, 2008). Certain areas are more prone to natural disasters than others—earthquakes, of course, are not randomly distributed across the country, but follow known fault lines, especially those on the West Coast. As a result, natural disasters can contribute to differing health outcomes between regions, even long after their immediate effects.

Occupation

Regional differences in the distribution of natural resources produce occupational differences, which in turn can result in regional differences in health. Coal mining, concentrated in states such as West Virginia, causes lung diseases such as pneumoconiosis and chronic obstructive pulmonary disease. Community exposure to mining in coal-mining areas has likewise been found to relate to worse health outcomes such as higher rates of cardiopulmonary disease, chronic obstructive pulmonary disease, and lung cancer. As a result, regional differences in occupation can have a significant impact on community health.

Direct Cultural Geographical Factors

Regional differences in culture also comprise geographical determinants of health. Such differences may be produced originally by topography, natural resources, farming potential, and the like, but are no longer so directly linked to the physical environment. Coal mining, for example, continues in West Virginia not so much because they have a culture that values fossil fuel extraction, or because early immigrants were predisposed to that activity—though both of those may also be true—but because that is where the coal is. However, for the sorts of cases discussed below, the persistence of regional differences seems instead to depend on continuing regional cultural differences. Examples of cultural regional variation include differences in diet, activities, stress, income, and community structure.

Diet

Dietary differences between regions can impact health outcomes. The southeastern United States leads the country in risk of stroke and hospitalizations for congestive heart failure. In fact, the disproportionate stroke mortality in this part of the country has led it to be dubbed the "stroke belt." The high prevalence of stroke in this region is partially attributable to dietary differences. Judd et al. (2013) found a direct relationship between consuming a traditional Southern-style diet and increased risk of stroke. This diet of fried foods, high-fat foods, and sugar-sweetened drinks partially mediated racial differences in stroke risk in this region as well (Judd et al., 2013). Unhealthy diets, which are differentially distributed across the United States, thus contribute to health disparities between regions.

Pastimes

Gambling is bounded by legislation to specific regions of the United States. Both visitors to and residents of gaming communities such as Las Vegas and Atlantic City exhibit abnormally high suicide levels. Elevated suicide levels for not only visitors but residents as well suggest that the increased prevalence of suicide is not the simply result of gambling attracting suicidal persons. Further research has confirmed regional effects for low suicide areas as well: being a visitor to or resident of an area with low suicide risk was associated with a decreased suicide rate (Shrira & Christenfeld, 2010). Firearm use, another activity that is differentially legislated by region, was found to correlate with suicide level as well, suggesting that these differences may in part be explained by availability of means to commit suicide (Shrira & Christenfeld, 2010). Activities characteristic of particular communities thus contribute to health outcomes such as suicide levels.

Stress

Stressors and stress levels vary geographically as well. Stressors can have acute, immediate effects on health or chronic effects, which manifest only as a result of cumulative exposure to the stressor. Residents of New York City appear to experience both acute and chronic stressors. Residents of New York City who die there do so 55% more often than the general population does from ischemic heart disease. People just visiting the city show a 34% increase in the proportion of mortality due to ischemic heart disease. New York City residents who die outside the city show an ischemic heart disease proportion that is only 80% of that shown by residents in the city (Christenfeld, Glynn, Phillips, & Shrira, 1999). This pattern of results suggests that exposure to New York City increases heart attack risk, and the visitor findings indicate that some of that risk is chronic and some acute. That is, just being in the city at the moment confers some risk, and having been in the city for some time adds to that risk. Geographical differences in stressors thus contribute to disparities in health outcomes between regions.

Income

Income varies not just by family but also by neighborhood, state, and country. It correlates with outcomes such as infant mortality: infants born into poverty have a 1.5 times higher risk of neonatal and postneonatal mortality, likely due to differential access to healthcare (Gortmaker, 1979). Indicators of low socioeconomic status have also been associated with birthweight, gestational age, and preterm delivery. As a result, regions experience differential infant mortality outcomes that are associated with varying income levels: one analysis found that infant mortality in any particular census tract (a subdivision of a county) in Ohio correlated with the percentage of low-income families that lived in the tract (Stockwell, Goza, & Balistreri, 2005). Exposure to stress may mediate some of income's effects on infant mortality. Among low-income women, chronic psychosocial stress is associated with low birthweight. Likewise, depression during pregnancy, which is twice as common among poor urban women than it is in middle-class women, is associated with preterm delivery and low birthweight.

Longevity, or life expectancy, also correlates with income. Poor Americans live an average of 5 years less than the most affluent Americans. Some argue that income inequality in its own right contributes to mortality as well, separate from the effects of absolute level of wealth (Kennedy, Kawachi, & Prothrow-Stith, 1996). States with less equal wealth distributions, such as Louisiana and Mississippi, were found to have greater all-cause mortality than states such as Vermont and New Hampshire, and wealth distribution across all 50 states correlated with all-cause mortality (Kennedy et al., 1996). Although findings on income inequality relating to health have been mixed, there seems to be a modest effect of inequality. Income, and perhaps even level of income disparity within a community, can contribute to regional differences in health outcomes.

Community Structure

Whether people live in an urban or rural setting can also influence longevity. Premature mortality, as measured in years of life lost before reaching 75, was found to be greatest in rural counties, particularly in the Southeast and Southwest (Mansfield, Wilson, Kobrinski, & Mitchell, 1999). Metropolitan and urban counties, by comparison, had lower premature mortality when using this metric (Mansfield et al., 1999). The gap between urban and rural life expectancies has widened over the past 40 years, largely due to increases in life expectancies in urban areas (Singh & Siahpush, 2014). Community structure itself can thus influence health outcomes.

Public Policy and the Geographical Influences of Health

Exploring the geography of health can have a variety of public health implications. Just as the cause of cholera was revealed by an analysis of the distribution of the disease along the Thames, regional differences in illness can provide information about its etiology. Furthermore, understanding the link between geography and health can help in determining where resources are needed or will be needed in the future. Beyond understanding or predicting disease, it can lead to interventions that do prevent illness. For example, the creation of walkable green spaces increases the longevity of urban seniors. Physically active lifestyles are associated with a variety of cardiorespiratory benefits. Policies intended to encourage active transport such as biking and walking lead to healthier populations: the creation of bike lanes and separating cycling from other traffic are associated with increased cycling.

Public health can be improved not only by altering the physical environment to promote exercise but also with alterations to culturally based food habits. Areas that lack access to supermarkets and healthy food, termed food deserts, result in poor diets and the health problems that relate to poor diet such as diabetes and coronary heart disease. These areas are generally low income and either urban or remote. Retail development by supermarket chains working in conjunction with the city council in one such British neighborhood improved diet-related outcomes, albeit modestly, suggesting that policy that develops supermarkets in such neighborhoods may be an effective intervention (Wrigley, Warm, & Margetts, 2003).

Policies aimed at regulating the quality of the environment also have an effect on public health. The establishment of air quality-control policies in the Los Angeles basin, an area with a problematic combination of high volume of automobiles, large seaport, and natural landscape that contains the resulting air pollution, caused long-term reductions in airborne pollution, which improved lung function growth in children living in this region (Gauderman et al., 2015). These policies included emission control as well as fuel reformulations (Gauderman et al., 2015).

Understanding both how regions differ in demography and how they have a direct effect on the health of their inhabitants serves a useful function in informing public health policy. When deciding how health services should be distributed regionally, demographic differences may be enough to inform effective policy. However, the identification of controllable factors that are regionally caused, rather than their being the result of demographic distributions, can lead to a more effective use of public health resources in addressing certain public health concerns more generally. While it is useful to dispatch more cardiovascular health services to the Southeast to combat the high stroke rate, identifying the dietary cultural contributions to stroke risk can spur the development of dietary interventions to reduce the disproportionate need for cardiovascular health services over time. This is not possible for uncontrollable regional factors; we cannot diminish or more equally distribute the fault lines across the United States.

Geography is not necessarily static—there is an emergent field of study on the potential impacts of climate change on regional differences in health, as temperature, agriculture, water supplies, pollution levels, and the like are redistributed geographically. For example, the distribution of vector-borne diseases, such as malaria, could change in response to rising temperatures and affect new populations. As climate change progresses, there will be an increased need for understanding, predicting, and responding to its shifting effects on population health.

Simultaneously, the expanding understanding of the genetic factors involved in various diseases will also increase the potential for the discovery of new geographic disparities in specific diseases. Identifying new vulnerabilities among demographic groups will inform how to best distribute services relating to the vulnerability across the country and where environmental interventions may be most effective.

We are not entirely dependent on medical breakthroughs to improve a population's health: while researchers continue to work toward medical treatments for obesity, for example, we can begin to address geography-level causes of the condition, such as by restructuring the built environment to decrease commute times. We will certainly continue to have new and effective medical treatments for those suffering from poor health, but we can also limit the number of people who need to resort to treatment by better understanding how geography contributes to their condition in the first place.

Author Biographies

Arseny A. Ryazanov is a doctoral student in the psychology program at the University of California, San Diego. He studies multiple aspects of social psychology—how locus of control relates to treatment of others, what encourages prosocial behavior, and whether we can predict incremental change in group preferences over time.

Kirstie K. Russell, a masters of public health candidate at the Dalla Lana School of Public Health at the University of Toronto, is interested in the social and ecological determinants of health.

Nicholas J.S. Christenfeld, a psychology professor at the University of California, San Diego, has investigated a broad array of only partially overlapping topics, including the role of stress in health and interventions that can reduce the severity and duration of its impact, and psychological factors in mortality, from imitative physician-assisted suicide to the cardiac perils of living in New York City.

"Healthy habits" are a frequent topic of conversation in everyday life. People want to "get into the habit" of exercise or healthy eating or "break bad habits" like smoking or drinking too much alcohol. These frequent references to habit tacitly acknowledge that good habits are difficult to form and bad habits difficult to stop. Psychological research indicates that habits have a strong "automatic" or "implicit" component. That is, individuals tend to perform habits with relatively little conscious thought or effort. The propensity for actions to be controlled automatically is an extremely adaptive human function, as it means that mundane actions can be carried out with little cognitive effort, which "frees up" cognitive "space" for processing higher-order goals and actions. Health behaviors that are habitual are, therefore, regulated and enacted in an efficient and effective manner. However, the same system can automate behaviors that are detrimental to health, making them difficult to change. Health psychologists are interested in studying habit to understand the processes that lead to habit formation and perhaps develop means to change habits by promoting healthy habits and breaking unhealthy ones.

Formally, habit is defined as "a process by which a stimulus automatically generates an impulse towards action, based on learned stimulus-response associations" (Gardner, 2015, p. 4). In contradiction to the colloquial use of the term, habit is not a behavior, but rather a psychological or cognitive determinant of behavior. Habit formation is the process by which regulation of health behavior shifts from being under conscious, deliberative control to being regulated largely by nonconscious, automatic processes (Gardner, 2015; Sheeran, Gollwitzer, & Bargh, 2013; Wood & Neal, 2009). When a person frequently and consistently enacts a health behavior in the context of a behaviorally relevant cue or—so as to form a strong mental association

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.

between the cue and behavior—a habit is formed. Research has demonstrated that the strength of people's habits is a strong influence on their health-related behaviors and this effect is independent of conscious regulation such as goal setting, planning, or intentions (Conroy, Maher, Elavsky, Hyde, & Doerksen, 2008; Gardner, de Bruijn, & Lally, 2011). Exciting advancements in the study of health-related habits demonstrate strategies that people may use to break unhealthy habits and the potential for targeting habit formation as a strategy for promoting maintainable healthy behaviors (e.g., Lally & Gardner, 2013; Webb, Sheeran, & Luszczynska, 2009).

Theory, Habits, and Health Behavior

Consideration for the role of habits in the study of health behaviors has been a relatively recent advancement, and as a result, most studies have incorporated a measure of habit[1] as a separate correlate of health behavior alongside psychological factors from conventional social cognitive theories of behavior change (Biddle, Hagger, Chatzisarantis, & Lippke, 2007). This research has been further advanced through the application of dual-process theories, which contend that behavior is a function of both nonconscious (e.g., habit) and conscious processes (e.g., goals, deliberation, attitudes, and values; Strack & Deutsch, 2004 #1742; Hagger, 2016 #8248). For example, Rothman, Sheeran, and Wood (2009) present a model for understanding which conscious and nonconscious processes are important for adoption versus maintenance of health-related behaviors and outline how habits likely play a key role in the maintenance of health-related behaviors. Similarly, Rhodes and de Bruijn propose habit as a key factor involved in the control of actions in health contexts (i.e., translating intentions into action; Rhodes & de Bruijn, 2013).

The common theme of dual-process models is that health behaviors can be predominantly controlled by either reflective consideration of the action (e.g., weighing up the advantages, disadvantages, consequences, and barriers with respect to the behavior) or impulsive processes that lead to automatic behavioral enactment. The influences from both types of regulatory systems are supported by evidence from neuroscience that shows that activity in the fronto-parietal and cingulo-opercular networks is associated with deliberative actions, whereas activity in subcortical areas of the mesolimbic reward system such as the nucleus accumbens is associated with habitual behaviors (Rebar, Loftus, & Hagger, 2015).

Given that habitual behaviors are rapid, efficient, and free of conscious control and occur beyond an individual's awareness, they tend to be the "dominant" response when individuals are presented with cues that initiate their action (Gardner, 2015; Verplanken & Aarts, 1999). For an individual to change or break a habit, therefore, they must consciously monitor their environment for the habit-triggering cue and, on its presentation, actively inhibit the automatic behavioral response. Without sufficient deliberative control over cues and associated automatic responses, referred to as self-regulation, the dominant response is likely to pervade in situations where the cue is presented. Even when individuals identify health goals and form plans to achieve these goals, habits may compete with these, and, given that the habitual pathways to action tend to predominate, they may lead to failure to carry out the good intentions.

Research on Habits and Health Behaviors

Research has demonstrated that habit is associated with a number of health-related behaviors (e.g., Gardner et al., 2011; Hyde, Elavsky, Doerksen, & Conroy, 2012; Webb et al., 2009).

Research has also examined the factors that determine whether health behavior is likely to be under habitual control or controlled by more deliberative, conscious processes. For example, an increasing body of evidence is demonstrating that intentions to engage in physical activity or eating healthily are better predictors of behavior for people if habits of these behaviors are weaker (Gardner et al., 2011; Rhodes & de Bruijn, 2013), and more recent evidence suggests this could be a time-dependent process in that people act on their habits unless they make particularly strong intentions to engage in a counter-habitual behavior on a certain day (Rebar, Elavsky, Maher, Doerksen, & Conroy, 2014). Furthermore, research has shown that individuals find it difficult to accurately recall habitual actions because such actions do not depend on awareness or conscious control (Hyde et al., 2012).

Research is also beginning to provide insight into the process by which habits form. For example, research has shown that habit formation requires more than mere repetition of the behavior (Hagger, Rebar, Mullan, Lipp, & Chatzisarantis, 2015; Lally & Gardner, 2013) and that the habit formation process is different for each person, but typically occurs quickly at first and gradually slows when a person nearly reaches full habit development (Lally & Gardner, 2013). Factors that have been shown to determine the formation of habits are planning and behavior enactment, strong cue–behavior implicit associations, or increasing the intrinsic value of the behavior by providing incentives or rewards (Lally & Gardner, 2013).

In addition, research is starting to emerge on how the formation of habits can be targeted within interventions aimed at promoting healthy habits (Gardner, Lally, & Wardle, 2012; Lally & Gardner, 2013). Habits form through repetition of behavior in a specific context, so the habitual response becomes strongly associated with a triggering cue, making the habitual response the strong default and alternative behavioral choices less salient (Wood & Neal, 2009). Simple intervention strategies to promote frequent and consistent performance of the desired habitual behavior in the context of an accessible cue (e.g., in the same manner, at the same time of day or part of a daily routine, in the same place) through a list of tips, messages via emails and SMS, or face-to-face training have shown not only to enhance health behavior but also to make the behavior more habitual. Additionally, incorporating "boosters" following intervention completion focused on action planning, self-efficacy, and satisfaction behavioral outcomes may serve to maintain intervention effects on habit.

Promotion of a healthy lifestyle often requires a combination of forming stronger healthy behavior habits (e.g., healthy eating, physical activity, medication adherence) and breaking habits for unhealthy behaviors (e.g., smoking, snack eating, sedentary behavior). Research has demonstrated that effective breaking of "bad" habits requires goal setting, cue monitoring, and effortful self-regulation (Lally & Gardner, 2013). Such efforts can be quite taxing, and engaging in effortful control over habits may be counterproductive, as it may lead to cognitive fatigue and reduced capacity for self-control, leaving people susceptible to temptations that cue up unwanted habitual responses (Hagger & Chatzisarantis, 2014). An option for reducing habitual unhealthy behaviors may be to avoid or minimize accessibility or presence of triggering cues by, for example, moving locations or to weaken the mental cue–response association through training techniques such as evaluative conditioning (Allom, Mullan, & Hagger, 2016).

Future Directions for Research on Habits and Health-Related Behavior

A number of priorities for future research on habits in the context of health-related behavior have been identified. Researchers are beginning to differentiate between habitual instigation (i.e., the initiation of a behavior) and execution (i.e., the movement through the sequence of the behaviors) (Gardner, Phillips, & Judah, 2016). A proposed model is that in early stages of taking up a new behavior, behavioral initiation is predominantly controlled by more deliberative, reflective processes in which an individual weighs up the benefits and detriments of the behavior in a given context and makes decisions on whether or not to act accordingly. This process becomes more "automated" or habitual over time with repeated decisions to engage in behavior raising the possibility of links being made between the behavior and the decision-making process and external or internal cues. However, while behavioral initiation may become more automated, more complex processes involved in executing the behavior may not become automatic as they require elaborate planning and deliberation. Such distinctions may provide a comprehensive framework for promoting complex health-related behaviors that involve more than a single act (e.g., physical activity, eating, sedentary behavior).

Another avenue of research, that is, essential for advancing theory of health-related habit is to understand how the influence of habit compares to and interacts with that of other nonconscious regulatory processes such as automatic evaluations (e.g., implicit attitudes) or primed motivation (Conroy et al., 2008; Hagger, 2016; Sheeran et al., 2013). Most research on health-related habit has been studied alongside consciously controlled psychological constructs, but this largely downplays and likely simplifies the impact that other nonconscious processes have on health behaviors. Researchers should consider merging what have, to this point, been largely separate avenues of research on habit and these other nonconscious regulatory processes that are not reliant on learning.

Finally, the role of implicitly presented cues in developing habitual responses should be explored. Research examining the potential for environmental contingencies, structural changes, and means to prompt behaviors (e.g., posters and advertisements) to promote healthy behavior, often beyond an individual's conscious awareness, has shown promise (Hagger, 2016). However, the research on the mechanisms and processes by which these contingencies affect behavior and assist in the development of habits is relatively sparse. Future research should explore the longevity of such prompts in promoting lasting behavior change and whether these develop into habits.

Conclusion

A health behavior is considered habitual if it is predominantly determined by "automatic" or "nonconscious" processes. Habitual behaviors tend to be developed over time through repetition and reward or reinforcement by external or internal contingencies or reinforcing agents. Habits may be represented schematically in memory and activated by the presentation of cues or prompts in the environment with which enactment of the habituated behavior is associated. As links between prompts and habitual behaviors tend to be very strong, changing habitual behaviors that are detrimental to health is challenging. However, the strong links also present an opportunity for interventionists as they provide a means to develop healthy habits and lasting behavior change. Research on habits has provided insight into the processes by which habits impact health behavior and an evidence base on which to develop interventions to break or change habits. Breaking bad habits requires effortful, goal-directed behavior, and self-regulatory skills such as goal setting and cue monitoring have been shown to be effective strategies to break health behaviors. Future research should seek to examine the role of priming interventions, implicit constructs, and the distinction between initiation and execution of health behavior to provide further insight into the processes that lead to health behavior.

Author Biographies

Martin S. Hagger is John Curtin Distinguished Professor in the School of Psychology and Speech Pathology at Curtin University, Australia. His research applies social cognitive and motivational theories to understand and to intervene and change diverse health behaviors such as physical activity, healthy eating, smoking cessation, alcohol reduction, and medication adherence. He is also at the forefront of theory development and has contributed to the advancement of social psychological theory including theory integration and self-control.

Amanda L. Rebar is senior lecturer in the Centre for Physical Activity Studies in the School of Health, Medical and Applied Sciences at Central Queensland University, Australia. Her research interests include physical activity motivation—specifically automatic regulation of physical activity (e.g., habits, automatic evaluations) and the mental health benefits of physical activity. She is also interested in structural equation modeling, hierarchical linear modeling, and the open-source data analysis program, R.

Note

1 It is important to note the use of terminology in this context. Habits as a plural term, or preceded by the definite article ("a habit" or "the habit"), refer to the concept of automated, impulse-driven responses. Habit in singular usually refers to a measure or construct of habit in an analysis or theory.

Health Behavior Change

Paul T. Fuglestad, Jody S. Nicholson,
and Lauren James

Department of Psychology, University of North Florida, Jacksonville, FL, USA

Most modern diseases and causes of death have substantial contributing factors that are behavioral. The Center for Disease Control and Prevention estimates that premature death and unnecessary healthcare costs can be greatly ameliorated by enacting behavioral changes. For decades, researchers across disciplines in the social and health sciences have sought to create theories of health behavior that can be used to encourage healthy change and inform intervention design and implementation. Although these theories and approaches to intervention share underlying similarities, they vary widely in terms of their behavioral foci, focal constructs, and processes and stages of change. For example, Michie, West, Campbell, Brown, and Gainforth (2014), in attempting to catalog all behavior change theories relevant to interventions, identified over 80 theories with more than 1,000 constructs. Furthermore, health behaviors are numerous and varied, including diet, physical activity, alcohol use, tobacco use, vaccinations, medication adherence, sexual behavior, toxin exposure, and screenings. Fortunately, many theories are applied to numerous health behavior domains, and there is substantial overlap in mechanisms of change among the most widely used health behavior theories (Sheeran et al., 2016; Sheeran, Klein, & Rothman, 2017). This entry begins by reviewing numerous influential theories and approaches that have been used to understand and influence health behavior change and concludes with a discussion of challenges to health behavior change and promising new directions.

Although health behavior theories can be categorized in many different ways (e.g., Do they focus on intentional/explicit processes or implicit/habitual processes? Do they emphasize cognitions regarding a threat or cognitions regarding a specific behavior?), a useful distinction can be made between continuum and stage-based models (Rothman, Baldwin, Hertel, & Fuglestad, 2011). Continuum models explain change as a steady process, whereas stage-based theories assume change is nonlinear and consists of steps.

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

Continuum models specify a set of target variables that are thought to always predict behavior regardless of individual differences or situations, and a person's behavior is thought to be a function of his/her standing on these specified variables. For example, a continuum model such as the *health belief model* might attribute changes in smoking cessation to incremental changes in the perception of susceptibility to a health threat (e.g., cancer) and barriers or benefits to quitting (e.g., quitting will reduce the likelihood of lung cancer). On the other hand, stage theories propose that people move sequentially through various stages in changing their health behavior and different variables are thought to be important for certain stages, but not others. For example, programming based on a stage-based model like the *transtheoretical model* would focus on different change variables for someone who is not planning to quit (*precontemplation* stage) and someone who is actively quitting (*action* stage). Using this model, a program might focus on *consciousness raising* to increase knowledge for someone in the *precontemplation* stage while using *stimulus control* to break association cues that illicit smoking behavior for those in the *action* stage of quitting.

Continuum Models

Health Belief Model and Protection Motivation Theory

The first major health behavior theory was the health belief model developed by Irvin Rosenstock and colleagues in the 1950s. This model attempts to specify when people will take action against some health threat, such as getting a vaccination to prevent an illness, using a condom to prevent STDs, or wearing sunscreen to prevent skin cancer. It specifies that people will be more likely to take action if they perceive that they are vulnerable to a threat (i.e., *perceived susceptibility*), that the threat would have negative consequences (i.e., *perceived severity*), and that the benefits of action outweigh the costs or barriers.

Similar to the health belief model, the protection motivation theory, developed by Ronald Rogers, proposes that taking action to change a health behavior is dependent on constructs such as perceived susceptibility, severity, and whether the recommended behavior actually prevents the threat. It was largely developed in the context of using fear appeals to encourage people to engage in protective action against health threats. Building on stress and coping research, the protection motivation theory focuses on the cognitive processes of *threat appraisal* and *coping appraisal* that feed into one's protection motivation. One's emotional response to a potential threat (i.e., *fear*) was added to the threat appraisal process to go along with perceptions of susceptibility and severity. Similarly, one's confidence to enact a particular behavior (i.e., *self-efficacy*) was added to the coping appraisal process to go along with perceptions of benefits and barriers. In a meta-analysis of the protection motivation theory, Milne, Sheeran, and Orbell (2000) found that variables related to threat appraisal (e.g., susceptibility, severity, fear) and coping appraisal (e.g., self-efficacy, response benefits and costs) were predictive of intentions and behavior. The impacts of threat and coping appraisals on health-related intentions and behavior were small to medium in effect size and generally less predictive of subsequent rather than concurrent behaviors. Small to medium effect sizes were also evident in a meta-analysis of the influence of experimentally manipulated perceptions of how likely one was to get an illness (i.e., perceived susceptibility) and how bad it would be to get it (i.e., perceived severity) on people's intentions and behaviors (Sheeran, Harris, & Epton, 2014).

Theory of Reasoned Action/Planned Behavior and the Prototype Willingness Model

Another widely used set of health behavior theories are the theory of reasoned action and the theory of planned behavior developed by Martin Fishbein and Icek Ajzen. In the theory of reasoned action, behavioral *intention* (e.g., one's intention to eat more fruits and vegetables) is posited to be the most proximal predictor of health behavior and is predicted by an individual's *attitudes* and *subjective norms.* Attitudes about the behavior are based on one's expectation of behavioral outcomes and the value of those outcomes (e.g., eating more fruits and vegetables will have positive effects on health). Subjective norms regarding the behavior are based on one's perceptions of norms regarding a behavior and whether one is motivated to comply with those norms (e.g., important others think it is a good idea to eat more fruits and vegetables). In recognition that some behaviors are less volitional or controllable, the theory of planned behavior adds a construct very similar to self-efficacy, *perceived behavioral control*, which is based on how easy/hard it would be to engage in the behavior (e.g. eating more fruits and vegetables is something that can easily be done).

Sheeran et al. (2016) summarized 18 meta-analyses that examined the associations of attitudes, norms, and self-efficacy with health-related intentions and behaviors (e.g. condom use, physical activity, smoking cessation, alcohol use, and screening behaviors). Averaged across the meta-analyses, these constructs were all moderately to strongly associated with behavioral intentions and actual behavior. Sheeran et al. (2016) also conducted a meta-analysis to examine the experimental impact of these constructs. To be included in the meta-analysis, an intervention had to experimentally manipulate attitudes, norms, or self-efficacy related to a health behavior. Importantly, all of these constructs were related to intentions and behavior. Although the effect sizes were somewhat smaller than those reported in meta-analyses of correlational studies discussed above, the effect sizes were generally in the medium range, suggesting that these common constructs are indeed important for promoting health behavior change.

Building on the theory of planned behavior, the prototype willingness model was developed by Meg Gerrard and Frederick Gibbons to more fully understand non-intentional but volitional behaviors (e.g., risky sexual or substance use behaviors). It adds the variable of *social prototypes* that measures one's perception of the prototypical person who engages in a behavior (e.g., someone who engages in unsafe sexual practices), including one's similarity to the prototype and/or one's overall evaluation of this prototypical person. Social prototypes are thought to primarily influence another additional construct—*behavioral willingness*—which is one's willingness to engage in a risky/unhealthy behavior under certain circumstances (e.g., an attractive partner wants to have sex without a condom). Evidence suggests that these constructs are important for predicting behavior when one is engaging in less thoughtful, more heuristic-based cognition (Gerrard, Gibbons, Houlihan, Stock, & Pomery, 2008).

Social Cognitive Theory

Social cognitive theory, developed by Albert Bandura, is a continuum model that explains how humans develop, learn, and maintain certain behaviors and is often described in relationship to a model of self-efficacy. Bandura defined self-efficacy as one's belief in one's ability to succeed in specific situations and viewed people as more self-regulatory than reactive to their environment. For example, how people perceive their situations can inform their decisions to behave in certain ways that can lead to an eventual change in their environments. Therefore, people's behavior can be predicted by knowing the beliefs they have about their own capabilities and environments. People's self-efficacy beliefs are thought to be dependent on four main sources of influence: (a) coaching and feedback (i.e., *social persuasion*), (b) observational learning and modeling (i.e., *vicarious experience*), (c) efficaciousness when agitated or depressed (i.e., *emotional/physiological states*), and (d) prior success with a task (i.e., *personal mastery experiences*). Beyond self-efficacy, behavior is also posited to depend on one's perceptions of environmental constraints that facilitate or prevent behavior (i.e., *barriers to change*), as well as one's attitude toward the behavior and beliefs in the likelihood that good or bad things will occur as a result of performing the behavior (i.e., *outcome expectations and evaluations*). As noted above, meta-analysis suggests that self-efficacy and attitudes toward the behavior are causally linked to health behavior change (Sheeran et al., 2016).

Stage Models

Transtheoretical Model

In contrast to continuum models of health behavior change, the transtheoretical model, developed by James Prochaska and Carlo DiClemente, is a popular stage model that conceptualizes the process of intentional behavior change. The model proposes that people move through five stages of change: (a) no intention to change behavior in the near future (i.e., *precontemplation*), (b) thinking about changing but have not decided (i.e., *contemplation*), (c) deciding to change behavior but have not successfully done so (i.e., *preparation*), (d) successfully changed behavior (i.e., *action*), and (e) preventing relapse (i.e., *maintenance*). The model posits that different barriers—which are referred to as processes of change or behavioral strategies—affect movement through the various stages. Early on (precontemplation and contemplation stages), behavioral strategies such as increasing knowledge (i.e., *consciousness raising*) and increasing concern regarding unhealthy behaviors (i.e., *dramatic relief*) matter most. Later (action phase), processes such as providing rewards for positive behaviors (i.e., *contingency management*), helping relationships (i.e., *social support*), and avoiding or removing cues to unhealthy behavior and adding cues to health behavior (i.e., *stimulus control*) matter most. The transtheoretical model incorporates elements of self-efficacy by taking into account the degree of confidence the individual has in their ability to maintain their desired behavioral change. This model can be helpful in determining the most appropriate interventions in health behavior change suited for the individual's current stage. As compared with the other models, it recognizes that there are individual differences that might make an intervention ineffective for some participants if they are not ready to engage in health behavior change. Meta-analyses and systematic reviews of the transtheoretical model suggest that it is effective in modeling health behavior change (e.g., Norcross, Krebs, & Prochaska, 2011). However, like most stage theories, there is mixed evidence with respect to its effectiveness relative to continuum models, the number and sequence of stages, the process by which people move from one stage to the next, and applicability across various health behavior domains (e.g. Armitage, 2009; Riemsma et al., 2003). For example, in a review of the transtheoretical model literature, Armitage (2009) suggests that a two-phase model incorporating motivational and volitional processes better conceptualizes the behavior change process than the five stages of the transtheoretical model.

Precaution Adoption Process Model

The precaution adoption process model, developed by Neil Weinstein and Peter Sandman, provides a framework to describe the particular sequence of change in which an individual might engage. The model focuses on an individual's mental state that impacts why they decide to initiate action and how that decision translates into behavior. Individuals progress through seven stages that range from being unaware of an issue (stage 1) or unengaged by an issue (stage 2), to acting upon an issue (stage 6) and maintaining the intent to act (stage 7). At stage 3, undecided about acting, an individual can proceed to either deciding to act (stage 5) and proceed along the stages, or decide not to act (stage 4), in which case there is no continued advancement along the stages and the individual is considered in a state of moratorium. In general, the precaution adoption process model differs from the transtheoretical model in that it is more focused on the mental state of each stage and less focused on time until an intended action. In the precaution adoption process model, individuals may regress back in stages, and it is critical to not assume equal spacing between stages. Some individuals may be in one stage for such a brief period; it seems they skipped it altogether. For example, a doctor's advice may move an individual from unengaged (stage 2) to acting (stage 6). Moreover, the difficulty of the action of interest may impact the utility of this model, as behavior change that is easy (e.g., changing toothpastes, wearing seatbelts) may make the stages matter less, making it possible to combine stages with a more comprehensive treatment.

Although the precaution adoption process model has not been tested as widely as the transtheoretical model or health action process approach (HAPA) (see below), its utility has been demonstrated in work on radon testing, osteoporosis prevention, and dietary change (Weinstein, Sandman, & Blalock, 2008). For example, in encouraging undecided people to commit to radon testing (moving from stages 3 to 5), an intervention demonstrating high risk was more effective than an intervention demonstrating the ease of testing. Conversely, in encouraging decided people to act (moving from stages 5 to 6), the ease of testing intervention was more effective than the risk intervention. Future research, however, should focus on providing a more comprehensive understanding of why an individual would transition between stages.

Health Action Process Approach

The HAPA, developed by Ralf Schwarzer, is a stage theory of health behavior change that proposes that individuals pass through varying mindsets on their way to behavior change and therefore interventions that tailor to these changing mindsets will be most effective. In this manner, the adoption, initiation, and maintenance of health behaviors should be conceived of as a structured process, including a *motivation* phase and a *volition* phase, with changing perceptions of specific types of self-efficacy throughout.

Similar to continuum models discussed above, constructs such as risk perceptions, outcome expectations (i.e., attitudes), and task self-efficacy are thought to predict the formation of goals and intentions, an important aspect of the motivational phase. In contrast, the volitional phase is impacted by self-monitoring behaviors and awareness of standards (i.e., *planning, action control*) and confidence in maintaining behavior change (i.e., *maintenance self-efficacy*) and responding to behavioral lapses (i.e., *recovery/coping self-efficacy*). The volitional phase is further differentiated between people that have translated their intent to action and those that have not (i.e., the *inactive stage*). Individuals in the inactive stage are motivated to change but do not act because they lack the skills and internal or external resources to translate intention to action. Therefore, planning becomes an important part of the process of change, and post-intentional planning becomes a mediator between intent and action. Planning can further be divided into *action planning* and *coping planning*. Action planning involves the initiation of health behaviors, whereas coping planning is required for initiation and maintenance. According to the model, perceived self-efficacy is required throughout the process of behavior change. However, the challenges that individuals face change during the process, and therefore the type of self-efficacy required also changes. For example, changing diet and physical activity indicates the need for action efficacy early on (the confidence to make difficult changes) but maintenance or recovery efficacy later in the process (the confidence to resist temptation and respond to lapses).

In general, research is supportive of the HAPA model (e.g., Schwarzer, 2008), although certain tenets are not always supported (e.g., Barg et al., 2012; Sutton, 2008). For example, in a study of the determinants of physical activity intentions and behaviors, action self-efficacy predicted behavioral intentions, whereas maintenance self-efficacy predicted planning and behavior; however, contrary to the model, planning did not predict behavior (Barg et al., 2012). Some have argued that the HAPA model is best thought of as a continuum model that builds on prior models like social cognitive theory and the theory of planned behavior by elucidating the intention to behavior link (Sutton, 2008).

Are Stage Models More Effective Than Continuum Models?

Although there is evidence for stage-based models as discussed above, meta-analyses of smoking cessation interventions and diet and physical activity interventions suggest that continuum and stage-based models do not differ in terms of effectiveness (e.g. Prestwich, Whittington, Dombrowski, Rogers, & Michie, 2014; Riemsma et al., 2003). Interestingly, Riemsma et al. (2003) also found that studies explicitly referencing theory were not reliably more effective than studies that did not explicitly reference theory. Of course, the interventions that did not explicitly use a particular theory may have targeted theoretically important constructs (e.g., self-efficacy, attitudes toward the behavior, etc.). Furthermore, many of the theory-based interventions did not explicitly link intervention techniques to theory constructs or did not measure the purported theory-based mediating constructs. As discussed by Sheeran et al. (2017), in order to promote health and advance health behavior theory, researchers will need to fully test mechanisms of change to know why an intervention succeeds or fails. Because stage models are inherently more complex and more difficult to use than continuum models, it is necessary to show that their effectiveness goes above and beyond continuum models.

Challenges and Promising New Directions

As pointed out by many health behavior theorists (e.g., Milne et al., 2000; Sheeran et al., 2016), there is extensive overlap in the constructs of health behavior theories even though they are problematically assessed with different measures. For example, the construct of *attitude* in the theory of reasoned action/planned behavior is conceptually very similar to *costs and benefits* in the health belief model or *outcome expectations* in social cognitive theory. Similarly, concepts related to self-efficacy are in the majority of health behavior theories. For example, Sheeran et al. (2016, 2017) identified constructs similar to attitude (i.e., expectations and evaluations of the behavior/outcomes of the behavior) and self-efficacy in most major health behavior theories. An important goal in health behavior change will be to develop a unified way to classify and measure these constructs of interest (see Michie et al., 2014).

Another future direction for health behavior change will be to elucidate behavior change processes that are less intentional or deliberative. In a meta-analysis of experimental studies by Sheeran et al. (2016), the associations of attitudes, norms, and self-efficacy with behavior remained predictive when controlling for intentions, perhaps indicating that these predictors of behavior change may not be entirely deliberative or controlled. Although few moderators were identified by Sheeran et al. (2016), one finding of interest was that attitudes and self-efficacy were less impactful for frequent versus infrequent behaviors. The authors suggest that these frequent behaviors may be more habitual or automatic. Newer health behavior theories do emphasize habit (e.g., habit theory; Wood & Neal, 2007) and implicit processes (e.g., health goal priming; Papies, 2016). Furthermore, many health behavior theories emphasize the processes that might enhance the associations between intentions and behavior. For example, the HAPA emphasizes action planning and coping planning (Schwarzer, 2008).

An important goal for health behavior theories going forward will be to specify what constructs are most important for what types of behaviors, what kinds of people, and what stage of change. For example, behavioral willingness (versus intention) is a better predictor of risky behaviors, whereas intention (versus willingness) is a better predictor of health protective behaviors (Gerrard et al., 2008). Sequential multiple assignment randomized trial (SMART) designs are becoming increasingly used to build individualized treatments to influence health behaviors. For example, Sherwood et al. (2016) are conducting a SMART intervention that is aimed at testing secondary intervention procedures with initial non-responders in a weight loss study. In this way, more intensive procedures can be utilized with only those that need them, and the most optimal procedures can be identified with respect to timing and content (e.g., introducing portion controlled meals versus introducing self-regulation training). Taking another tack, researchers have had success tailoring intervention messages and strategies to match people's underlying psychological dispositions (Rothman et al., 2016). In this way, interventions can capitalize on people's self-regulatory strengths by encouraging them to pursue goals in ways that fit their natural inclinations.

As discussed above, models of health behavior change are generally effective in promoting initial changes in behavior and generally focus on the processes related to deciding and starting to make a change. However, even people who succeed in making changes in their behavior often fail to maintain those changes (Sarwer, von Sydow Green, Vetter, & Wadden, 2009). Strategies to promote maintenance have begun to emerge, such as continually reinforcing the determinants of initial change (a continued care model), instilling the strategies and skills necessary for maintenance at the outset of intervention, and targeting maintenance-specific predictors once people have had initial success (Rothman, Baldwin, Burns, & Fuglestad, 2016). For example, Rothman et al. (2011) have specified which predictors are most important for initiating change (outcome expectations, self-efficacy) and maintaining change (satisfaction with outcomes, satisfaction with the behaviors). Interventions on smoking cessation and weight loss provide support for these propositions (Rothman et al., 2011). A direct comparison of a continued care treatment with a satisfaction-based maintenance treatment found that both were similarly effective in encouraging behavioral maintenance (Rothman et al., 2016).

Conclusion

Clearly, theory and research have made great progress in affecting positive changes in health behavior. As demonstrated in various meta-analyses, constructs such as self-efficacy, attitudes, threat susceptibility, self-monitoring, and stages of change have been shown to effectively predict and influence healthful changes in behavior (e.g., Norcross et al., 2011; Sheeran et al., 2014, 2016). However, many challenges remain. For example, it is unclear whether continuum or stage-based models are more effective and/or useful in influencing behavior change (Prestwich et al., 2014). It is also unclear as to how to best classify and operationalize health behavior theories and constructs (Michie et al., 2014). Going forward it will be important to conduct direct comparisons of competing theories and to experimentally examine how interventions affect theoretical mechanisms of change and how those mechanisms lead/do not lead to behavior change (Sheeran et al., 2017). Finally, although theories of health behavior change are generally effective in getting people to make initial changes in their behaviors, long-term maintenance of those behavioral changes remains challenging.

Author Biographies

Paul T. Fuglestad is an assistant professor at the University of North Florida. His work applies theory from personality and social psychology to understand and affect health behavior change.

Jody S. Nicholson is a developmental psychologist and an assistant professor at University of North Florida. Her research focuses on parents' role in children's health behavior decisions.

Lauren James is a clinical research coordinator in the Center for Healthcare Delivery Science at Nemours Children's Specialty Care and works to improve health outcomes for children, adolescents, and their families. Through several grant-funded studies, her research involves working on the design, development, and testing of web-delivered resources for youth with type 1 diabetes and their parents.

Health Behavior Interventions

Casey K. Gardiner, Arielle S. Gillman, Courtney J. Stevens, and Angela D. Bryan

Department of Psychology and Neuroscience, University of Colorado Boulder, Boulder, CO, USA

Of the 10 leading causes of death in the United States, 7 are chronic diseases that have associated behavioral risk and protective factors (Johnson, Hayes, Brown, Hoo, & Ethier, 2014). These data suggest that health behavior change interventions have an enormous potential impact in preventing morbidity and premature mortality. However, designing and conducting a successful health behavior intervention is not a simple process; there are myriad methodological, theoretical, and practical factors that warrant consideration when attempting to translate findings from the health psychology/behavioral medicine literature into a feasible intervention that is suitable for use with the general public. While other chapters in this volume address specific health concerns that may warrant interventions or how to evaluate intervention effects, the present entry endeavors to highlight key considerations for and offer suggestions that are broadly relevant to the implementation of health behavior interventions across domains. Our aim is to provide an overview of the important considerations that merit attention before conducting an intervention in order to maximize its impact.

What Is the Nature of the Behavior?

The first step when attempting to design an intervention for improving a specific health outcome is to specify the behavior that is to be increased or decreased. While this may seem intuitively obvious, the lack of explicit specification regarding the target behavior to be modified has led to misguided campaigns for health promotion in the past. For instance, Johnston and Dixon (2008) point out that when researchers first demonstrated the link between tobacco use and lung cancer, a great deal of effort was put into attempting to manufacture a safer cigarette (e.g., adding filters, reducing tar content). Thus, the focus was placed on modifying the lethality of the cigarette rather than on modifying the behavioral action of smoking. Granted, financial incentives may have influenced the push for "safer" cigarettes, but even if it were possible to achieve a safe

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

cigarette, the flaw in this logic is the focus on the outcome (i.e., avoiding cancer) rather on the modification of the behavior (i.e., smoking cigarettes) that engenders that outcome.

Consider the similar focus that is placed on weight loss in the health literature. Surely, weight loss is a desirable outcome for many individuals dealing with obesity and/or with illnesses made more severe as a result of being overweight/obese (e.g., heart disease, arthritis, asthma, etc.). However, *weight loss* is not a behavior that can be performed. Rather, weight loss is an outcome that may (or may not) be achieved via changes in specific daily behavioral routines (e.g., what foods are consumed, amount of time spent engaging in sedentary activities, number of hours slept, etc.). Thus, when designing interventions to promote health, it is imperative that researchers explicitly define what *behavior* is to be targeted (Michie & Johnston, 2004).

Once the behavior in question has been clearly identified, (e.g., time spent walking per day), additional concerns must be addressed regarding the details of when, where, how, and under what conditions a behavior will be carried out (Michie & Johnston, 2004). For instance, researchers need to specify guidelines regarding the duration, pace/intensity, and number of days per week the individual will be asked to walk. Reviews of the literature have found that the answers to these questions are rarely specified adequately in intervention research (Johnston & Dixon, 2008; Michie & Johnston, 2004), and this lack of specificity may contribute to the generally small effect sizes observed in health intervention research.

Numerous aspects of the intervention, including its content and behavioral goals, may vary greatly depending on the nature of the target behavior, given that behavior is a very complex phenomenon that varies across numerous dimensions, for instance, the extent to which a behavior is performed publicly or privately (e.g., blood donation versus cancer screening), the level of effort required to perform the behavior (e.g., teeth flossing versus cardiorespiratory exercise), the frequency with which the behavior ought to occur (e.g., yearly flu shots versus daily fruit and vegetable consumption), how socially acceptable the behavior is (e.g., seat belt use versus acquiring clean needles from a needle exchange program), and whether the behavior in question is to be approached or increased versus avoided or decreased (e.g., increasing sunscreen use versus avoiding alcohol consumption; see McEachan, Lawton, & Conner, 2010).

Without careful consideration of these dimensions that define the behavior in question, researchers may fail to consider the critical factors that prompt (e.g., cues in the environment) and reinforce specific behaviors, or may use the wrong intervention techniques to try to change those behaviors. For example, approach-/avoidance-based interventions that successfully decrease substance use (a behavior that should be decreased) do not appear to be effective in promoting healthy eating behavior (a behavior that should be increased; Becker, Jostmann, Wiers, & Holland, 2015; Gardiner & Bryan, 2015). This is likely due to key differences that characterize the behaviors in question in addition to the increase/decrease dimension, perhaps most notably that eating is necessary for survival and thus may be more resistant to change or may require change by different mechanisms. At best, this type of oversight may result in researchers and health professionals aimlessly embarking upon or recommending interventions that lack theoretical support and/or ignore critical information known to change the behavior in question (Michie & Johnston, 2004). At worst, this oversight may result in burnout, attrition, adverse events, and/or new or worsening health conditions.

Whom Will the Intervention Target?

In addition to selecting a target behavior on which to intervene, it is necessary to identify the target population for the intervention. The first fundamental question to ask is whether the potential intervention participants are available and likely to benefit from a health behavior intervention. Specifically, the targeted individuals should be in need of health behavior change. For example, a student or university employee might wish to conduct an intervention with college student athletes, given that they are an easy population to access and track through the university's athletic department. However, this population might not be the best choice for interventions on the full range health behaviors that would be relevant to the general population. For example, in spite of low levels of physical activity on a national level (e.g., Troiano et al., 2008), it is unlikely that college student athletes would gain much from an intervention designed to increase physical activity. Similarly, while interventions to change eating behavior for the general population may focus on decreasing consumption of unhealthy foods and increasing consumption of healthy foods, this may not be an appropriate behavioral goal for student athletes who may have completely different dietary issues (e.g., eating disorders, adequate caloric and nutrient intake). On the other hand, college athletes may be an ideal target population for behavior change interventions designed to decrease binge drinking or risky sexual behavior. In sum, determining whether a population stands to benefit from a particular behavior change intervention needs to be carefully considered based on experience with the population, epidemiological research, and broader health behavior research.

Once the population and behavior have been jointly identified, it is wise to tailor the intervention design to the population in question. Such tailoring would include selecting intervention delivery mechanisms that are most likely to be suitable for that group, based upon their environment and typical behavior. For example, a dietary intervention delivered at farmers markets (e.g., coupons to enhance access to fruits and vegetables, exposure opportunities designed to improve children's attitudes toward healthy foods) might be quite effective in Vermont, where there are 15 farmers markets per 100,000 residents, but such an intervention could reach a far smaller percentage of the population in Texas, where there are only 0.7 farmers markets per 100,000 residents (Centers for Disease Control and Prevention [CDC], 2013b). The selection of a population and setting can inform other characteristics of the intervention design, perhaps especially if the target population is specialized in some way (e.g., homeless youth, incarcerated individuals, patients with particular physical or mental health conditions). Intervention content can be delivered using a multitude of techniques, including (but not limited to) online formats, text messaging, television advertisements, print materials, and in-person sessions. When selecting and developing an intervention, the interventionist must determine what type of intervention modality might be most feasible and effective given the population target, health behavior(s), setting, and available resources.

How Will the Intervention Change Behavior?

Perhaps the most imperative question when designing an intervention is this: What are the determinants of the health behavior for the population that—when addressed in a successful intervention—will lead to behavior change? In answering this question, the literature is very clear; it is wise to choose a theoretical framework. Research suggests that behavior change interventions grounded in theories are more successful in changing behavior (e.g., Glanz & Bishop, 2010) than those that are not theory based. The literature in social and health psychology offers many possible theoretical foundations for health behavior interventions. One example is the theory of planned behavior (TPB; Ajzen & Madden, 1986), which has been applied to numerous health behaviors across many domains, including substance use, health screening, eating, exercise, sexual health, and oral hygiene (Godin & Kok, 1996). The theory posits that behavior is most proximally predicted by intentions to engage in the behavior. Intentions are in turn predicted by attitudes (positive or negative evaluations) about the behavior, subjective norms (the perceived social forces to perform or not perform the behavior), and perceived behavioral control (beliefs regarding the ease or difficulty of behavior performance). An intervention based upon the TPB could seek to change any or all of those four constructs.

Social cognitive theory (Bandura, 1977) also has applications for health behavior change. This theory suggests that perceived self-efficacy, or the belief that one can successfully complete an action, is a critical determinant of behavior engagement, such that stronger self-efficacy should be associated with increased behavior. The theory also suggests methods for enhancing self-efficacy, including behavior performance (i.e., practice) and modeling, which can be components of health behavior interventions. Research has demonstrated that interventions including behavior practice (e.g., role-playing condom negotiations and applying a condom to a penile model; Bryan, Aiken, & West, 1996) cause increases in self-efficacy.

Self-determination theory (Ryan & Deci, 2000) presents yet another potential framework for health behavior interventions. The theory posits that by meeting innate human needs, such as autonomy, competence, and relatedness, individuals will be more able to self-regulate their behavior in a fashion that supports behavior maintenance (Ryan, Patrick, Deci, & Williams, 2008). Interventions based upon this theory may attempt to enhance feelings of autonomy or build intrinsic motivations to maintain behavior. For example, therapies that support the development of patient competence can enhance autonomous regulation of behavior and perceived competence, which are associated with improved health behavior outcomes (e.g., smoking abstinence, exercise behavior volume; Stevens & Bryan, 2015; Williams et al., 2015).

Beyond these commonly applied theories, there are scores of others, with a recent review noting over 80 extant theories that have been applied to health behavior change (Davis, Campbell, Hildon, Hobbs, & Michie, 2014). These include those that apply broadly to many behaviors, as well as theoretical models that are specific to particular health behaviors. Different theoretical orientations offer different strengths and weaknesses, and an examination of the literature can guide the selection of a theoretical model that may be most appropriate to the target behavior, population, and intervention approach. For example, intervention sessions conducted in person may offer opportunities to enhance self-efficacy through role play or behavior practice, while those delivered online or via print materials require different approaches and may be more successful in targeting other constructs. Overall, the selection of a theory provides a useful framework for understanding the mechanisms by which an intervention can cause behavior change, which can in turn drive the development of intervention content designed to affect each posited mediator, a process sometimes referred to as "intervention mapping" (see Bartholomew, Parcel, Kok, Gottlieb, & Fernandez, 2011).

What Materials Will You Use to Intervene?

After the target behavior, population, and theoretical basis of the intervention are identified, an important next step in selecting an appropriate intervention is to identify whether empirically supported interventions for the target behavior already exist. A great number of successful interventions based on a variety of theoretical perspectives are easily accessible to individuals who wish to implement such an intervention themselves. As such, we recommend that those attempting to conduct an intervention to change behavior do not "reinvent the wheel" and instead save time and resources by implementing an empirically supported health behavior intervention if this is possible.

For example, the Centers for Disease Control and Prevention (CDC) website has a list of empirically supported HIV prevention interventions for sexual risk behavior reduction (CDC, 2013a), where specific interventions can be selected. Based on the behavioral target and population, one might choose the CLEAR (Choosing Life: Empowerment! Action! Results!) intervention (CDC, 2015), which is an individual-level intervention that uses a cognitive behavioral approach to change substance use and risky sexual behavior. As another example, the American College of Sports Medicine (ACSM) releases thorough position stands that provide recommendations for empirically supported intervention techniques for increasing exercise behavior (see Donnelly et al., 2009). These websites and articles often have detailed instructions to help individuals begin implementing these interventions. Each site also provides a set of references that detail the empirical support for the intervention and typically include instructions for implementing the intervention as well as information about any specialized training that might be required.

Literature searches for primary articles in academic databases can also serve as an important resource for finding empirical papers that provide tests of the effectiveness of health behavior interventions for specific behaviors or populations. Review papers or multi-study papers might be especially useful in guiding intervention selection. For example, Kahn et al.'s (2002) review paper discusses the varying success of physical activity interventions implemented at different levels (i.e., individual level, community level) that might aid practitioners and program managers in selecting an appropriate intervention for a given population. As another illustration, Johnson and Goldstein's (2003) article titled "Do Defaults Save Lives?" discusses potential benefits of a "nudge"-style intervention to increase organ donation, an approach that the authors suggest might be particularly effective in controlled settings, such as a school. Research of this type is particularly useful when it provides evidence about approaches that have been effective and those that have been ineffective in catalyzing health behavior change in different settings or with different populations. Additionally, Michie, van Stralen, and West (2011) have begun to develop an exhaustive classification framework for the full range of techniques that can be applied to change behavior, which may provide broader guidance for those developing novel interventions in domains where prior empirically supported interventions are not available.

Once an intervention modality has been selected that is expected to be effective with the target population, tailoring intervention tone and content to the characteristics of the population can lead to better engagement in the intervention and more substantial intervention effects on behavior. For example, in a sample of juvenile justice-involved adolescents, an intervention including techniques that allowed the participants to assert autonomy, control the intervention discussion, and be characterized as "experts" on their own experience (in contrast to their typical role as passive recipients of rules in an authoritarian context) was more successful in changing risky sexual behavior than was a standard psychosocial intervention style that has previously been successful in college students (Bryan, Schmiege, & Broaddus, 2009; Schmiege, Broaddus, Levin, & Bryan, 2009). Cultural and environmental factors relevant to the target population also warrant investigation prior to conducting the intervention, as even the best designed intervention cannot succeed if participants cannot participate in the intervention or engage in the behavior. For example, a psychosocial intervention for physical activity cannot succeed if participants do not have the opportunity to exercise (e.g., working multiple sedentary jobs, lack of access to appropriate facilities), and individuals cannot benefit from the intervention if they are unable to enroll in it (e.g., participants who cannot attend in-person sessions that occur in locations inaccessible via public transportation). Thus, it is wise to develop an understanding of characteristics of the target population, including a thorough needs assessment and collection of qualitative data about the barriers for integrating the particular health behavior at focus into their daily lives, prior to selecting intervention content and delivery methods. Considering the population and the social, micro- and macroenvironment in which their behavior occurs (cf., Egger & Swinburn, 1997) can offer critical insights that may guide intervention design choices.

How Do We Know if the Intervention Is Successful?

Selection of a very specific health behavior, target population, theoretical approach, and intervention modality/content are the primary considerations for conducting a health behavior intervention. However, whether an intervention is conducted in the context of formal research or in order to inform policy makers and stakeholders as they plan for future interventions, it is wise to develop a plan to collect data that will allow for the assessment of intervention efficacy. Such assessments should be incorporated into the intervention design from the start, so that changes in the determinants of behavior, overt behavior itself, and/or health outcomes expected as a result of behavior change can be tracked. Aiken (2011) describes in detail the phases of intervention evaluation that allow for the determination of (a) whether an intervention led to behavior change and (b) which of the theoretical constructs thought to underlie the behavior were the “active ingredients” that led to behavior change. Typically, this approach is facilitated by the careful implementation of the intervention in, ideally, a randomized experiment with a standard of care control or comparison condition (although see West, Cham, & Liu, 2014; West et al., 2008, for alternatives to the randomized controlled trial). The second step involves the use of statistical mediational analysis to determine whether the intervention led to changes in the theoretical mediators of behavior change (e.g., self-efficacy) and whether that change in the mediator was then associated with observed changes in the behavior (cf., Fairchild & MacKinnon, 2009). The advantage of this approach to intervention implementation and analysis is that it allows for the researcher or program planner to determine not just *whether* an intervention was successful but also *why* it was successful and made changes to the intervention based on that knowledge (cf., West & Aiken, 1997). Imagine that an intervention was conducted to increase fruit and vegetable consumption with adolescents. There is existing literature to support the idea that the constructs of the TPB are associated with fruit and vegetable consumption (e.g., Guillaumie, Godin, & Vézina-Im, 2010). Further imagine that a TPB-based intervention was implemented in a randomized experimental trial in which the intervention was compared with a no-treatment control group. The intervention resulted in very small changes in behavior in the intervention group and no change in the control group. Is the answer to throw out the intervention and start over given the small effects? If the investigators had gone the extra step to conduct a mediational analysis, they might find that while the intervention was successful at changing norms and attitudes, it was unsuccessful at changing perceived behavioral control/self-efficacy, a key determinant of fruit and vegetable consumption. This information would tell intervention designers that they need not start over; rather, they need to bolster the intervention content meant to increase self-efficacy for fruit and vegetable consumption.

The importance of valid and reliable measures of both the behavior and the constructs expected to mediate changes in behavior cannot be overstated. Without these measures at both baseline and after the completion of the intervention, in both the experimental intervention and control groups, an analysis of whether and why changes in behavior occurred as a result of the intervention is impossible (West & Aiken, 1997). As the great methodologist and statistician Ronald Fisher said (*ca.* 1938), "To call in the statistician after the experiment is done may be no more than asking him to perform a postmortem examination: he may be able to say what the experiment died of." Thus, attention to research design and measurement prior to the initiation of the project makes all the difference.

In sum, the development, implementation, and evaluation of interventions to change health behavior warrant substantial forethought in order for the intervention to have its best chance of success and for intervention designers to understand why the intervention worked (or did not) and how it might be improved. This preliminary work can be accomplished in the set of steps we have outlined here. Interventionists should first specify the exact behavior they wish to change and address the characteristics of the population and the sociocultural context of their engagement in the behavior, including understanding the best mode of content delivery for that population. Next is the specification of a theoretical basis of the mechanisms of behavior change and the selection and tailoring or development via intervention mapping of a theory-based intervention. Finally, implementing the intervention using adequate measurement and a research design that permits both an outcome analysis (whether an intervention resulted in behavior change) and a mediational analysis (which theoretical constructs were successfully changed by the intervention and led to behavior change) allows for the evolution of ever-more successful behavior change efforts. Notably, these steps need not be followed in the specific order that we set forth. For example, it is possible to seek out an extant intervention for a particular behavior or population before defining a theoretical orientation, but once the theoretical orientation of such an intervention is determined, it is important to measure constructs that are posited to affect behavior within that framework. Nevertheless, it remains important to address each of these concerns. This initial investment of time and effort can provide great dividends, by enhancing the responsiveness of populations to interventions and ultimately in promoting health behavior changes that lead to decreased morbidity and mortality and better quality of life.

Author Biographies

Casey K. Gardiner, PhD, recently completed graduate training at the University of Colorado Boulder, where she was a National Science Foundation Graduate Research Fellow. Her research examined psychological and neurobiological factors that contribute to health behavior change and maintenance, with particular emphasis on healthy eating behavior and incentive interventions. She is now a management consultant in Boston, MA.

Arielle S. Gillman, PhD, recently completed graduate training in social health psychology at the University of Colorado Boulder and is now pursuing her MPH at Johns Hopkins University as part of her postdoctoral research fellowship with the National Cancer Institute at the National Institutes of Health. Her research broadly focuses on understanding factors that drive the uptake and maintenance of healthy behaviors, including self-regulation, motivation, and decision-making processes, in order to eventually apply these findings through theory-based and empirically supported interventions to increase health behavior.

Courtney J. Stevens, PhD, recently completed graduate training at the University of Colorado Boulder, where she was supported by a National Research Service Award (NRSA) predoctoral training fellowship (NIH/NCI F31 CA180483-01; PI: Stevens). She is currently an NIH T-32 postdoctoral fellow at the Dartmouth Centers for Health and Aging.

Her research is focused on affective/experiential determinants of health behaviors and how health behaviors with high transdiagnostic treatment potential (e.g., exercise, mindfulness practice) are adopted and maintained over time and may be used to augment current best-practice treatment models.

Angela D. Bryan, PhD, is a professor in the Department of Psychology and Neuroscience at the University of Colorado Boulder. She has been continually funded by the National Institutes of Health to study health and risk behavior change for the past 18 years. Her work takes a transdisciplinary approach, integrating genomics, physiology, and neuroscience to the study of the psychological processes that underlie behavior change.

Importance of Behavior Maintenance to Health Outcomes

In the United States, and increasingly around the world, chronic diseases have become the most common cause of death. If healthy patterns of behavior are sustained, the onset of some conditions may be prevented or delayed, and the severity of many of these conditions may be reduced (van Dam, Li, Spiegelman, Franco, & Hu, 2008). For example, compared with continuing smokers, the risk of mortality caused by coronary heart disease is reduced by half after 1 year of abstinence from smoking and drops to a level similar to those who have never smoked after 15 years of abstinence (U.S. Department of Health and Human Services, 1990). However, these health gains are reduced or lost if an individual relapses. Although behavior maintenance is important, maintenance is a challenging phase of the behavior change process, and individuals who are able to change their behaviors often have difficulty sustaining these changes over time.

Describing Behavior Maintenance

Regardless of the specific behavior, maintenance requires sustaining a behavior, but some key aspects of behavior maintenance can vary across a number of dimensions including the number, frequency, time interval, regularity, and consistency of the behavior (Rothman, Baldwin, Hertel, & Fuglestad, 2004). At its core, behavior maintenance arises when the results of a cost–benefit analysis of experienced consequences of a behavior lead that behavior to be sustained over time (Rothman, 2000). Yet, what an individual has to do to maintain a behavior over time can vary dramatically. For instance, health behaviors differ in the number of times they need to be repeated. In some domains, a behavior needs to be repeated only a few times,

---

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

whereas in other domains maintenance requires a large number of repetitions. For example, maintenance in the context of human papillomavirus (HPV) vaccination involves attending three vaccination appointments, whereas maintaining a regimen of insulin injections involves administering thousands of shots over time in order to maintain one's health. Health behaviors also differ in how frequently they must be repeated over a given time interval. In the context of breast cancer screening, maintenance may involve getting a mammogram once per year, whereas in the context of kidney disease, dialysis typically involves attending three sessions per week. Health behaviors also differ in the regularity of their timing. Taking a medication is a single behavior that likely occurs at a regular time interval, whereas safe sexual practices, such as condom use, occur on a more variable basis and potentially under differing circumstances. Finally, health behaviors differ in their consistency. Maintaining a healthful pattern of eating likely requires a diverse array of behaviors such as avoiding unhealthy foods, eating and preparing healthy foods, and resisting tempting foods. These behaviors will occur across a variety of contexts and times, whereas regular tooth flossing involves the consistent repetition of the same behavior, often in the same context.

How Is Behavior Maintenance Operationalized in Health Behavior Models?

There are two main categories of health behavior models: process models and stage models (Rothman & Salovey, 2007). Each of these classes of models takes a different approach to operationalizing maintenance and delineating factors that facilitate and inhibit behavior maintenance.

Process Models

In process models, behavior maintenance is operationalized as a continuation of the processes that initiated a given behavior (e.g. theory of planned behavior [Ajzen, 1991]; health belief model [Janz & Becker, 1984]). Process models identify variables that predict a behavior, such as intentions for that behavior, attitude toward the behavior, or past behavior. These variables are then combined into an equation whereby individuals' scores on the predictor variables determine their position a continuum of behavior likelihood. Individuals placed at the lowest end of these continuums are very unlikely to engage in a behavior, whereas individuals at the high end are very likely to engage in the behavior. Importantly, strengthening any one of the predictor variables moves an individual forward on the continuum. For example, having a more positive attitude about a behavior even in the absence of change in intention for that behavior would predict moving forward on the continuum, but strengthening intention and positive attitude would move someone even further along the continuum. Of note, each theory specifies only one prediction equation. Therefore, the model that is hypothesized to predict an initial pattern of behavior is the same as the model that is hypothesized to predict a later, maintained, pattern of behavior.

Stage Models

Stage models assume that behavior change involves movement through a sequence of discrete stages. Individuals categorized as being in the initial stage often lack awareness of the need for behavior change; they then move through a stage in which they prepare to take action, then one in which they initiate a behavior, and the final stage is often labeled behavior maintenance or resolution (e.g. transtheoretical model [TTM; Prochaska & Velicer, 1997]; precaution adoption process model [PAPM; Weinstein, 1988]). Transitions into and out of each stage are specified by a distinct set of rules that assign individuals to a given stage. Individuals move through these stages at different rates and, in some cases, may not always move forward in sequential order. In addition, setbacks can lead an individual to revert back to a previous stage. Because these models specify different prediction models for each stage transition, they offer a framework that can distinguish between factors that predict an initial change in behavior and factors that predict a later, maintained pattern of behavior. Thus, these models have the potential to explain the observation that people are able to change their behavior initially but have difficulty maintaining that behavior over time.

Factors That Influence Behavior Maintenance: A Brief Overview

Many theoretical models of health behavior regard behavior maintenance as self-reinforcing. Implicit in these models is a positive, reinforcing feedback loop in which one's beliefs facilitate the performance of a behavior, which in turn reinforces one's beliefs, which then again reinforce one's behavior. However, this premise is often at variance with the observation that people who are motivated to and able to make changes in their behavior do not always sustain these changes over time. This has led researchers to search for factors that may determine when these self-reinforcing processes succeed and when they fail. Feeling satisfied with a health behavior, perceiving a health behavior as internally motivated, and adopting a prevention-focused self-regulatory style are three factors that have been proposed to support successful maintenance. We consider each of these perspectives, in turn.

The Role of Satisfaction in Maintenance

Rothman (2000) argued that behavior is sustained as long as an individual is satisfied with a given health behavior and that the hypothesized self-reinforcing system fails, in part, when an individual is no longer satisfied with a given health behavior. When faced with the decision to maintain a pattern of behavior, individuals usually know the actions they need to take to maintain their health. Therefore, when grappling with maintaining a pattern of behavior, people focus their attention on the extent to which they are satisfied with the behavior itself and the outcomes it has produced (e.g., Baldwin et al., 2006; Rothman et al., 2004). Maintenance is expected to continue as long as the advantages of maintaining the behavior (e.g., losing weight or positive comments from friends about your weight loss) outweigh the disadvantages of maintaining the behavior (Rothman, 2000; Rothman et al., 2004). Because the individual has demonstrated that she/he can successfully enact the pattern of behavior, to the extent that the person remains satisfied with the new behavior, she/he will choose to sustain it. This means, in turn, that she/he will continue to reap the benefits of the new pattern of behavior. Framed this way, maintenance should be reinforced as long as one believes the benefits of the behavior outweigh the costs. Importantly, social factors, such as reference group norms, may have a significant impact on how people carry out these cost–benefit and satisfaction assessments (e.g., Baldwin, Rothman, & Jeffery, 2009).

The Application of Self-Determination Theory to Maintenance

Self-determination theory (SDT) (Deci & Ryan, 1985) provides an alternative perspective on promoting behavior maintenance by suggesting that a behavior will be sustained when an individual feels that the behavior is internally motivated and consistent with one's sense of self. Specifically, the extent to which an individual develops an autonomous motivation to perform a behavior (i.e., feels that this motivation originates from the self) and integrates engaging in the behavior into his/her self-concept is thought to be the key to maintenance of that behavior over time (Ng et al., 2012; Ryan & Deci, 2000). Approaches that focus on developing autonomous motivation have been shown to facilitate rates of behavior maintenance across a range of behavioral domains (e.g., Ng et al., 2012; Williams et al., 2006). Conceptualized in terms of self-reinforcing maintenance processes, SDT suggests that when people integrate a behavior into their self-concept, they are much more likely to engage in it, and engaging in it will, in turn, reinforce it as valuable part of their self-concept.

Importantly, this approach also emphasizes the role of the social context in supporting or impeding motivation (Ryan & Deci, 2000). SDT defines three psychological needs critical to supporting the process of internalization: autonomy, competence, and relatedness. Autonomy reflects the idea that one had agency over choosing one's action. Competence involves a person's need to feel efficacious in obtaining a desired outcome. Relatedness reflects the extent to which one feels that they have support from close or important others. Autonomous motivation is thought to be at its highest when all these needs are met, and these needs can all be facilitated or hindered by social processes. For example, autonomy may be facilitated by a healthcare provider, who acknowledges the patient's perspectives and opinions on treatments before prescribing a course of treatment. Competence could be supported by one's friends or family members acknowledging that they believe the person has the capacity to sustain a course of action over time or helping the person reframe past failures as opportunities to learn. Relatedness could be facilitated by close others being empathetic to the difficulties of behavior maintenance.

The Effect of Regulatory Focus on Maintenance

Regulatory focus theory (Higgins, 1996) proposes that promotion focus and prevention focus, two separate motivational systems, regulate how an individual engages in goal-directed behavior; individuals high in promotion focus are engaged in the eager pursuit of desired outcomes, whereas people high in prevention focus are engaged in vigilantly avoiding undesired outcomes. Because behavior maintenance typically involves vigilantly avoiding or minimizing slips or lapses, Fuglestad, Rothman, & Jeffery, (2008) have proposed that these tasks may be a particularly good fit for people who are prevention focused, rendering them better able to maintain a pattern of behavior. Consistent with this perspective, they have shown that people with high prevention focus are more likely to successfully maintain behavior changes over time and respond better after setbacks (Fuglestad et al., 2008; Fuglestad, Rothman, & Jeffery, 2013). A prevention-focused individual's behavior is reinforced as long as she/he is not experiencing negative outcomes, and the absence of negative outcomes will continue to reinforce the behavior. Regardless of someone's inclination toward being promotion or prevention focused, social environments and messages may play an important role in facilitating or inhibiting one's regulatory focus. Therefore, social environments and messages that facilitate focus on prevention may help facilitate behavior maintenance (Cesario, Higgins, & Scholer, 2008).

Emerging Directions in Behavior Maintenance Interventions and Research

Given the importance of sustaining health behavior over time, a number of interventions have sought to promote behavior maintenance. The most effective maintenance interventions employ multiple strategies. These strategies include disseminating information, changing people's attitudes, creating a supportive environment whenever possible, and providing the skills to navigate an unsupportive environment (e.g., Janssen, Gucht, van Exel, & Maes, 2013). These interventions tend to provide individuals with a range of resources such as counseling sessions with a health psychologist, goal setting strategies, and strategies that focus on identifying potential barriers to maintenance. They also help individuals develop self-regulation skills including self-monitoring, developing specific action plans, getting progress-related feedback, developing realistic outcome expectancies, and discussing their strategies with their partner or close others in order to increase social support (e.g., Janssen et al., 2013).

Although there is some evidence that in combination these strategies can bolster successful maintenance, our understanding of which strategies may be particularly effective in promoting maintenance remains limited and is a priority for future research. In particular, consideration should be given to determining whether specific strategies are more effective for specific groups of people, for particular behavioral domains, or in particular contexts given the many effects that social factors and people's environment have on their ability to maintain their health. People are implicitly or explicitly informed about appropriate behavior, including appropriate health behavior, by their peers and social environments, and they look to their social network to assess risk for a given disease, to ways of reducing that risk, or to models of whether and how to engage in health behaviors.

Technological innovations have led and will likely continue to lead to the development of new, innovative ways to promote and research behavioral maintenance. Wearable devices help people track their steps, online communities can provide support and information, and people can track their eating using applications on computer and smartphones. These technologies should help to expand the range of theory-based strategies available for effective behavior maintenance, especially considering that maintenance often requires continued focused efforts that develop and change over time. As this happens, we will also learn more about whether these strategies are effective and hone the strategies that will be most beneficial for each individual.

Author Biographies

Lisa Auster-Gussman is a doctoral student in the social psychology program at University of Minnesota. Her current research focuses on the relationship between beliefs about health conditions, such as their etiology or controllability, and social cognitive and behavioral variables including stigma, self-blame, and self-regulatory processes. Her research focuses on how these relationships affect health behavior change and maintenance.

Rachel J. Burns is a postdoctoral fellow at McGill University. She received her PhD in Psychology from the University of Minnesota. Her research lies at the intersection of social psychology and health psychology and identifies the social, cognitive, and motivational processes that shape how people make health-relevant decisions and manage their health behavior.

Alex J. Rothman is currently associate dean for Research and Graduate Programs in the College of Liberal Arts and professor in the Department of Psychology, University of Minnesota. His program of research concerns the application of social psychological theory to illness prevention and health promotion and is a synthesis of basic research on how people process and respond to health information with the development and evaluation of theory-based interventions to promote sustained changes in healthy behavior.

The Health Belief Model

History of the Health Belief Model

Behavioral scientists working for the US Public Health Service developed the health belief model in the 1950s, and it remains today one of the most widely applied conceptual frameworks of health behavior used by health educators, other health professionals, and psychologists (Rosenstock, Strecher, & Becker, 1988). At the time there were medical diagnostic tools such as chest X-rays for tuberculosis (TB) screening that were underused because many people with TB did not recognize their symptoms and did not seek medical care for what they deemed a mere cough. There was a parallel need to increase use of preventive services such as immunization and medical adherence in general, in addition to health screening. At the beginning, the health belief model was rooted in information giving to increase people's awareness of and concern about the serious health risks associated with certain preventable illnesses, including illnesses that could be cured if caught early enough. Health educators also wanted people to understand that they could reduce these health risks by taking certain actions. The (primarily) psychologists theorized that people are afraid of getting serious illnesses and that health-related behaviors reflect both a person's level of fear of perceived health threats and the expected fear-reduction potential of taking a recommended action. People consider whether the outcomes of the behavior change outweigh its practical and psychological obstacles. In short, individuals assess the net benefits of changing their behavior to reduce the threat to their health and decide whether to act (Murphy, 2005).

The model identifies and organizes interventions around four aspects of this assessment: perceived susceptibility to ill health, or risk perception, perceived severity of ill health, perceived benefits of behavior change, and perceived barriers to taking action. Later, health belief theorists added the concept of self-efficacy as a factor in health behavior decision making. Individuals' perceptions of risks, benefits, and obstacles add up to their readiness to act or lack

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

of readiness. If a person is ready to change behavior to obtain the perceived benefits, health promotion messages—through mass media, peer education, and other interventions—act as cues to action, transforming readiness into overt behavior. These cues are particularly important when unhealthy behaviors are habitual such as not wearing seat belts, overeating, not exercising, or smoking. The health belief model can also help identify leverage points for change. A smoker who may not think he is capable of quitting on his own —that is, who has low self-efficacy—can be coached on proven ways to quit and encouraged to enroll in a supportive smoking cessation program (Rimer & Glanz, 2005).

The health belief model of behavioral change was later categorized as *individual centered.* In addition to the health belief model, the category includes social cognitive theory (in spite of the word "social," it focuses on individual learning through observation), the theory of reasoned action, the stages of change model, and the AIDS risk reduction model. Although they differ in several ways, all these theories focus on the individual's perceived susceptibility to a threat to health and benefits that would result from changing behavior, as well as on constraints to such change. They assume that people are rational and will do the right thing once they are provided adequate information and understand that change is in their personal self-interest. The model would be effective unless a person is neither concerned about nor afraid of negative health consequences, or is simply not rational, or not currently in a rational frame of mind (e.g., when intoxicated).

Behavioral researchers came to realize that complex health behaviors such as those involving sexual intercourse or addiction take place in a dynamic (i.e., reciprocally influential) social and cultural context, and an individual's thinking and decision making reflect this context (Sweat & Denison, 1995). Therefore, social and cultural factors surrounding and going beyond the individual must be considered in designing preventive interventions. A second group of theories takes both individual and social factors into account. This group includes diffusion of innovations theory, social influence or social inoculation model, social network theory, and theory of gender and power (Green, 2003).

Key Constructs in the Health Belief Model

The health belief model was originally based on four cognitive constructs:

- Perceived susceptibility (individual's assessment of the risk of becoming ill, that is, realizing an unwanted outcome).
- Perceived severity (individual's assessment of the seriousness of the illness, condition, or unwanted outcome and the potential consequences).
- Perceived barriers (individual's assessment of the influences that discourage adoption of the promoted action or new behavior).
- Perceived benefits (individual's assessment of the positive consequences of adopting the promoted action).

These constructs can be expanded to apply to specific areas of behavioral change. To use the example of HIV infection, the thinking might proceed thus:

1 Perceived susceptibility to a particular health problem: Am I at risk for HIV? What behaviors put me at risk—having (unprotected) sex with multiple partners? Intravenous drug use?
2 Perceived severity of the condition: How serious is AIDS? How hard would my life be if I were infected? Who would take care of me? Could I afford medication?

3. Belief in effectiveness of the new behavior: Are condoms effective against HIV transmission? Would reducing the number of sexual partners reduce my risk? Would using clean needles reduce my risk?
4. Cues to action: I am hearing frequent radio messages about AIDS and how to avoid it. I notice that free condoms are available at in men's rooms. I watched AIDS weaken the health of a family member. I went to the funeral of a close friend who died of AIDS.
5. Perceived benefits of preventive action: If I start using condoms, or become monogamous, I can avoid HIV infection. The needle exchange clinic is a long distance, but clean needles will prevent injecting HIV into my bloodstream.
6. Barriers to taking action: I do not like using condoms, and I cannot afford them anyway. Having several sex partners at the same time gives me the variety I like and makes me feel like a real man (UNAIDS, 1999).

As noted earlier in the example of smoking cessation, the health belief model has also been adapted to include the construct of self-efficacy, the belief that one is capable of carrying out the behavior. Consequently, it is sometimes referred to as the expanded health belief model (Strecher & Rosenstock, 1997). Using the expanded model, a seventh question would be added for the AIDS example above: Am I capable of convincing my sexual partners to use condoms every time?

Recognizing that an individual's behavior is affected by a wider context, many organizations implementing public health promotion and prevention strategies employ a multilevel framework often referred to as the social ecological model that includes factors beyond the individual level. For example, UNAIDS researchers concluded that prevention has to operate at four levels: superstructural, structural, environmental, and individual. A superstructural factor might be an international tariff that makes imported condoms too expensive for sexually active youth living in countries where condoms are not manufactured locally. Policies that exclude unmarried youth from receiving condoms from public health clinics or addicts of any age from receiving sterile syringes represent a structural barrier. Environmental influences could include what one's peer group is saying and doing about AIDS prevention, as well as cultural norms and values transmitted through family and religious teachings. Individual factors beyond health risk and benefit analysis include whether a person is a risk taker or timid by nature and whether the person tends to be a leader or a follower.

Predicting Behavior With the Health Belief Model

A review of the effectiveness of the health belief model to predict and explain behavior found that perceived severity was a weak predictor of behavior, perceived susceptibility was not a predictor in most studies, and perceived barriers and perceived benefits were consistently the strongest predictors of behavior (Carpenter, 2010). While the health belief model is still widely used to guide intervention design, a recent meta-analysis concluded there is insufficient evidence to attribute the use of the model in health interventions to effectiveness in changing behaviors (Jones, Smith, & Llewellyn, 2014). The authors report that while the studies they reviewed state that they used the health belief model, only 6 of the 18 studies followed the full model, and only 5 measured model constructs before and after the intervention. Increasingly, behavior change interventions do not rely on a single theory or model. Recognizing that behavior is influenced by many factors, behavior change strategies draw on several theories simultaneously. To advance knowledge about effective behavior change strategies, further studies should be done to clearly demonstrate how the intervention design is informed by the theories and to measure the theoretical constructs before and after the intervention, as well as the associated changes in behavior.

Author Biographies

Edward C. Green, PhD, is a medical anthropologist who served as senior research scientist at the Harvard Center for Population and Development Studies. In retirement, he is currently a research professor at the Department of Anthropology, the George Washington University, and director of the New Paradigm Fund.

Elaine M. Murphy, PhD, is a visiting scholar at the Population Reference Bureau in Washington, DC, and an international health consultant. She has worked for 30 years in the areas of population and reproductive health (family planning).

Dr. Kristina Gryboski is a medical anthropologist who has worked in global health for over 20 years as a researcher, program manager, technical writer, and trainer in nutrition, maternal and child health, gender, and reproductive health.

Health Consequences and Correlates of Life Stories

William L. Dunlop, Tara P. McCoy,
and Grace E. Hanley

Psychology Department, University of California, Riverside, Riverside, CA, USA

I'm in a chain of memories
It's my will

John Frusicante (2001)

The life story is somewhat of a curious construct. Most everyone has some idea what a life story *is*, yet few in the field of health psychology actively study it. "Why should they?" the reader may reasonably ask. "There already exist countless more tractable psychological constructs that have proven themselves to be robust indicators – as well as determinants – of physical and psychological health." Fair point. To this we would respond that a consideration of life stories is only necessary if researchers wish to attain a deeper, more thorough, and psychologically rich understanding of the persons they aim to study (Dunlop, 2015). It is also worth noting that there exists a growing literature recognizing the *unique* predictive ability of aspects of life stories, exhibited in relation to health behaviors and outcomes (e.g., Adler et al., 2015; Dunlop & Tracy, 2013; Dunlop, Walker, & Wiens, 2013).

Before offering a summary of previous research examining life stories in relation to physical and psychological health, it is necessary to provide a more thorough discussion of what exactly a life story is and what it is not. Following this summary, we will provide an overview of previous research that has considered aspects of life stories in relation to health-related outcomes. Although we do not anticipate that this entry will convert each and every reader into a life story "believer," we do hope that it increases the level of interest among health psychologists in the life story.

The Time of Our Lives

Lives are complicated things. Just when people feel as though they finally have a handle on all of their various tasks, responsibilities, roles, and requirements, something changes. Something *always* changes. Indeed, this fact, the fact that lives are constantly in flux, gets to the very heart of the matter: In large part, lives are complicated because they are always morphing. Can people ever claim to be living the same life they were living 5 years or even 5 months ago? The nature of modern circumstances, as well as common sense, would seem to dictate otherwise.

Yet, despite all the rampant change, people continually lay claim to the fact that they are, numerically speaking, the same person they were in 2005, 1995, and so on (age permitting). This claim of "personal persistence" (Chandler, Lalonde, Sokol, Hallett, & Marcia, 2003) is larger than any one life that falls under its purview. Indeed, the very moral, social, and economic bedrocks of civilization are predicated on the notion that people take ownership of their past and have some invested interest in the manner in which their lives play out in the future (Chandler et al., 2003). In the absence of such a temporal thread, "contracts and debts and promises would all fly out the same window, all prospects for a just and moral world would evaporate, and judgment day would simply go out of business" (Chandler et al., 2003, pp. 7–8).

The life story represents an important psychological resource because it can be used to justify, to the self and others, a connection between the many different temporal "versions" of the self as well as the varied experiences of which it has been a part—that is, it can be used to create a sense of personal persistence or temporal continuity (Chandler et al., 2003; Dunlop & Walker, 2014). The "active ingredient" in this process is autobiographical reasoning (Habermas & Bluck, 2000).

Autobiographical Reasoning: A Primer

Readers looking for some reprieve from the nebulous nature of the life story via autobiographical reasoning will be disappointed. Autobiographical reasoning is just as, if not more, complex than the life stories in which it manifests: this form of reasoning actually is not one thing, but four (at least; Habermas & Bluck, 2000). First, a given life story must make "sense" within a particular social and cultural context; it must accord to the *cultural concept of biography* (Habermas, 2007). This concept includes tacit assumptions regarding the events that are "worthy" of one's life story (e.g., graduating from college, having a child; Habermas, 2007) as well as the manner in which these specific events, and the life story as a whole, should be told.

Second, one may consider the *temporal coherence* of the life story in question. Some stories contain sufficient detail regarding when a particular experience occurred, as well as a logical (most frequently temporal) progression between the various events that the narrator deems self-defining. When these features are present, the story is said to have a high level of temporal coherence. Third, the *thematic coherence* of life stories is noteworthy. As Habermas and Bluck (2000) observed, narratives have a tendency to espouse certain themes or maxims in the stories they construct. Individuals differ in the degree to which the themes in their stories are consistent and coherent. Finally, life stories vary in their degree of *causal coherence*. Narrators differ with respect to the degree to which they associate changes in the self with accumulations of experience (e.g., "summer school made me more studious") as well as the accumulation of experiences with properties of the self (e.g., "I was quite shy at the time, so I decided to study by myself in the library").

Where the Rubber Meets the Road: Measuring Life Stories

How do researchers assess life stories? Before answering this question, it is important to recognize the distinction between the life story as a psychological construct and the life story as a *measurable* psychological construct. One intriguing feature of autobiographical stories is that they are, invariably, "created within a specific situation, by particular individuals, for particular audiences, and to fulfill particular goals" (McLean, Pasupathi, & Pals, 2007, p. 262). In this sense, the elements of life stories that are produced in research contexts do not represent a pure "assessment of internal representations but rather…an emergent product of representations and features in which narratives are told" (p. 264; see also McCoy & Dunlop, 2016).

When researchers set their sights on measuring life stories, they most commonly ask participants to provide a series of key autobiographical scenes from their participants' lives, such as "high points," "low points," and "turning points" (see McCoy & Dunlop, 2016). An example prompt is as follows (McAdams, 2008):

> Please describe a scene, episode, or moment in your life story that stands out as an especially positive experience. This might be the high point scene of your entire life, or else an especially happy, joyous, exciting, or wonderful moment in the story. Please describe this high point scene in detail. What happened, when and where, who was involved, and what were you thinking and feeling? Also, please say a word or two about why you think this particular moment was so good and what the scene may say about who you are as a person and your life.

Several aspects of this prompt are worth noting. First, individuals are pushed for a single, definitive event rather than a general period in their lives (see also Baranski, Morse, & Dunlop, 2016). Second, as much detail as possible is requested. Together, these two elements of prompts (specificity and detail) have proven to offer the most psychologically meaningful narratives.

From our experience, we believe that autobiographical narratives represent some of the most interesting and illustrative data that can be extracted from participants. Consider, for example, the following narrative, which was produced by an undergraduate at our institution (University of California, Riverside) during a recent study conducted in our lab:

> On [date], I got a tattoo – a compass on my chest. This was obviously a big deal for me, and it remains my pride and joy. My girlfriend and her mother were there with me when I got it, but my parents, who I'm generally close to, still don't know about it. I got the tattoo because I felt something missing from my body, like the flesh on my chest where the tattoo was supposed to be was just missing. I could feel the loss and see a lighter part of my skin where there should have been ink. When I got the tattoo, it felt right. My body was complete again. With such a positive change of who I am as a person (and I do think that my tattoo helps to define me), it feels weird not to tell my parents. I'm not afraid they'll be mad at me (which they will) but that they'll be mad at themselves. They don't understand that tattoos aren't just for sailors, gangsters, and convicts and they'll blame themselves for not raising me properly. I can hear my mom saying, "What would your grandfather say?" I know that they'll find out about it someday, and I am prepared to take care of them when they do. I don't want to hurt them with what I have to hide.

Perhaps we could have gotten much of the same information about this particular participant if we had administered questionnaires pertaining to adult attachment, relations with his or her parents, and family environment. Perhaps not. In any case, we contend that considering participants' narratives serves as a stark reminder that we are studying people—real, living, and breathing people—rather than the cold variables that, as academic psychologists, we tend to focus on.

Researchers have collected autobiographical narratives in a variety of ways. Some, for example, have collected participants' oral narratives via semi-structured interviews (e.g., Dunlop & Walker, 2014; McAdams, 2008), whereas others have collected participants' written responses via paper-and-pencil assessment packages or computer-mediated programs (e.g., Dunlop et al., 2013; McAdams et al., 2006). Despite the current focus on the contextualized, or situated, nature of stories (e.g., McLean et al., 2007), until recently researchers have generally assumed that the narrative material gathered via these various assessment procedures was comparable. Our research group (McCoy & Dunlop, 2016) has just completed a study that challenges this assumption.

In our study, approximately 400 participants were asked to provide 3 autobiographical key scenes from within 1 of 4 assessment contexts, constituting a 2(interviewer present, interviewer absent) × 2(written responses, spoken responses) study design. The resulting narratives were quantified in terms of 15 linguistic (i.e., word based) categories and 6 more conceptual themes (the specific categories and themes are irrelevant at this time, though they will be explored in detail later in this entry). Of the 15 linguistic categories considered, 14 exhibited a significant main effect for, or interaction with, assessment context. A similar pattern was observed when we considered the conceptual content of participants' narratives. Here, five of the six categories differed significantly across assessment contexts. The take-home message from this research is that assessment contexts substantially influence the content of autobiographical narratives.

Where the Rubber Really Meets the Road: Quantifying Narratives

Unlike other personality characteristics, notably personality traits, there exists no single framework or conceptual paradigm that the majority of narrative researchers endorse. In contrast, it is not uncommon for researchers to create coding systems for various constructs embedded within narratives on the basis of research questions or the nature of the data in question (e.g., Dunlop et al., 2013). Despite this idiosyncrasy, the following three coding systems have developed considerable traction within the field.

Agency and Communion

Agency, represented by themes such as independence and self-assertion, and communion, represented by themes such as togetherness and social unity. What this really means is that the understanding of many topics, including autobiographical narratives, has been aided through the consideration of the fundamental modality represented by conflicting desires to "get ahead" (agency) and "get along" (communion; Hogan, 1982).

Redemption and Contamination

Earlier we noted that life stories and autobiographical narratives need be considered in relation to the social and cultural contexts in which they manifest. A related point is that certain forms of narratives are generally supported by certain cultures, relative to others. Within American contexts, the redemptive story represents one such supported, or master, narrative (McAdams, 2006). A redemptive story manifests when a bad beginning (e.g., getting dumped by a girlfriend) leads to a positive ending (e.g., finding a more compatible match). The inverse of redemption is contamination, which manifests when promising beginnings give way to spoiled endings.

Transformational Processing

Autobiographical narratives have also been noted to differ in terms of affective tone (e.g., positive valence, negative valence) and complexity (e.g., the degree to which the narrator recognizes, and integrates, multiple perspectives in his or her story; see McAdams et al., 2004). Together, these variables constitute the transformational processing framework.

Health Consequences of Life Stories

Life stories represent more than mere conceptions of the past. Some theorists, such as Sarbin (2004), have argued that, once formed, there exists a push to keep the particular story going. This reasoning is suggestive of the possibility that adopting the "right" type of story may actually be associated with certain health trajectories. Recognizing the gravity of this theorizing, our research group (Dunlop & Tracy, 2013) sought to examine differing autobiographical narratives in relation to subsequent health trajectories. We did this by studying recently sober alcoholics (i.e., those sober 6 months or less) enrolled in Alcoholics Anonymous (AA). AA represents a particularly interesting group for narrative psychologists, as stories are central to this recovery program (O'Reilly, 1997). Indeed, as sociological researchers have noted, in AA there exists the expectation that recovery is aided through the adoption of an appropriate narrative, in this case a redemptive narrative.

In our study, we prompted recovering alcoholics for stories of their most recent drink and then distinguished those narratives that contained redemptive imagery from those narratives that did not. Of note, participants who produced redemptive narratives were initially otherwise demographically, psychologically, and health-wise indistinguishable from non-redemptive participants. Over time, however, the redemptive group was much more likely to maintain their sobriety relative to the non-redemptive group. In addition, redemptive participants increased in their self-reported health over time. The sum total of these results remained significant after controlling for the "usual suspects" in addictions research, such as attribution style, optimism, and depression. Far from being merely reflective, the elements of our life stories exhibit heavy bearing on the lives we come to lead (Sarbin, 2004).

The research summarized above represents but the tip of the iceberg. A sizable literature notes a strong relationship between the various conceptual elements of key autobiographical scenes and various markers of physical and psychological health (e.g., Adler, 2012; Dunlop et al., 2013). Among these various research pursuits, the work of Adler (2012; Adler, Turner, et al., 2015; Adler, Lodi-Smith, Philippe, & Houle, 2015) is particular noteworthy. For example, he has shown that changes in the agency of participants' narratives predict subsequent changes in self-reported health over the course of psychotherapy (Adler, 2012). More recently, Adler, Turner, et al. (2015) have also shown that various aspects of narratives (e.g., redemption) predict subsequent health trajectories over a span of 4 years.

In addition to his empirical contributions in this area, Adler, Lodi-Smith, et al. (2015) has recently published a thorough literature review documenting both the typical themes or aspect narratives researchers consider (the three conceptual systems noted earlier are present on this list) and the numerous studies that have shown that the relationship between aspects of key autobiographical scenes remains significant predictors of psychological health and well-being even after controlling for certain demographic and personological variables. To take one study from this review, Adler, Kissel, and McAdams (2006) noted that the tendency to construct contaminated key autobiographical scenes corresponded negatively with well-being. This relationship remained significant after controlling for participants' degree of neuroticism. The conclusion to be taken from this illustrative review is that life stories and key scenes hold considerable incremental validity within the realm of psychological adjustment, health, and well-being.

Collectively, the work of our research group (e.g., Dunlop et al., 2013; Dunlop & Tracy, 2013), Adler's research group (Adler, 2012; Adler, Turner, et al., 2015; Adler, Lodi-Smith, et al., 2015), and others (McAdams, 2006) leads to the following conclusions: (a) aspects of life stories often correspond with participants' current levels of physical and psychological health (e.g., McAdams, 2006), (b) changes in the elements of life stories predict changes in psychological health (e.g., Adler, 2012), (c) life stories serve as powerful predictors of subsequent health trajectories (e.g., Adler, Turner, et al., 2015; Dunlop & Tracy, 2013), and (d) both concurrently and longitudinally, life stories have proved themselves to be independent predictors of the aforementioned outcomes, even after controlling for a host of non-narrative psychological and health-based variables (e.g., Adler, Lodi-Smith, et al., 2015; Dunlop & Tracy, 2013).

Conclusion

Life stories matter. For health psychologists, life stories should matter more. These stories have proven themselves to be significant predictors of a host of health-related outcomes and processes. These stories have also been recognized as determinants of subsequent development trajectories and our own "character and personality style" (Sarbin, 2004, p. 7). The implications this construct holds for health psychology, thus, are self-evident.

Author Biographies

William L. Dunlop is an assistant professor of social/personality psychology at the University of California, Riverside. He uses idiographic, nomothetic, and idiographic–nomothetic approaches to examine psychological differences between people, as well as to understand the nature and development of individual lives.

Tara P. McCoy is a graduate student at the University of California, Riverside. She studies the relation between self-defining autobiographical narratives and social contexts. Here most recent work has explored the influence assessment contexts yield on individuals' narratives.

Grace E. Hanley is a doctoral graduate student of social/personality psychology at the University of California, Riverside. Her broad interests include life narratives and self-continuity. She is currently studying the domain specificity on life narratives in relation to certain life outcomes.

Health Consequences and Correlates of Social Justice

Todd Lucas

C. S. Mott Endowed Professor of Public Health Associate Professor of Epidemiology and Biostatistics Division of Public Health College of Human Medicine Michigan State University, Wayne State University, Detroit, MI, USA

In 1999, the US congress directed the Institute of Medicine to examine the extent to which racial and ethnic minorities receive disparate health services, to explore factors that contribute to these inequities, and to recommend policies and practices to eradicate them. The resulting report, *Unequal Treatment: Confronting Racial and Ethnic Health Disparities in Health Care* (Nelson, Smedley, & Stith, 2002), became an authoritative source for documenting the existence of racial and ethnic healthcare disparities in the United States. Perhaps the most important contribution of *Unequal Treatment* is that it identified and organized a substantial body of evidence to support that significant differences exist in the delivery of healthcare between racial and ethnic minorities and nonminorities in the United States and that these disparities remain even when differences in income, age, insurance status, and illness severity are accounted for. For example, *Unequal Treatment* showed that when minorities in the United States are ill, they are less likely to receive desirable medical procedures such as bypass surgery and organ transplants, and they are more likely to receive less desirable procedures such as lower limb amputations. *Unequal Treatment* thus revealed to clinicians and policy makers that death rates from illnesses such as heart disease and cancer are significantly higher among racial and ethnic minorities due in no trivial part to disparities in healthcare delivery.

In broader terms, *Unequal Treatment* underscores that the concept of social justice is understood by many as the extent to which resources are distributed fairly across a society based on factors such as race, gender, education, and income. That uneven distribution of health resources may contribute to social inequity has been increasingly appreciated and attended to in healthcare training and delivery and in accompanying research and health policy. Although resource inequity comprises a valuable perspective indeed, a less appreciated and psychologically oriented view is that social justice encompasses not only the extent to which health resources are accessible to various segments of a society but also the subjective evaluations of fairness that occur as individuals react to everyday social exchange. A psychologically oriented notion of social justice illuminates that social justice can arise from everyday contexts, environments, and occurrences, and justice-oriented cognitions and emotion can contribute to health and illness. This broader notion emphasizes four key characteristics of social justice that are fundamental to identifying social and psychological antecedents and to understanding both

the readily apparent and more subtle ways in which justice acts as social determinant of health. First, a psychologically oriented view emphasizes that social justice can be connected to health both within and outside of formal healthcare delivery settings and systems. Second, the health consequences of social justice stem not only from the extent to which health resources are equally accessible to members of a society but also from the extent to which individuals are treated fairly and respectfully during everyday social exchange. Third, the social justice framework is exceptionally well suited to considering health disparities, though social justice carries health implications for both the socially advantaged and disadvantaged members of a society. Fourth, a psychological orientation emphasizes that health and illness are affected not only through differential access to health resources and treatments but also through biological stress processes and health behaviors that contribute in fundamental ways to a social justice perspective of health.

Social Justice as Distributive Justice

Clinicians, medical scholars, and policy makers have most often viewed social justice through the lens of *distributive justice*. Generally speaking, distributive justice refers to the fairness of resource allocations and outcomes (for recent review, Jost & Kay, 2010). Within health and medical contexts, such resource allocations most readily encompass access to healthcare goods and services. This can include initial entry into a healthcare system, as well as access to effective or desired medical treatments once inside. As highlighted by distributive justice theory and research, one or more allocative principles may be used by individuals in deciding whether health resources are allocated fairly. For example, people may consider the extent to which health resources are equally versus equitably (i.e., proportionally based on one's own as well as others social contributions) disbursed. Alternatively, people may consider whether health resources are available to those most in need. Health outcomes associated with resource distributions generally entail differences in both the desirable (e.g., cure and quality of life) and undesirable (e.g., morbidity, mortality, adverse events) outcomes that stem from differential access to health resources, and these may be similarly evaluated according to one or more allocative principles.

Emphasis on distributive justice within the social justice framework has galvanized at least two broad approaches to addressing health inequity. First, health inequity may be addressed through *social engineering*, which is rooted in modifying social and environmental factors to better ensure distributive social justice. Very often, social engineering in the context of health inequity is accomplished through legislation. For example, the Patient Protection and Affordable Care Act may be regarded as a social engineering approach to addressing distributive health inequity to the extent that it attempts to facilitate more equitable access to healthcare. Social engineering also includes attempts to alter other environmental contexts to better promote distributive justice. For example, inequities in primary prevention of illness might be addressed by altering the built environment to facilitate exercise, or to provide better access to healthy food (for review, Blacksher & Lovasi, 2012).

With an eye toward future research, a more recent perspective of health inequity that overlaps with distributive justice arises from emerging research on implicit bias among healthcare providers (for review, Penner, Blair, Albrecht, & Dovidio, 2014). This nascent literature is revealing that healthcare providers may hold subtle biases against patients based on sociodemographic characteristics, such as race or ethnicity. Importantly, these implicit biases are uncontrollable and subconscious, and they exist despite that virtually all clinicians are not explicitly racially biased. Ultimately, implicit bias among healthcare providers may manifest as distributive social injustice when it alters clinical decision making in ways that result in health inequity. For example, and unbeknownst to the provider, implicit biases may alter the allotment of specific medical treatments to racial minorities, or they may create communication errors or feelings of mistrust during provider–patient interactions that produce inequitable health outcomes (Penner et al., 2014).

Social Justice Beyond Distributive Justice

Social justice describes not only the disbursement of benefits and burdens according to allocative principles but also the rules and norms that govern decisions affecting individuals and groups, and it ensures that people are treated with dignity and respect. Along these lines, the concept of *procedural justice* may be understood as an evaluation of the fairness of decision processes that are used to determine outcomes (for recent review, Jost & Kay, 2010). In the context of health and illness, procedural justice underscores that assessing social justice requires one not only to assess how health resources and outcomes are allocated but also to consider the rules and deliberations that determine such allocations.

A consideration of procedural justice suggests at least two additional connections between the social justice framework and health inequity. First, procedural justice is important to the extent that fair processes can ensure a fair distribution of health resources. For example, health insurers and managed care organizations are required to follow rules and adopt publicly accountable procedures in determining coverage decisions, and these processes may be vital to ensuring that members of a society have fair and adequate access to healthcare (e.g., Chan, 2002). In focusing on such *instrumental functions* of procedural justice, individuals may especially evaluate the extent to which decision processes include *voice*, or the opportunity to provide input into an allocative decision process prior to determining an outcome. Allocative processes may be similarly and simultaneously evaluated according to additional criteria, such as the extent to which decision procedures are consistent, accurate, free of bias, and correctable.

A second and more subtle way in which fair processes contribute to social justice is through the *relational function* of procedural justice. From a relational perspective, fair processes also matter to individuals because they communicate the extent to which one is seen as a valued and respected member of the larger society. For example, having voice may profoundly affect social justice even if it serves no instrumental function in a decision-making process. This is because having a voice can provide individuals with reassurance that they are respected by decision-making authorities. In similar fashion, *fair process effects* suggest that inequitable allocations of health resources and outcomes may be more palatable to members of a society if those members can be sure that allotments were at least arrived at using fair allocative procedures. In the context of healthcare delivery, the relational functions of procedural justice may be an especially crucial precursor to creating trust among healthcare recipients in the overarching healthcare system (Gilson, 2003).

In parallel to procedural justice, at least two additional directions for connecting social justice to health and illness beyond the realm of distributive justice are suggested by ongoing research. First is the closely related concept of *interactional justice*, referring to the fairness of treatment that is accorded to persons by others when implementing allocative procedures or determining outcomes (for recent review, Jost & Kay, 2010). Interactional justice consists of *informational justice*, focusing on the extent to which explanations for why certain procedures were used or outcomes were determined, and also *interpersonal justice*, reflecting the extent to which people are treated with politeness, dignity, and respect by authorities during allocative decisions and processes. Informational justice highlights that when interacting with healthcare systems and authorities, people may or may not be given an adequate account of the health allocations and outcomes affecting them and also the accompanying deliberative rules and processes. Interpersonal justice suggests that such accounts may be delivered respectfully and politely to individuals, or else disrespectfully and impolitely.

A second and related ongoing direction considers other known psychosocial determinants of health and illness that could reflect procedural justice. For example, psychosocial concepts such as *medical mistrust*, *cultural competency*, and *perceived racism* carry important implications for the health and wellness, and they may partly reflect the extent to which individuals consider rules and interpersonal treatment to be fair. Thus, emerging literature suggests that procedural and interactional justice may carry implications for attending to social justice in a number of related psychosocial contexts. This especially includes encounters with healthcare providers or other healthcare system authorities, who can profoundly affect impressions of procedural and interactional justice through routine social exchange.

Social Justice as Psychological Justice

As highlighted by *Unequal Treatment* (2002), social justice is objective in the sense that the allotment of many health resources across various segments of a society can be quantified, as can the extent to which illness and healthcare-associated hardship disproportionately burdens these segments. Although this constitutes a critically important perspective, justice must also be more broadly construed as a psychological perception of individuals and communities and a psychosocial determinant of individual health and wellness in and of itself. In other words, social justice encompasses both the objective indices of inequity, as well as the subjective impressions of fairness held by individuals and groups. Importantly, both of these sources may be linked to health and illness.

Recognizing that justice also encompasses a psychosocial perception underscores two ways in which justice can be subjectively measured and linked to health within the social justice framework. First, justice may be operationalized as a momentary evaluation of a specific context or occurrence. That is, situational or *state justice* refers to judgments of fairness associated with specific settings and social interactions. State justice evaluations underscore that contextual factors are important to individuals in deciding whether momentary occurrences and social interactions are fair in nature. For example, the concept of *relative deprivation* suggests that perceptions of distributive justice in health contexts may depend on the extent to which one perceives his or her access to health resources to be equal to that of comparable others, irrespective of any objective level of health resource access (for recent review, Pettigrew, 2015). Considering state justice further underscores that perceptions of justice are adaptable and multidimensional and that individuals may simultaneously hold impressions of social justice and injustice. These aspects are perhaps best exemplified by the *organizational justice* measurement framework, which highlights that perceptions of fairness associated with evaluating specific contexts may be assessed in terms of evaluating an individual's impressions of distributive, procedural, and interactional justice criteria (e.g., Pérez-Arechaederra, Briones, Lind, & García-Ortiz, 2014).

In tandem to state justice judgments, a psychosocial consideration of social justice also suggests attending to individual differences tendencies, or *trait justice* (for recent review, Dalbert, 2009). In health contexts, an individual differences approach underscores that stable and enduring tendencies to perceive justice in the world also carry health implications. Individual differences further highlight the multidimensional nature of justice, and they suggest that some justice tendencies may be more strongly implicated in health and well-being than others. At present, two individual differences distinctions have been especially well considered in health contexts. First is the distinction between personal and general justice beliefs. Whereas p*ersonal justice beliefs* describe a stable propensity to view that the world as fair to one's self, *general justice beliefs* refer to the tendency to view the world in broad terms as fair or to believe in justice for others. A sizable body of research supports that these two justice tendencies are only moderately correlated with one another and that personal justice beliefs are especially associated with health and wellness outcomes (for review, Lucas & Wendorf, 2012). A second and more recent individual differences distinction considers distributive and procedural justice beliefs (Lucas, Zhdanova, & Alexander, 2011). In addition to characterizing impressions of fairness that accompany momentary social occurrences, procedural and distributive justice also encompass stable dispositional tendencies to perceive outcomes and allocations (*distributive justice beliefs*) versus rules and processes (*procedural justice beliefs*) as fair and deserved. Procedural and distributive justice beliefs are similarly moderately correlated with one another, and initial research suggests that each may be uniquely implicated in health. For example, whereas distributive justice may be especially associated with enhanced positive affect, procedural justice may play an especially prominent role in reducing negative affect. Other research suggests that procedural justice beliefs in particular may be associated with healthy behavior, including diet and exercise (Lucas, Alexander, Firestone, & LeBreton, 2008).

At least two future directions are evident for furthering a psychosocial consideration of justice and for deciphering links from psychologically oriented social justice to health and illness. First, and in terms of individual difference approaches, emerging literature suggests that the general–personal and distributive–procedural justice distinctions can be concurrently specified, such that individuals may be described by tendencies to believe in *distributive and procedural justice for self and others* (Lucas et al., 2011). Initial research using this four-factor measurement approach has suggested a potential to refine links between dispositional justice beliefs and health outcomes. For example, distributive justice beliefs for self have been shown to exclusively predict measures of *personal health*, such as self-rated health, whereas procedural justice beliefs for self exclusively predicted *interpersonal health*, such as conflict at work. Such gradated distinctions may carry potential implications for observing specific links to health and illness in a number of contexts.

A second future direction is suggested by growing consideration of the ways in which trait and state sources of justice jointly act as a social determinant of health and illness. One example is *worldview verification theory*, which suggests that individuals are highly motivated to maintain consistency between lived experiences and enduring worldviews and that health outcomes ultimately stem from inconsistencies between justice experiences and beliefs (Major & Townsend, 2012). According to worldview verification theory, health and wellness fundamentally depend on whether state and trait justice judgments are in agreement, even if these sources sway toward injustice. Thus, worldview verification suggests the seemingly ironic notion that perceptions of injustice may protect health better than perceptions of justice, so long as state and trait sources of injustice perceptions are congruent with one another. In support, recent research reveals that for racial minority individuals, justice dispositions and externally imposed justice jointly influence adaptive coping, and the degree of consistency between these two sources is ultimately crucial (Lucas et al., 2016, for recent example).

Health Consequences of Social Justice

Social justice is of interest to many because of its potential to influence the health and well-being of individuals and communities. Not surprisingly then, a psychosocial consideration of justice has revealed that perceptions of fairness affect the health of individuals in numerous ways (for reviews, Elovainio, Kivimäki, & Vahtera, 2002; Jackson, Kubzansky, & Wright, 2006; Lucas & Wendorf, 2012). Perhaps most clearly evident are associations between perceived fairness and mental health, especially including an inverse relationship between fairness and indices of negative emotion and depression. In addition to mental well-being, justice perceptions have been increasingly implicated in physical health. Most notably, research suggests that perceived injustice is prospectively associated with an increased incidence of cardiovascular illness. Strikingly, some research suggests that perceived injustice may be as strongly implicated in cardiovascular illness as traditional risk factors such as cholesterol, body mass index, and physical activity, and the contribution of perceived injustice to cardiovascular illness appears to be unique from that of seemingly related psychosocial variables.

From a mechanistic standpoint, health effects of psychological justice are thought to occur predominantly through links to stress. Stress pathways are empirically supported through studies linking perceived fairness to biological indices of stress reactivity, including activation of the sympathetic–adrenal–medullary axis (Tomaka & Blascovich, 1994) and also the hypothalamic–pituitary–adrenal axis (Lucas et al., 2016; Vermunt, Peeters, & Berggren, 2007). Recent research suggests that justice may also be linked to inflammatory reactivity (Lucas et al., 2016). Accordingly, justice theory has emphasized that perceived injustice may act as a stressor (Vermunt & Steensma, 2001). A justice approach to stress implicates cognitive appraisals of stressors, including evaluations of the threat value of an unfair event (i.e., primary appraisal) and also whether personal resources are adequate to cope with unfairness (i.e., secondary appraisal). Links to psychological and biological stress reactivity seem highly consistent with research suggesting that justice is especially important to heart health and depression, which have also been strongly linked to stress. More recently, research has identified health behaviors such as smoking, diet, and exercise and other forms of health detection and prevention as additional pathways through which justice beliefs may affect health (e.g., Lucas et al., 2008). One additional and particularly intriguing health pathway suggested by available literature is the connection between justice perceptions, insomnia, and metabolic risk (for recent example, Levine, Basu, & Chen, 2015). Other recent research is considering the ways in which perceptions of justice contribute to experiences of pain, which in turn may contribute to physical and mental wellness (McParland & Eccleston, 2013).

At least three future directions are relevant to further understanding the physical and mental health consequences of justice perceptions. First, future research must explore the extent to which perceptions of justice are particularly linked to stress and health among minority groups and individuals. This especially includes racial minorities, for whom justice perceptions may be intertwined with other known psychosocial determinants of stress and health, such as perceived discrimination and racial identity. Second and related, although a handful of studies have shown the ways in which justice may be related to acute biological stress reactivity, future research will be needed to better understand the ways in which justice perceptions are related to chronic stress. Critically, this includes the better understanding of the contributions of justice to chronically deregulated stress system functioning, which may be an important antecedent to broader health disparities. Third, future research must continue to explore the ways in which justice perceptions are linked to specific and impactful health behaviors. This includes further exploring how justice plays a role in the use of protective health behaviors such as diet and exercise and also health-compromising behaviors such as smoking and substance use. Attending to health disparities that are underscored by the social justice framework may prove particularly useful in linking justice to health behavior. For example, the extent to which perceived justice affects adherence to prescribed medical regimens remains virtually unexplored, despite evidence that adherence among racial minorities is affected by perceived racism. Related efforts to encourage preventative health behavior often include the use of health communication strategies. The extent to which justice can be used as the basis of health messaging also holds considerable promise for future intervention research.

Author Biography

Todd Lucas is an associate professor in the Department of Family Medicine and Public Health Sciences and the Department of Psychology at Wayne State University (Detroit, MI). Dr. Lucas is a social and health psychologist. His research considers self and social regulation processes in stress and health. He is especially focused on the role of perceived fairness in health and social disparities.

Health Consequences of Prejudice and Discrimination

Tessa L. Dover, Jeffrey M. Hunger, and Brenda Major

Department of Psychological and Brain Sciences, University of California
Santa Barbara, Santa Barbara, CA, USA

Prejudice and discrimination feature prominently in psychological research over the past 60 years. Most of this research focused on understanding the *causes* of prejudice and discrimination. It was not until the 1980s that research began in earnest to consider the *consequences* of prejudice and discrimination for those who are their targets. Since then a wealth of research has addressed the mental and physical health effects of perceived prejudice and discrimination (for reviews, see Lewis, Cogburn, & Williams, 2015; Pascoe & Smart Richman, 2009; Williams & Mohammed, 2009). This research has shown that prejudice and discrimination can compromise the physical health of low-status, disadvantaged, and stigmatized groups in multiple ways (Lewis et al., 2015; Major, Mendes, & Dovidio, 2013; Williams & Mohammed, 2013). Below, we describe the different pathways through which prejudice and discrimination can get "under the skin" to undermine physical health. We also highlight critical moderators of how individuals cope with prejudice and discrimination that have implications for health.

Defining Terms

Discrimination and prejudice are related but distinct constructs and can take several different forms. *Prejudice* refers to negative attitudes toward a group. Prejudice can be explicit (acknowledged by the prejudiced individual) or implicit (based on underlying associations that may not be known or acknowledged by the prejudiced individual). Prejudice can also be "old-fashioned" (hostile or overt) or more "modern" (subtle or disguised). Prejudice may or may not be accompanied by poor treatment of the target group. *Discrimination*, in contrast, is behavioral. It refers to poor or unequal treatment of individuals based on their group membership. Many consider prejudice to be a precursor to discrimination, though discrimination can occur at both structural and interpersonal levels. For example, a policy may be discriminatory because

---

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

it favors one group over another, even though the policy cannot have "prejudiced attitudes" about a group.

Discrimination also takes several forms. *Acute discrimination* refers to a specific incidence of discrimination, with discrete start and end points—such as being refused service because of group membership. *Pervasive discrimination* refers to more chronic experiences of group-based mistreatment or the extent to which discrimination is experienced in day-to-day life. *Experienced* and *anticipated* discrimination can also be differentiated. A large body of work has assessed the health consequences of having experienced discrimination. A smaller but growing body of research also assesses the health consequences of anticipating being the target of prejudice and discrimination. Overall, this work suggests that the health consequences of prejudice and discrimination stem not only from direct experiences of overt maltreatment but also from the extra cognitive and emotional demands that anticipating prejudice places on targets as they navigate the social world.

A large literature has demonstrated the negative impact of discrimination and prejudice on indices of mental health, including stress, depression, anxiety, negative affect, lower self-esteem, and lower life satisfaction (see Pascoe & Smart Richman, 2009). Mental health is a primary component of overall health and well-being as well as a strong predictor of physical health. Due to space concerns, the current entry focuses primarily on the consequences of discrimination and prejudice for *physical* health. Indices of physical health reviewed here include self-reported health; mortality; cardiovascular, endocrine, and immunological functioning and reactivity; health behaviors; treatment outcomes; and several other biomarkers.

Pathways to Poor Health: Mechanisms of Discrimination and Prejudice Affecting Health

Although the association between discrimination and poor health is well documented, research understanding the mechanisms underlying this relationship is still in its infancy. Below we differentiate between two types of mechanisms (see Pascoe & Smart Richman, 2009, for a discussion of this framework). *Direct effects* refer to the ways in which systemic inequality and biased treatment erode health without any action or psychological input from the target (e.g., receiving poorer treatment by healthcare providers). *Indirect effects* refer to health-eroding behaviors or psychological states that occur in *response* to perceived or anticipated discrimination (e.g., the physiological stress response that accompanies exposure to discrimination, increased alcohol use in order to cope with perceived prejudice).

Direct Effects: Systemic and Interpersonal Mistreatment

The first pathway through which prejudice and discrimination undermine health is direct. By exposing targets to health-compromising environments and limiting access to resources important to promoting health (e.g., education, low-cost healthy foods), both interpersonal and institutionalized prejudice/discrimination can erode health for targets. Below, we briefly discuss four domains in which discrimination and prejudice directly compromise health: housing, education, employment, and healthcare.

In the housing domain, both institutionalized discrimination (e.g., "redlining" policies or using race/ethnicity as a consideration for mortgage accessibility) and interpersonal discrimination (e.g., landlords idiosyncratically favoring White tenants over tenants of color) have limited and continue to limit access to housing for targeted groups. Such segregation and housing disparities directly affect the health of targets by determining access to good schools, safe environments, healthy food, outdoor spaces, low pollution, police protection, and economic mobility. In fact, Williams and Collins (2001) suggested that segregation and racialized housing policy are primary contributors to Black/White health disparities in the United States.

Well-documented racial and ethnic disparities also exist in access to quality private and public education. Moreover, teachers and administrators unequally allocate disciplinary policies such as expulsions, suspensions, and other punishments that can hinder performance in school to Black and Latino school children. Race-based school "tracking," in which White students are encouraged to take more advanced classes than their non-White counterparts, is also common. These often-subtle disparities can directly affect health outcomes over time as academic success and educational achievement are strongly linked to health outcomes.

As with housing and educational discrimination, employment discrimination has shaped and continues to shape the health of targets. Prejudice on the part of hiring managers related to race, ethnicity, age, sexuality, and gender not only affects the ability to acquire the financial resources for a healthy lifestyle but also erects a substantial barrier to obtaining employer-subsidized health insurance.

The healthcare setting is another domain in which prejudice and discrimination directly undermine health. Several large-scale studies have demonstrated that Black, Latino, and poor individuals have less access to healthcare services than their White, Asian, and rich counterparts (e.g., Smedley, Stith, & Nelson, 2002). Moreover, once targets of discrimination and prejudice do gain access to the healthcare system, the quality of treatment, the nature of patient–provider interactions, and the resulting treatment recommendations they receive are often poorer than those of more advantaged groups. Medical conditions tend to be more accurately diagnosed and aggressively treated among White, young, and male patients compared with equivalent Black, older, and female patients—even with identical symptomology (e.g., Schulman et al., 1999).

Healthcare providers also evince strong negative implicit attitudes toward racial minority patients, overweight patients, and patients in other targeted groups, which may compromise the care these groups receive. Levels of implicit bias among healthcare providers have been shown to predict (a) their own behavior in clinical interactions, (b) treatment recommendations, and (c) their patients' treatment outcomes. As such, health disparities likely result partially from implicit and explicit prejudice among healthcare providers that translates into poorer treatment (for a review, see Dovidio et al., 2008).

Indirect Effects: Stress

A second pathway by which experiencing or anticipating prejudice and discrimination can undermine health is by heightening the experience of stress, precipitating a cascade of neuroendocrine, immunological, and cardiovascular responses that can undermine health over time (Major et al., 2013; Pascoe & Smart Richman, 2009).

A large literature has examined the effects of perceived prejudice and discrimination on cardiovascular reactivity. Exposing individuals to discrimination or to potential discrimination against themselves or members of their group in the laboratory has been shown to lead to increased cardiovascular reactivity among racial/ethnic minorities, women, and overweight individuals. Discrimination has also been shown to activate the stress-responsive hypothalamic–pituitary–adrenal (HPA) axis, the primary output of which is cortisol. This relationship is complex, however, because both heightened cortisol reactivity and blunted reactivity have been shown in response to discrimination, and under certain circumstances, both can be maladaptive. Emerging research is also examining other biological systems that may be implicated in the development of physical illnesses in response to discrimination. For example, both weight- and race-based discrimination correlate with oxidative stress, a pathogenic process implicated in chronic conditions such as diabetes and hypertension (e.g., Szanton et al., 2012). Limited research also suggests that experiencing prejudice and discrimination is associated with markers of systemic inflammation such as C-reactive protein and interleukin-6 (e.g., Lewis, Aiello, Leurgans, Kelly, & Barnes, 2010). Inflammation can precipitate the development of age-related diseases such as cardiovascular disease and arthritis.

Indirect Effects: Health Behaviors

Experiencing or anticipating being the target of prejudice and discrimination can also alter health behaviors that are essential to maintaining physical well-being. Contending with the stress of prejudice and discrimination is effortful and can tax cognitive resources necessary for self-regulation. As a result, targets of prejudice and discrimination may experience diminished capacity to engage in some health-promoting behaviors. In addition, people may engage in behaviors that have negative health implications as a way of coping with the stress that accompanies experienced or anticipated discrimination. Below we discuss four types of health-related behavior that have been examined in response to prejudice and discrimination: eating behavior, substance use, exercise/physical activity, and healthcare behavior.

Perceived weight-based, gender-based, and race-based discrimination are associated with emotional eating and a host of disordered eating attitudes and behaviors (e.g., Moradi, Dirks, & Matteson, 2005). Likewise, perceiving race-based discrimination during adolescence is prospectively associated with poorer eating habits (e.g., greater fast-food consumption) as an adult. Experiencing or anticipating prejudice and discrimination may contribute to unhealthy eating behaviors by increasing cortisol production, which can spur a drive for high-fat and high-sugar foods; by decreasing the ability to engage in self-control; and by leading individuals to consume highly palatable (but unhealthy) foods to cope.

Adults reporting discrimination on the basis of race/ethnicity, gender, weight, and sexual orientation are more likely to meet diagnostic criteria for a substance use disorder such as nicotine, alcohol, or drug dependence. This relationship also emerges among adolescents. For example, in a longitudinal study of African American youth, greater reports of race-based discrimination at baseline were associated with more alcohol and marijuana use over time (Gibbons et al., 2010). Likewise, lesbian, gay, and bisexual (LGB) youth also report higher levels of substance use than their heterosexual counterparts; the odds of LGB youth engaging in substance use are 190% higher than heterosexual youth, presumably a result of minority stress (Lick, Durso, & Johnson, 2013).

There is also evidence that individuals alter their physical activity in response to perceived prejudice and discrimination, although this may depend on the target group. Research in the weight domain shows that experiencing weight-related criticism among adolescents and weight-based discrimination among adults is related to a greater motivation to avoid exercising in public as well as less physical activity. In the race domain, however, this relationship is more inconsistent. Some researchers found no relationship between perceived discrimination and physical activity; others found a negative relationship, while others still found a *positive* relationship. Whereas racial and ethnic minorities may engage in *increased* physical activity to cope with stress associated with perceived discrimination, overweight individuals likely avoid physical activity in an attempt to limit their exposure to the stigma prevalent in this domain (see Bastos, Celeste, Silva, Priest, & Paradies, 2015; Borrell, Kiefe, Diez-Roux, Williams, & Gordon-Larsen, 2013).

In the healthcare domain, patients from targeted groups often report low levels of trust in their healthcare providers and in the healthcare system in general. This lack of trust, perhaps in response to the healthcare biases evident among healthcare providers, can in turn impede patient adherence to treatment plans and reduce the likelihood that disadvantaged individuals seek medical care. Targets of discrimination and prejudice perceive greater levels of discrimination in the healthcare system compared with their nontargeted counterparts, and perceptions of discrimination are associated with greater healthcare avoidance (Burgess, Warren, Phelan, Dovidio, & Van Ryn, 2010).

Beyond any actual bias held by their healthcare provider, members of targeted groups may experience discomfort in intergroup interactions where discrimination or prejudice is deemed possible. As such, targets of prejudice and discrimination may experience stress, discomfort, and cognitive impairment in their clinical settings—all of which may have negative implications for physical health.

Moderators of the Effect of Discrimination and Prejudice on Health

Not all potential targets of discrimination and prejudice experience, anticipate, and perceive the same amount of unfair treatment. Nor do discrimination and prejudice affect all members of disadvantaged groups equally. Several key moderators of the discrimination–health relationship have been identified, many of which exacerbate or ameliorate the health consequences of discrimination and prejudice by affecting an individual's *perceptions of* or ability to *cope with* the stress of discrimination and prejudice. As such, most of the moderators identified by researchers have their effects on the indirect pathways—by moderating how much stress discrimination and prejudice elicit or by moderating how individuals behaviorally cope with that stress.

As is typical of research on stressors in general, people who have more *social support* (i.e., networks of friends or family that can lend tangible or emotional resources to the target) tend to have more healthful responses to discrimination than those with less social support. This is theorized to occur because those with wider and more helpful social connections have additional coping resources to draw on when experiencing discrimination and prejudice, thus lessening the stress of experiencing discrimination or prejudice.

An individual's *coping style* can also moderate the effect of discrimination and prejudice on health. Those who engage in active, problem-focused coping strategies (i.e., dealing with the stressor "head-on") may experience fewer negative consequences of discrimination than those who engage in more passive coping strategies (i.e., avoiding or ignoring the stressor). However, some recent work has pointed to the limits of active coping styles as well (see, e.g., Brody et al., 2013).

Group identification (the extent to which one feels strongly connected to one's group) also influences responses to discrimination and prejudice. Several correlational studies point to group identification as a buffering factor for mental health. This research suggests that feeling connected to one's group makes discrimination less distressing and less likely to lead to depression (e.g., Mossakowski, 2003). However, experimental work suggests that group identification can also exacerbate the extent to which group-based discrimination is stressful. For example, Eliezer, Major, and Mendes (2010) found that for women high in gender identification, reading about sexism resulted in a more sustained cardiovascular threat response and anxiety compared with women low in gender identification.

Beliefs about fairness also shape how individuals perceive and cope with discrimination and prejudice. Specifically, the negative effects of discrimination on physical health tend to be more pronounced for Black Americans and women who believe the world was fair compared with those who believed the world was generally unfair. Dover, Major, Kunstman, and Sawyer (2015) found that Latino individuals who were treated unfairly by a White peer exhibited a maladaptive cardiovascular profile only when they generally saw the system as fair (vs. unfair). When Latinos believed the world was unfair, they responded to discrimination with an adaptive cardiovascular response. Research in this area suggests that believing that the social system is unfair can potentially buffer individuals from the stress of acute experiences of discrimination and prejudice.

Conclusion

The health implications of prejudice and discrimination are clear: a large body of work has documented the numerous direct and indirect pathways through which discrimination and prejudice undermine the heath of targets. While important strides have been made over the past decade to unpack the mechanisms through which discrimination can lead to poor physical health, added research is clearly warranted. In particular there is a need for theoretically based research that integrates multiple methods (e.g., experimental and intensive longitudinal designs) and additional dimensions of prejudice and discrimination (e.g., discrimination-related vigilance) with indicators of physical health that span levels of analysis (e.g., biological/physiological, behavioral) to more accurately and adequately capture the health effects of prejudice and discrimination. Moreover, additional emphasis should be placed on understanding the individual and system-level variables that moderate how individuals cope with discrimination and prejudice. Ultimately, this will foster a better understanding of these processes and allow researchers, policy makers, and public health practitioners to create theoretically and empirically supported interventions to ameliorate the undue health burden associated with prejudice and discrimination.

Author Biographies

Tessa L. Dover is a social psychology PhD candidate in UC Santa Barbara's Department of Psychological and Brain Sciences. She researches the mental and physical health consequences of group-based unfairness among high-status and low-status groups. Her main focus involves the interplay between group status and fairness beliefs in predicting responses to identity-relevant social cues.

Jeffrey M. Hunger is a doctoral candidate in social psychology at the University of California, Santa Barbara. Broadly speaking, he is interested in using insights from social, personality, and health psychology to understand and improve the well-being of stigmatized populations. His current research focuses primarily on the mental and physical health consequences of weight stigma.

Dr. Brenda Major is a distinguished professor in the Department of Psychological and Brain Sciences at the University of California, Santa Barbara. She is an international expert in the psychology of stigma and how people perceive and cope with stigma and discrimination. A core theme of her work is psychological resilience—how people maintain their sense of self-esteem, psychological well-being, and physical health despite exposure to discrimination, negative life events, and adversity.

The Health Correlates and Consequences of Friendship

Robert G. Kent de Grey and Bert N. Uchino

Department of Psychology, University of Utah, Salt Lake City, UT, USA

In his *Nicomachean Ethics*, Aristotle is credited as stating, "a friend is a second self." Friendships, however, entail importance beyond the pleasant affective experience of having close others. Social ties are critical to cognitive and affective development across the lifespan and have benefits beyond this as well. In a recent meta-analysis involving more than 308,000 participants, the quality of one's social relationships was linked with reduced risk of mortality (Holt-Lunstad, Smith, & Layton, 2010). The magnitude of this association was comparable with smoking cessation and exceeded many other conventional risk factors (e.g., physical inactivity, obesity).

Although most of the prior epidemiological work has not separated out specific relationship types (e.g., family, friends), there are strong reasons to believe that friendships in particular might be important to health. In contrast to relationships with family members, friendships are voluntary (nonbinding) relationships and thus are an important source of support across a variety of situations. Of course, this does not mean that friends have entirely positive influences. Under some circumstances friendships may adversely relate to health. In the present entry, we thus provide a general overview on links between friendships and health, including potential mechanisms, individual differences, intervention opportunities, and important future directions.

Epidemiological Evidence Linking Friendships to Health

Research suggests friendships may decrease risk for health problems and early mortality. These health benefits are evident across the lifespan and can be seen in early life friendships. In a long-term study, researchers assessed the number of friendships reported by 5,814 Scottish schoolchildren and linked them to self-rated health 36–39 years later (Almquist, 2012). For women, a greater number of childhood friends correlated with higher ratings of health. Among male participants, those who listed no friends at the time of the initial survey reported lower adult health

quality. Finally, another large-scale study of 11,617 adolescents reported on their experiences with close friends. Fourteen years later, analysis of HbA1c (glycohemoglobin, an index of blood glucose levels associated with, and used in the monitoring of, diabetes mellitus) showed that, for female participants, having close male friendships was associated with reduced odds of elevated metabolic risk marker levels (Ehrlich, Hoyt, Sumner, McDade, & Adam, 2015).

It is also important to note that the health correlates and consequences of friendship can sometimes approach or exceed the effect size for social support from family members. For instance, in an analysis using data from the longitudinal Health and Retirement Study, 7,514 US adults were surveyed in 2006 regarding social environmental variables. These responses were used to predict the onset of six conditions (high blood pressure, heart condition, cancer, stroke, lung disease, and arthritis) in 2010. Factors related to friends were more predictive of these health outcomes than factors related to family (Hill, Weston, & Jackson, 2014). In summary, although more work is needed, the available epidemiological evidence suggests that friendships are consequential for health.

Mechanisms Linking Friendships to Health

Mechanisms underlying the association between friendships and health are made salient by two major perspectives: the stress-buffering and direct effects models. Of these theoretical approaches, the more well known is the stress-buffering hypothesis, which holds that social support is healthy primarily because it buffers against the damaging effects of stress. Stress arises in part from the appraisal process—the evaluation of our coping abilities and the demands placed on them. Social support may decrease the perceived and objective coping burdens relative to available resources, as support has been shown to lessen the negative effects of many types of stressors.

The stress-buffering model has been tested with regard to friends in well-controlled laboratory studies. For instance, Christenfeld et al. (1997) examined this by stressing participants with a speech task and assigning them to receive support from a friend or stranger (confederate), or to receive no support. Social support from a friend resulted in the largest reduction in cardiovascular reactivity during stress. Compellingly, supportive behaviors were standardized across conditions, suggesting that differences were not due to friends merely knowing participants more intimately and providing better support on the basis of this knowledge. Although support from friends in such studies is generally beneficial, some studies have revealed more complex results and led to the suggestion that future work should pay closer attention to the support context, for example preferences for support.

In addition to the stress-buffering hypothesis, another major perspective is the direct effects model. This perspective broadly emphasizes the overall benefits of integration into a social network. Social control is one important aspect of this model and suggests that embedment in a social network is healthy because it creates social roles that provide self-esteem and meaning in life. Friends and others may also exert direct social control by attempting to influence individuals to change their health behaviors. Consistent with the social control hypothesis, an analysis of 469 elderly members of a Thai community found friends (but not family) had a direct link to health promoting behaviors such as exercise, healthful eating, and stress management (Thanakwang & Soonthorndhada, 2011).

Friendships may also be related to health behaviors that are not completely voluntary. A relatively large literature suggests aspects of sleep, such as quality and duration, are related to health outcomes, including mortality rates. In a community sample of 175 US middle-aged to older adults, participants reported how many friends/family ties they had and characterized the quality of those friendships. The number of supportive friendships (but not supportive family members) was a significant predictor of better self-reported sleep quality (Kent, Uchino, Cribbet, Bowen, & Smith, 2015).

While the overall findings for the direct effects model suggest that friendships can contribute to positive health behaviors, relationships can have negative consequences in some circumstances (e.g., risk taking and substance abuse). In addition, overt social control may arouse resentment or serve as a source of significant stress if the individual is unwilling or unable to engage in healthy behavioral change. For instance, one study found that perceptions of direct social network control (including friends) was related to greater aging at the cellular level (Uchino et al., 2015). Similarly, research suggests that receiving highly visible social support from friends or others may harm self-esteem or contribute to depression, both of which may be detrimental to health. Thus, high levels of direct social control and highly visible or unsolicited social support appear to relate to negative health outcomes.

Friendships may also have negative influences on health via normative influences (Rook & Pietromonaco, 1987). For example, the social interconnection of 12,067 adults in the Framingham Heart Study was repeatedly assessed along with body mass index (BMI) from 1971 to 2003. Longitudinal models showed that the chances of becoming obese increased 37% if one's spouse became obese and rose by 40% if one's adult sibling became obese, but the largest increase was a 57% greater risk of obesity if a participant had a friend who became obese during the study (Christakis & Fowler, 2007). This social contagion of bad health habits via friends is consistent with findings indicating that friends are surprisingly similar on measures such as frequency and duration of participation in organized physical activity, fast-food habits, body image, and alcohol use (see, e.g., Fletcher, Bonell, & Sorhaindo, 2011). This phenomenon of friend similarity in alcohol use is well documented in university settings, where social norms have been found to exert large influence on drinking behaviors, even when such norms do not reflect the beliefs of most individual students.

Individual Differences, Friendships, and Health

A number of factors may influence the relationship between friendship and health. Men and women differ in important ways that may relate to friendship. One possibility is that females may be more sensitive to the quality of their relationships due to more complex relational schemata. For instance, women may be more affected by adverse interpersonal processes because their self-esteem is more contingent on interpersonal functioning. Women may thus be more sensitive to or expend greater effort in response to relationship concerns. This may translate to health-relevant physiological processes as well; a study of 303 normotensive adults found that conflict within close relationships predicted nocturnal blood pressure dipping for women, but not for men (Holt-Lunstad, Jones, & Birmingham, 2009). Absence of such nightly decreases in blood pressure has been shown to predict both cardiovascular and all-cause mortality.

Exploration of cultural differences is also an area of increasing interest in relationships and health. Importantly, friendship appears to have value and health relevance across many nations, though its specific relation to aspects of well-being may vary. Most of this work has focused on differences between individualistic and collective (especially Asian) cultures. In such work, there is a significant distinction between explicit (i.e., seeking and using support) and implicit (i.e., the comfort of simply having close relationships) support. Due to relational concerns (e.g., worries about placing a burden on friends who are obligated to be helpful), individuals from more collective cultures may experience greater benefit during stress from implicit forms of support, in which they simply feel more connected with others.

Interventions Utilizing Friends and their Influence on Health

The research reviewed thus far suggests that interventions targeting friendships might be useful in improving health outcomes. Although more work is certainly needed in this area, several intervention approaches are consistent with this possibility. "Befriending" specifically focuses on the friendship formation processes by recruiting outside relationships to serve as the basis for affirming social support over time. A meta-analysis suggests a modest effect for such interventions in improving outcomes in different patient populations (e.g., caregivers, prostate cancer patients; Mead, Lester, Chew-Graham, Gask, & Bower, 2010).

Another important intervention related to building friendships involves support groups. Interventions examining peer support groups suggest beneficial effects on adjustment and well-being (Hogan, Linden, & Najarian, 2002). Researchers have also found that participation in support groups seems to influence the size and composition of one's friendship network. For instance, studies of individuals with substance abuse problems suggest that self-help groups result in decreased contact with drug-using network members and increased contact with support group friends (Humphreys & Noke, 1997). These network members then become crucial sources of support in offering advice and guidance to help individuals remain abstinent.

Success has also been shown for relationship interventions that teach individuals the skills necessary to acquire responsive support (Hogan et al., 2002). In one intervention, adolescents were assigned to enroll in a semester-long course that focused on friendship development as well as positive peer and teacher relationships (Eggert, Thompson, Herting, Nicholas, & Dicker, 1994). Students also learned how to elicit support regarding personal problems. Results of this study showed that individuals in the intervention had an increase in their friendships and in self-esteem. Moreover, compared with adolescents not provided with the intervention, individuals with social skills training showed a trend toward less drug use, a decrease in drug-related problems, and an increase in grade point average.

More generally, friends may be an important source of support for individuals attempting healthy behavioral change. In one study, researchers combined a support intervention with standard behavioral treatment (SBT) for weight loss (Wing & Jeffery, 1999). Participants either came alone or were asked to bring three friends who were interested in weight loss. Importantly, individuals who participated in the support intervention with friends were more likely to complete the program and maintain their weight loss over the 10-month period. One interesting aspect of this study was the finding that individuals who recruited three friends to join them for the protocol were less likely to have participated in prior organized weight-loss programs. These data suggest an additional benefit of recruitment with friends as it may increase participation for individuals who may not wish to go alone. In summary, although more work is needed, the existing literature highlights the promise of friendship-based interventions to improving health outcomes.

Future Directions

As reviewed in this entry, friendships can have both positive and negative influences on health. Of course, this is true of family relationships as well, and future work that directly contrasts different types of relationships and the functions they serve will be important to advance theory and highlight unique intervention opportunities. Future work should also examine the utility of considering positive and negative aspects of relationships in combination. Corresponding to the colloquial concept of the "frenemy," an ambivalent friend is one characterized by both high levels of positivity and negativity. Although one might ask why we would continue to be friends with such ambivalent ties, research indicates that individuals have a sense of commitment to them based on a long history of interactions. Importantly, existing research indicates that friendship ambivalence is quite common and related to negative health-relevant biological outcomes (Holt-Lunstad, Uchino, Smith, & Hicks, 2007).

It is also impossible to ignore the fact that an increasing proportion of social interaction takes place online. Scientific examination of differences between online and offline friendships is still in its infancy. People may be more willing to self-disclose when getting to know someone online vs. in person, which could facilitate friendship formation. The Internet may also preserve friendships that would otherwise deteriorate over time. In one study, the number of Facebook friends was a stronger predictor (vs. offline interpersonal network size) of perceived social support, less physical illness, and greater well-being among participants with a high number of objective life stressors (Nabi, Prestin, & So, 2013). While causality in such research presently remains largely unknown, research indicates that Facebook members who use the site multiple times daily score eight percentage points higher than average Americans on a measure of social support (Hampton, Goulet, Rainie, & Purcell, 2011). The same researchers interpret their findings to mean that "someone who uses Facebook multiple times per day gets about half the boost in total support that someone receives from being married or living with a partner" (Hampton et al., 2011, p. 35). While this claim requires a great deal of additional research before substantiation, such a bold statement hints at the potential importance of this emerging research area.

As mentioned above, much existing epidemiological research does not separate specific relationship types (e.g. friends, family, coworkers). Future work should distinguish between relationship categories to show how friendships may differ from other social ties in terms of health relevance. When relationship types are aggregated, researchers may not be able to detect effects that pertain to specific kinds of social ties (see, for example, Kent et al., 2015).

Conclusions

Friendship may serve as an important source of social support during stress, promote healthy behaviors, and contribute to healthful social norms, all of which may link to positive health outcomes. However, unsolicited, intrusive, or highly visible support attempts, as well as direct social control, may be mechanisms by which friendships can adversely influence health. Additional research is needed to more fully understand the health consequences and mechanisms associated with friendship, which can rival family relationships in terms of health relevance.

Author Biographies

Robert G. Kent de Grey, MS, is a PhD candidate in social and health psychology at the University of Utah studying relationships and health. He also researches in the Cancer Control and Population Sciences Program at the Huntsman Cancer Institute. Specific subareas of interest include online social networks and virtual interactions, as well as proenvironmental attitudes and behaviors. He serves as a consulting environmental and social psychologist to the University of Utah Sustainability Office.

Bert N. Uchino, PhD, is a professor of social and health psychology at the University of Utah. His graduate studies at The Ohio State University were supervised by Dr. John T. Cacioppo. Uchino also researches the influence of social factors on aging processes as part of the Interdepartmental Program in Neuroscience at the University of Utah. In 2004, Yale University Press published his book *Social Support and Physical Health: Understanding the Health Consequences of Relationships.*

Health Correlates and Consequences of Social Comparison

Dana M. Litt[1], Anne M. Fairlie[1], Melissa A. Lewis[1], and Michelle L. Stock[2]

[1]Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, USA
[2]Department of Psychological & Brain Sciences, The George Washington University, Washington, DC, USA

Based on the rapid growth of health psychology over the past few decades, it is clear that issues surrounding health and disease have been major areas of study in modern psychological research. Although there are many psychological approaches and theories that have been applied to health psychology, social comparison theory (Festinger, 1954) has proven to be one of the most important for applications to health-related cognitions and behaviors (Buunk & Gibbons, 1997). Social comparison was originally conceived as a way for people to evaluate themselves in the absence of objective standards (Festinger, 1954) and has been further suggested to be a process through which people search for self-relevant information and how to gain important self-knowledge (e.g., Buunk & Gibbons, 1997). Although Festinger and other early social comparison researchers did not directly discuss social comparison in relation to health behaviors, researchers have argued that the theory is directly relevant to many health-related issues (Buunk & Gibbons, 1997; Litt, Stock, & Gibbons, 2014). As such, a more recent literature has examined the role that social comparison plays in health risk behaviors (Gibbons, Stock, Gerrard, & Finneran, 2015). This is not surprising given that past research has shown that people's risk judgments and decisions are highly affected by comparative reference points (van der Pligt, 1996). Additionally, in a volume that summarized applications of social comparison theory to health (Buunk & Gibbons, 1997), research indicated that people compare themselves with risk prototypes as well as other people who currently engage in risk behaviors when considering whether or not to engage in risky behavior (Gibbons et al., 2015). Combined, this research suggests that social comparisons play an important role in decisions to engage in health risk behaviors.

As this chapter will show, social comparison theory has contributed significantly to the theoretical foundation of health psychology. The primary goal of this entry is to provide a brief

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

overview of social comparison theory, highlight specific scientific developments related to health behavior, summarize the role that social comparison plays on health and illness, describe the role that social comparison plays in both the etiology and intervention of health and health risk behaviors, and describe important future research directions.

Social Comparison and Illness/Disease

The role of social comparison in mental and physical health has received considerable attention across a broad range of areas including cancer (Brakel, Dijkstra, & Buunk, 2012), diabetes (Schokker et al., 2010), and HIV (Siegel, Lekas, Schrimshaw, & Brown-Bradley, 2011). People dealing with illness and disease symptoms may evaluate their own attitudes, behaviors, and circumstances as a way to understand themselves, process their emotions, and guide future behavior (Suls, Martin, & Leventhal, 1997). As part of the self-evaluation process, people compare themselves with other individuals who are also dealing with the illness, particularly in cases where there is uncertainty regarding their own health or treatment (Suls et al., 1997).

Social comparison can play a role in how individuals manage and cope with chronic illness in a variety of ways. Direction of the comparison refers to the standing of the target in relation to that of the person making the comparison. In the case of illness, upward comparisons are in reference to someone who is perceived as better off (e.g., more responsive to treatment, fewer symptoms), and downward comparisons are in reference to someone who is perceived as worse off (e.g., less likely to fully recover). Perceived similarity to the target may be based on a range of attributes, including illness severity, the type of treatment being received, and even basic demographics (e.g., age, gender). Mode of comparison refers to the manner in which the person learns about the comparison target. Information about a target can be obtained proximally through contact or affiliation with the target (e.g., other patients), distally whereby a person may receive information about the target from another source (e.g., media, another person without the illness) or even through fabricated targets (Buunk & Gibbons, 1997). People may either identify with the target by perceiving themselves as similar to or likely to become similar to the target, or they may make contrasts between themselves and the target such that differences between themselves and the target are highlighted (Mussweiler, Ruter, & Epstude, 2004). Arigo, Suls, and Smyth (2014) found that identifying with or interacting with someone who is perceived to be coping better (upward identification) as well as contrasting oneself to or being exposed to information about someone whose illness is more severe (downward contrast) can be beneficial to patients. In addition, people who are high in neuroticism may frequently engage in social comparison without receiving its beneficial effects and may instead reinforce negative self-perceptions (Buunk & Gibbons, 1997).

People may also compare their attitudes and situation to that of others in order to gain information about the course of the disease, treatment/care, or their likelihood of recovery as well as to gauge how well they are coping with the disease and managing their symptoms. A recent review by Arigo, Suls, et al. (2014) summarized social comparison research that focused on individuals with chronic illnesses. Of the 37 studies included in the review, almost half of the studies included samples of patients currently diagnosed with cancer or in remission, while the remaining studies included samples of patients diagnosed with a variety of diseases including arthritis and cardiovascular disease. Despite some ambiguous results, several consistent trends emerged as a result of this review. For one, identifying or having actual contact with someone who is coping better tends to be beneficial for patients. However, being exposed to information about someone with more severe illness tends to be less beneficial. In contrast, downward comparisons about coping and upward comparisons about illness severity seem to be unhelpful.

Social comparison processes may operate at different points during the course of an illness, ranging from the individual's initial evaluation of symptoms to the individual's decision about treatment planning once the illness has become severe. In order to receive healthcare, a person must first decide to seek out medical care in order to obtain an evaluation of his or her symptoms, which can result in a diagnosis and a treatment plan. Research has shown that social comparison processes can enhance or impede the decision to seek medical treatment (Suls et al., 1997). Mojitabai (2008) demonstrated that, among adults in the United States, individuals who perceived themselves as more worried or anxious than others were more likely to seek care from a doctor or mental health professional compared with those who did not perceive themselves as more worried or anxious. Therefore, social comparison processes come into play early on as individuals consider their symptoms and decide whether or not treatment, or even consultation with a health professional, is needed. The occurrence of seeking delayed care, after the onset of symptoms such that the illness has had a chance to progress, also has implications for the severity of symptoms among those being treated. Delayed onset of care has further implications for the role of social comparison processes once a diagnosis has been made and individuals are seeking treatment. For example, if for a particular type of illness or symptom, people tend to delay the onset of healthcare, the "typical" patient may be more sick than an individual who chooses to receive medical attention early.

As noted by Arigo, Suls, et al. (2014), studies on illness and disease have varied greatly with respect to the type of disease (e.g., arthritis, HIV, sickle cell disease) or even the subtype of the disease (e.g., lung cancer, breast cancer). Moreover, certain diseases may be perceived as being more directly tied to an individual's behaviors, which may suggest specific behavioral changes that may aid in controlling or managing the illness in as far as the behaviors can reduce symptom severity and slow disease progression. In addition to the type of illness or disease, social comparison processes may operate differently depending on other characteristics or features of the disease (e.g., severity, clinical prognosis, treatment options, perceived control over managing symptoms). Social comparisons may also serve different functions and result in different outcomes depending on the stage of diagnosis or treatment (e.g., time of initial diagnosis, ten years since diagnosis) and the patient's current health status. For example, research has shown that individuals who were previously treated for cancer responded differently to social comparison information on coping strategies and negative emotions, such that self-reported quality of life varied by the patient's current physical health and the individual's sensitivity to social comparison (Brakel et al., 2012).

Much work on social comparison has evaluated the roles of upward and downward comparisons in relation to individuals' attitudes, perceptions of health or illness, and behaviors. However, comparative optimism has been given particular attention in the literature given its role in illness and risk perception. Comparative optimism, which is well documented in the literature on social comparison, refers to an individual's belief of being at lower risk for a health-related issue or other negative event or the belief of being better at something than his or her peers (Harris, Griffin, & Murray, 2008). In some ways this relates to the lay notion that adolescents tend to believe that a negative outcome (e.g., contracting a sexually transmitted infection from unprotected sex) will not happen to them; instead adolescents tend to perceive that others, who are presumably unlike them, are more at risk for experiencing the negative outcome. Comparative optimism does not account for the degree of accuracy in the perception of risk. At times, the perception of being at lower risk may be accurate; however, when the perception of being at lower risk is inaccurate, this results in bias or unrealistic optimism (Suls et al., 1997).

Social Comparison and Risky Behaviors

Social Comparison as a Predictor of Risk

People may compare themselves to others with respect to virtually any attribute or behavior. Comparisons can be made with varying levels of human interaction such that the target of the comparison may be identified in the media or it may be the person sitting next to someone on the bus. Given the far-reaching applications of social comparison theory, a large body of research has evaluated social comparison processes in the areas of health and risk behaviors. Notably, social comparison is implicated in specific models of health risk behavior such as the prototype willingness model (see Gibbons et al., 2015 for a review). At the heart of this theory is the notion that prototypes, or social images of the typical person who engages in a health risk behavior, influence behavior through a social comparison process (Gibbons et al., 2015).

Although too vast to review in detail, there has been extensive work examining social comparison processes in the areas of unhealthy eating behaviors, body image, and body dissatisfaction (Arigo, Schumacher, & Martin, 2014; Fitzsimmons-Craft et al., 2015). Other health and risk behaviors for which social comparison processes have been evaluated are sexual behavior (Fielder, Walsh, Carey, & Carey, 2013) and substance use (Litt et al., 2014).

Social Comparison Orientation as a Moderator of Risk Cognitions

People vary in the extent to which they compare themselves to others as a way to evaluate their own attitudes and behaviors, and studies have found that links between risk cognitions and behaviors vary according to the degree to which individuals engage in social comparison (Litt et al., 2014). Social comparison orientation pertains to the extent to which individuals compare their own attitudes and behaviors to that of their family and/or peers (Litt et al., 2014; Litt, Lewis, Stahlbrandt, Firth, & Neighbors, 2012).

Social comparison orientation has been shown to moderate the link between same-sex descriptive drinking norms (i.e., perceived quantity and frequency of alcohol consumption of the typical male/female) and alcohol-related consequences, but not alcohol use, among college students (Litt et al., 2012). Among those higher in social comparison, descriptive norms for drinking were positively associated with alcohol-related negative consequences; among those lower in social comparison, the association between descriptive norms for drinking and consequences was not significant. More recent research found that social comparison orientation moderated the effects of perceived friend use and sibling use on change in alcohol use over three years such that adolescents who reported engaging in social comparison more often reported greater increases in alcohol use when perceived friend use or sibling use was high (Litt et al., 2014). Future research is warranted on the manner in which social comparison processes may modify the effects of other known risk factors, including but not limited to perceived social norms.

Social Comparison and Intervention

Relatively little research has *formally* evaluated social comparison theory in the context of health behavior interventions. It should be noted that many constructs such as social norms or unrealistic optimism are directly implied and implicitly connected to social comparison theory but are not central to social comparison theory per se. Moreover, most conceptualizations of peer influence require social comparisons as an integral part of the influence process. In order for others to have indirect influence on us (as opposed to direct requests to engage in a particular behavior), we must consider their expectations. Thus, while there are a few formal studies focusing directly on social comparison theory-based interventions, it has been suggested that there are few studies related to social influence and health behavior that are not related to social comparison theory. For this chapter we focused on interventions in which social comparison interventions were formally evaluated or in which social comparison orientation was evaluated as a moderator of intervention efficacy.

In another study, Mahler, Kulik, Gerrard, and Gibbons (2010) examined the impact of adding upward or downward social comparison information on the efficacy of an appearance-based sun protection intervention (UV photos and photoaging information). College students were randomly assigned to one of four conditions: control, intervention, intervention plus upward social comparison, and intervention plus downward social comparison. The results demonstrated that all those who received the basic UV photo/photoaging intervention reported greater perceived susceptibility to photoaging, less favorable tanning cognitions, and greater intentions to protect themselves from the sun relative to controls. Of specific interest to social comparison, while the basic intervention increased sun protective behavior during the subsequent 5 weeks relative to controls, the addition of downward comparison information negated this benefit. Moreover, upward comparison information produced sun protection levels that were only slightly (and nonsignificantly) greater than in the basic intervention condition. Thus, these findings did not support an addition of a social comparison component.

As mentioned above, social comparison orientation has been evaluated as a moderator of an intervention aimed to reduce high-risk drinking and negative consequences (Carey, Henson, Carey, & Maisto, 2007). Findings indicated that the personalized feedback intervention that included a normative comparison component was less efficacious for individuals who were higher in social comparison, which suggests that individuals who are higher in social comparison are strongly influenced by the perceived behavior of others. In addition, as Carey et al. (2007) found, the influence of perceived behavior may be more difficult to change for those higher in social comparison. One reason this may be is that individuals who are higher in social comparison may be more aware of the health and/or behaviors around them. Thus, when taking into consideration the normative comparison information designed to initiate social comparison in an intervention study, those higher in social comparison orientation may also have more instances to rely on. Having more sources of information to draw from may lead those higher in social comparison to be defensive or to disregard the normative information presented in an intervention.

Based on the few studies in which social comparison theory has been formally evaluated with intervention studies, findings provide mixed support. Of importance, these studies are across various health behaviors. Future research is needed to examine multiple social comparison-based interventions for one health behavior.

Future Directions

Clearly, social comparison theory has greatly enhanced our knowledge about a number of important health-related processes and outcomes. Through the years, social comparison theory has grown from a relatively narrowly defined theory into one that sheds light on a broad cross section of human behavior including health behaviors. The application of social comparison theory to health is continuously expanding, with more and more issues being explored from a social comparison perspective. Despite the huge growths in this area of inquiry, there are still several issues that remain to be fully resolved and as such should be the focus of future research. One promising area of inquiry comes out of the dual-processing literature (Gibbons et al., 2015), specifically examining the extent to which social comparisons are the result of more heuristic and affective processing versus reasoned and thoughtful processing. Although there is preliminary work indicating that social comparison moderates health cognitions (e.g., descriptive norms, prototypes, willingness) within the more socially reactive, heuristic, and affective processing pathways of dual-processing models such as the prototype willingness model (Gibbons et al., 2015; Litt et al., 2014; Stock, Gibbons, Beekman, & Gerrard, 2015), the process through which social comparison operates in the greater scheme of decisions regarding health behaviors and health risk behaviors still deserves attention. It is also important that research bridging social psychology and neuroscience approaches be conducted. We anticipate work in the future that will examine brain activity during different types of comparison processes and opportunities (e.g., can reactions to upward versus downward comparison be detected at a neural level?). Are different parts of the brain activated depending on who the comparison target is or what health dimension is being compared, or whether the comparison is made in relation to health risk or health protective behaviors. An additional important avenue for future research is directly related to the functionality of social comparison as a means to effect positive changes for health-related behavior. Specifically, there is a need for research that looks at the motivational effects of induced comparison with certain targets, for example, healthy eaters or light drinkers, to determine if social comparison can be harnessed in such a way to directly impact health-related outcomes. Finally, social comparison has implications for individual-level interventions that include both personal and comparison-based risk information (Stock et al., 2015). In particular, interventions that offer personalized feedback, including social norms, may be more effective for individuals who tend to compare their own attitudes and behaviors to that of others. Future research should continue to examine the ways in which social comparison is integrated into interventions as well as whether interventions should be targeted to those most likely to make social comparisons on health dimensions. Overall, we remain optimistic that more light will be shed on many unresolved issues in the coming years, and we see an active future ahead for social comparison theory and its applications to health behavior.

Author Biographies

Dana M. Litt, PhD, is an assistant professor at the University of Washington in the Department of Psychiatry and Behavioral Sciences. Dr. Litt's primary research interests lie in examining social psychological principles as applied to the etiology and prevention of health-related risk behaviors. Her research addresses questions related to the utility of including socially based variables in prevention programming for substance use, particularly with respect to social comparison, social images, and social norms.

Anne M. Fairlie, PhD, is an acting assistant professor in the Department of Psychiatry and Behavioral Sciences at the University of Washington. Dr. Fairlie's research focuses on psychosocial factors influencing substance use among young adults. In particular, she is interested in how occasion-specific psychological and contextual factors predict day-to-day variations in alcohol use, including extreme drinking and negative consequences.

Melissa A. Lewis, PhD, is a full professor in the Department of Psychiatry and Behavioral Sciences at the University of Washington. Dr. Lewis' research interests lie in examining social psychological principles in broadly defined health-related behaviors. She studies social and motivational mechanisms involved in etiology and prevention of addictive and high-risk behaviors (e.g., drinking, risky sexual behavior, hooking up). She has expertise in personalized feedback interventions aimed at reducing drinking and related risky sexual behavior.

Michelle L. Stock, PhD, is an associate professor in the Department of Psychology at The George Washington University. She received her PhD in psychology from Iowa State University in 2007. Dr. Stock's program of research includes a focus on the application of the prototype willingness model and social comparison processes to provide a framework for understanding cognitive (heuristic and reasoned), affective, and situational factors that influence risky health decisions.

Health Effects of Traumatic Events

Judith Andersen[1] and Roxane Cohen Silver[2]

[1]*Department of Psychology, University of Toronto, Mississauga, ON, Canada*
[2]*Department of Psychological Science, University of California, Irvine, Irvine, CA, USA*

Globally, traumatic stress is quite common. Each day, events such as war, natural disasters, accidents, and murders claim the lives of hundreds of people. Traumatic events are defined as those that threaten serious injury or threat of death to oneself or others or witnessing the death or serious injury of another person. When an individual's personal physical integrity is compromised, such as in the case of sexual assault, it is thought to be traumatic. Traumas can have specific characteristics and may impact individuals in different ways. For example, traumas can be experienced in childhood, adolescence, adulthood, or old age. Traumas can be individually or collectively experienced, and they can be acute (i.e., short term) or chronic.

There are different types of traumas to which people can be exposed. Individual traumas can include sudden and unexpected losses of persons or property. Interpersonal traumas are those that are perpetrated by humans against one another. There are traumas shared by communities, such as gang violence and school shootings. Natural disasters like hurricanes and earthquakes displace thousands of people and can bring suffering, injury, homelessness, and even death to many individuals. Mass traumas such as terrorist attacks are becoming more common around the world. Researchers have posited that traumas may be organized into the following categories: injury and illness (e.g., witnessing or experiencing an accident, serious illness or injury), loss (e.g., death of close other), social environmental events (e.g., financial hardship, homelessness, discrimination, exposure to chemical or biological agents), relationship events (e.g., forced separation from family, marital discord, unwanted pregnancy), natural disaster (e.g., flood, fire, earthquake), interpersonal violence (e.g., rape, sexual or physical abuse), and collective violence (e.g., loss of loved one to homicide or suicide, witnessed violence between parents or adults, war exposure) (see e.g., Blum, Silver, & Poulin, 2014).

Within the last 50 years, healthcare providers working with individuals who previously experienced trauma, such as war veterans and survivors of childhood maltreatment, began to notice a link between trauma experiences and physical health problems. Researchers began to investigate how traumatic experiences may lead to chronic disease and health ailments over time.

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

We now understand that there are a number of direct and indirect pathways by which traumatic experiences may lead to medical ailments and chronic disease conditions.

For example, trauma may directly impact health through injury or death from the experience itself, such as in the case of physical abuse or war wounds. Alternatively, the experience of trauma can stimulate stress processes that, over time, are maladaptive to physical health. Developments in neuroscience and neurobiology have shown that the internal, physical pathways by which traumatic experiences can lead to physical health problems include the possibility that an individual's stress response may become more sensitive, resulting in problems regulating blood pressure, glucose metabolism, the immune system, and even gene expression. It is also possible that ongoing disruption in core biological processes such as stress hormones and cardiovascular function can lead to chronic disease conditions over time, especially if the individual does not seek medical care.

McEwen (2002) reviewed the process by which the experience of severe stress impacts the body. Specifically, when encountering severe stress, the body responds by activating a cascade of neurochemical reactions involving the sympathetic branch of the autonomic nervous system and the hypothalamic–pituitary–adrenal (HPA) axis. These activating chemicals stimulate the liver to produce high amounts of glucose (high blood sugar) and directly speed up heart rate and respiration. While these processes are adaptive when stressors are short term and resolved quickly, it is clear that if the stress response is chronically activated or unable to shut off, individuals are at risk of diabetes (high blood sugar), as well as respiratory, immune, digestive, and cardiovascular problems. Long-term cardiovascular activation is associated with high blood pressure and the possible development of atherosclerosis. Further, these core physiological systems work synergistically, and their disruption is thought to contribute to many comorbid diseases and even early mortality.

There are also indirect pathways by which trauma exposure has been shown to impact physical health. The most common are behavioral and psychological mechanisms. For example, often when an individual experiences a traumatic stressor, it is unexpected and overwhelming. Many people do not have the coping resources necessary to manage the emotional distress or life disruption associated with the event. Therefore, as a coping strategy, individuals may engage in negative health behaviors such as poor sleep habits, poor diet, excessive alcohol or drug use, or smoking. Researchers have demonstrated that negative health behaviors are related to many physical health problems and chronic conditions, including obesity, cancer, heart disease, pain, and other health conditions.

Following a traumatic experience, many individuals may also experience mental or emotional distress such as anxiety or depressive symptoms. While most individuals recover their equilibrium in the months following the experience, some individuals develop more severe symptoms of clinically diagnosable mental health conditions. Anxiety disorders such as posttraumatic stress disorder (PTSD) and mood disorders are common mental health conditions associated with traumatic exposure. Decades of research have demonstrated that the symptoms of anxiety and depressive disorders are associated with disruptions in the sympathetic nervous system and the HPA axis (Schnurr & Green, 2004). Specifically, PTSD is associated with high cardiovascular reactivity to stress and disrupted levels of cortisol, a central stress hormone in the HPA axis, which is implicated in many organic and somatic disease conditions. Specific symptoms of PTSD, such as hyperarousal, are associated with repeated activation of the cardiovascular system, which is associated with high blood pressure, atherosclerosis, hypercoagulation, and cardiac arrhythmias that may result in myocardial infarction. Depressive symptoms such as apathy and exhaustion are related to disruption in HPA functioning, specifically cortisol and the corticotrophin-releasing hormone (CRH). Further, depression is associated with disruptions in the immune system due to HPA activity and maladaptive levels of cortisol. Specifically, researchers posit that specific immune chemicals, called cytokines, are more active in depressed individuals (Loftis, Huckans, & Morasco, 2010). Cytokines signal "sickness behavior" by causing the skin and body to feel pain and exhaustion in order to stimulate the individual to slow down and let the immune system identify and manage the invader. However, in the case of depression, it is not a bacterial or viral infection but rather emotional distress that is related to disruptions in cortisol that further stimulate cytokine activation. The resulting pain and tiredness are symptoms that further exacerbate feelings of depression.

Health problems stemming from traumatic exposures may differ depending on the type and length of exposure. For example, researchers studying the impact of acute trauma, such as exposure to the September 11th terrorist attacks, report a rise in risk of cardiovascular ailments in the 3 years following the attacks, with the greatest risk experienced by individuals who reported ongoing worry and anxiety about future attacks (Holman et al., 2008). Adolescents who have been bullied and harassed at school are more likely to report somatic complaints with no known cause (e.g., headaches, pain, gastrointestinal distress) and poorer overall general health. In the above examples, the mechanisms that seem to best explain both cardiovascular ailments and somatic complaints are the repeated activation of the stress response, colloquially known as the "fight-or-flight" response. This response is accompanied by emotions such as anger and fear and physical reactions such as an increase in breathing and heart rate. Further, digestion and immune processes are halted during fight or flight. Therefore, general gastrointestinal distress, pain, somatic complaints such as frequent colds and flus, and cardiovascular ailments like high blood pressure can result from frequent stress responses.

Some types of traumatic experiences are associated with severe health problems that occur in multiple systems of the body. For example, experiencing violence or childhood maltreatment such as physical and sexual abuse or neglect is considered particularly damaging for long-term health. The health effects of exposure to violence have also been studied in depth by researchers examining the experiences of combat veterans. Pizarro, Silver, and Prause (2006) found that among combat soldiers, exposure to trauma (e.g., witnessing death or dismemberment, losing friends or family in battle, fearing for one's life, killing other people) was directly related to physician-diagnosed cardiovascular disease and gastrointestinal ailments in later life. The age at which the soldiers were exposed to these traumatic events was also important to consider. The youngest soldiers who witnessed the most deadly combat had shorter lifespans, despite surviving the war itself.

Age at exposure to trauma is an important variable for understanding why childhood maltreatment is particularly detrimental for health. Childhood trauma has been linked to autoimmune conditions, cancer, heart disease, and sexual and reproductive health problems in later life. Scientists who study childhood development explain how the effects of childhood trauma may be so pernicious based on a theory of "biological imbedding." During childhood and adolescence, trauma may alter the shape and function of biological systems as they develop. For example, trauma may sensitize the HPA axis that impacts stress hormone function, stress response reactivity, and emotional competence. The development of brain areas associated with anxiety and depression, memory and attention, and attachment and social skills may also be negatively impacted by childhood trauma. Taken together, the adaptations the body is forced into making in response to childhood trauma exposure become maladaptive for health and functioning over the life course. Researchers conducting a study called the Adverse Childhood Experiences (ACE) research project (e.g., Felitti et al., 1998) interviewed thousands of adult survivors of childhood maltreatment and found a dose–response relationship between the number of adverse childhood experiences and both health risk behaviors and chronic disease.

These researchers report that individuals who experienced four or more adverse childhood experiences were two times more likely to report ischemic heart disease, any cancer, and stroke.

While experiencing early, violent, or chronic trauma has clear implications for health, researchers have found that exposure to trauma does not always negatively impact health in a linear relationship. There are indications that there may be a curvilinear effect of trauma exposure on health (Seery, Holman, & Silver, 2010). Researchers uncovered nonlinear patterns by examining the health of individuals exposed to a collective trauma in adulthood. Results of this study revealed that individuals who had experienced one or two events, such as the death of a loved one or divorce, before the mass trauma faired better than individuals who had never experienced any negative events and those who had previously experienced frequent or severe traumas. The authors explain these findings in light of a human's propensity to seek coping resources and support in order to survive during times of stress. Those who had prior exposure to one or few traumas had the opportunity to garner social support and may have enhanced their confidence in their ability to cope during adversity. Those who had never experienced any trauma or who had experienced chronic or severe trauma may have been less able to garner the needed supports and coping resources.

The good news is that because clinicians and researchers have discovered both the indirect and direct links between trauma and physical health, there are treatments that help people recover from traumatic experiences and avoid chronic disease conditions and negative physical health symptoms. Health psychologists have worked to design interventions that reduce the likelihood that someone will become ill following trauma and approaches within a therapeutic context that improve health when an individual has already begun to experience physical health problems. Health interventions target psychosocial processes, such as negative mood, catastrophic thinking, excessive anxiety, depression, and worry. Research has shown that psychosocial processes and cognitions are directly linked to an individual's neuroendocrine and immune system and can exert negative and positive responses. Therapies can be divided into several categories and may be recommended to a patient based on his or her symptoms and preferred method of treatment. For example, there are cognitive behavioral stress management techniques and techniques that directly target maladaptive physiology. The National Center for PTSD is a repository of information about trauma and treatment. Recommended treatments for trauma include cognitive processing therapies and prolonged exposure therapy. Other therapeutic treatment options for trauma include approaches that directly target symptoms of stress, such as relaxation, meditation, emotional disclosure, and biofeedback. Sleep hygiene and substance abuse counseling may also be necessary if an individual is struggling in these domains. It is thought that effective therapies for trauma also improve health because they target both maladaptive coping behaviors and exaggerated stress reactivity that, over time, contributes to disease processes.

Social support and positive social interactions have been shown to be extremely helpful in preventing health problems following trauma and as a treatment intervention after health symptoms arise. For example, social support group therapy has been shown to improve the quality of life of cancer patients and even extend their lives. Researchers examining genetic factors in aging and illness have found that individuals in high stress environments and those experiencing traumatic stress are more likely to suffer from premature aging and health problems. The premature aging is demonstrated by the rapid shortening of their telomeres, the caps at the end of a person's chromosomes, which fray as a person ages. A therapeutic intervention to slow the process of premature aging includes social support groups specifically targeted to help individuals with the stress they are experiencing. Positive support during and following trauma also helps individuals to cope with traumatic stress without engaging in negative health behaviors that increase the risk of disease, such as drug and alcohol use or overeating.

In conclusion, researchers have demonstrated that trauma exposure is associated with an increased risk of physical health problems across the lifespan. Trauma exposure may strike individuals or may be experienced collectively by a population. Researchers have shown multiple pathways by which trauma exposure can raise health risks, such as through increased stress responses or immune disruption. Fortunately, factors such as social support and healthy living may protect individuals against the deleterious effects of trauma on health.

Author Biographies

Judith Andersen is an assistant professor in the Department of Psychology and Affiliated Faculty of Medicine at the University of Toronto, Mississauga. She is a health psychologist who specializes in the psychophysiology of stress and stress-related mental and physical health issues.

Roxane Cohen Silver is a professor of psychology and social behavior, public health, and medicine at the University of California, Irvine. Trained as a social psychologist, her research examines individual and community responses to stressful life experiences, including collective traumas such as terrorist attacks, war, and natural disasters.

Health Implications of Gratitude

Kristin Layous

Department of Psychology, California State University East Bay, Hayward, CA, USA

Most of the world's cultural, religious, and philosophical traditions celebrate gratitude as a virtue. Supporting the age-old wisdom about the importance of gratitude, accumulating empirical evidence demonstrates that gratitude is related to many social and psychological benefits. Specifically, cross-sectional, longitudinal, and experimental evidence reveals that a habit of gratitude is associated with greater well-being, more prosocial behavior, and better relationships (Wood, Froh, & Geraghty, 2010). In addition to these social psychological benefits, many researchers also suggest a link between gratitude and physical health. This entry reviews the literature on gratitude and psychological, social, and physical health, noting some complications and limitations as well as some promising findings.

Defining Gratitude

One confusing aspect of the gratitude literature is the multiple ways in which gratitude can be defined. Gratitude is a habit or trait (i.e., one's general tendency to be grateful), a state or emotion (i.e., a momentary feeling of gratitude), or an expression (i.e., one actively expresses gratitude verbally or in writing). Furthermore, some research focuses on gratitude as a response to a benefit received from another person (i.e., benefit-triggered gratitude; McCullough, Kilpatrick, Emmons, & Larson, 2001) or nonperson entity (e.g., God or nature; Emmons & McCullough, 2003), and other research uses the umbrella term "appreciation" to represent feelings of gratitude that do not have a clear source (e.g., a good night's rest). This entry covers all of these types of gratitude but specifies which type of gratitude is targeted in each study described.

Defining Health

Health can also be defined and measured in myriad ways. The World Health Organization (WHO) defines health as consisting of physical, mental (or psychological/subjective), and

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

social well-being. This broad conception of health is helpful when considering the potential role of gratitude in people's lives. Indeed, gratitude is related to all three aspects of health specified by the WHO, and many posit that although gratitude may act directly on physical health, it more likely acts indirectly by strengthening social and psychological well-being or by stimulating health-promoting behaviors (e.g., Hill, Allemand, & Roberts, 2013; Wood et al., 2010).

Physical health too may be defined in many ways—as the absence of disease, the absence of risk factors for disease, the ability to perform necessary daily activities, or the longevity of one's life. Consequently, researchers use many different methods to measure physical health, with some relying on self-reported physical health, which is highly related to psychological or subjective well-being (Friedman & Kern, 2014). Given the different ways in which physical health can be assessed, I try to be clear about which studies include what measures, and, even when a correlation between gratitude and physical health is reported, I allow for the possibility that another intermediary mechanism (e.g., psychological well-being) could be at play.

Gratitude and Positive Affect

Gratitude is itself a positive emotion, which could mean that the entire body of literature linking positive emotions to health can be applied to the relationship between gratitude and health (e.g., Pressman & Cohen, 2005). Indeed, the state of gratitude is often found among the many emotions included in positive emotion composites, and gratitude may behave similarly to those other positive emotions and has the same effect on health and health behaviors. However, gratitude may also have a distinct effect on health that is not explained by general positive affect. Truthfully, gratitude and general positive affect are not easily disentangled, but this chapter will consider those instances in which gratitude was uniquely studied and related to health in some way. For more information on the link between positive affect and health, see Jenkins, Acevedo, and Pressman in this volume.

Gratitude and Psychological Well-Being

The frequency with which people experience positive emotions is just one part of their psychological well-being. Other parts include the infrequency with which they experience negative emotions and their global sense that their life is satisfying and meaningful (Diener, Suh, Lucas, & Smith, 1999; Ryff, 1989). Importantly, trait gratitude is positively related to positive affect, global well-being, vitality, optimism, and hope and negatively related to anxiety, depression, envy, and neuroticism (Froh, Yurkewicz, & Kashdan, 2009; McCullough, Emmons, & Tsang, 2002). Among college students, gratitude at the beginning of the semester predicts lower likelihood of depression and stress at the end of the semester, controlling for baseline levels (Wood, Maltby, Gillett, Linley, & Joseph, 2008). The reverse direction of baseline stress and depression predicting gratitude at the end of the semester was not supported. Thus, these findings suggest that trait gratitude is not only related to well-being but also predictive of future well-being.

In a stronger test of the causal influence of gratitude on well-being, multiple randomized controlled experiments have now found that prompting people to express gratitude over time—either by counting blessings or writing gratitude letters—can shift reports of trait gratitude (e.g., Emmons & McCullough, 2003; Kerr, O'Donovan, & Pepping, 2014) and boost psychological well-being (e.g., Davis et al., 2016; Emmons & McCullough, 2003).

Boosting psychological well-being could also have an impact on physical health. Indeed, meta-analyses and reviews have found that psychological well-being is predictive of short-term outcomes like immune system response (Howell, Kern, & Lyubomirsky, 2007) and long-term outcomes like longevity (Chida & Steptoe, 2008; Howell et al., 2007, but see Friedman & Kern, 2014). In addition, gratitude could also affect physical health by decreasing stress, which has an adverse relationship with physical health.

Gratitude and Social Relationships

Trait gratitude is also related to qualities that promote healthy relationships such as empathy, perspective taking, and prosocial behavior (McCullough et al., 2002). Theory suggests that gratitude helps people recognize the good things people have done for them and motivates them to either repay their benefactor or pay the kind act forward, which strengthens relationships (McCullough et al., 2001). Indeed, trait gratitude is related to general perceptions of social support (Froh et al., 2009; Wood et al., 2008), and even momentary instances of gratitude seem important for relationships, as people who report feeling grateful toward their partner on one day also feel more satisfied with their relationship and more connected to their partner on the following day (Algoe, Gable, & Maisel, 2010). Furthermore, feelings of gratitude on one day also predict the degree to which people are responsive to their partner's needs on the following day and committed to their relationship the following day and 9 months later (Gordon, Impett, Kogan, Oveis, & Keltner, 2012).

Experimental evidence suggests that the link between gratitude and healthy relationships may be causal. For example, in one experiment, people randomly assigned to write gratitude letters felt more globally connected to others than those assigned to a control group that did not complete the gratitude activity (Kerr et al., 2014). In another experiment, people assigned to express gratitude to a close friend reported more positive perceptions of their friends than those assigned to neutral or positive comparison groups (Lambert & Fincham, 2011).

That gratitude relates to, predicts, and causes beneficial effects on relationships and perceptions of social support has implications for understanding the link between gratitude and physical health. The association between social support and psychological and physical well-being has been well documented, with prospective and experimental evidence suggesting a causal relationship (e.g., Cohen & Wills, 1985). Theory suggests that social support may buffer people from the deleterious effects of stress on psychological and physical well-being and that being socially integrated (i.e., having relationships and social roles in one's life) may promote positive states including mental health and health-promoting physiological responses. Accordingly, gratitude could also affect physical health via improvements in perceptions of social support and relationship quality.

Gratitude and Physical Health and Health Behaviors

Although the exact pathways by which gratitude may affect physical health and health-promoting behaviors are still largely theoretical, accumulating evidence has demonstrated a relationship between gratitude and physical health. One study found that trait gratitude and self-reported physical health were positively correlated in adults, even when controlling for key personality traits, and suggestive cross-sectional evidence indicated that psychological health, healthy activities, and willingness to seek help for health concerns mediates the pathway between gratitude and self-reported physical health (Hill et al., 2013). Similarly, a study in adolescents found a correlation between trait gratitude and reduced physical symptoms, which cross-sectional evidence suggested was explained by relational fulfillment (Froh et al., 2009). In one of the few studies that included objective measures of health, researchers found that feelings of appreciation are related to "coherence" or entrainment among the oscillatory systems in the autonomic nervous system, that is, when people feel appreciative, the body's heart, respiratory, and blood pressure oscillations synchronize, which is associated with efficiency in bodily processes (McCraty & Childre, 2004).

As mentioned before, gratitude could improve physical health by inhibiting negative attitudes and emotions, by promoting psychological well-being and health-promoting behaviors, or by strengthening perceived social support (Wood et al., 2010). Another way that gratitude could improve physical health is by improving sleep quality and duration. Indeed, in a community sample, trait gratitude was related to greater subjective sleep quality and duration, less time to fall asleep, and less daytime dysfunction, even after controlling for personality (Wood, Joseph, Lloyd, & Atkins, 2009). Cross-sectional evidence suggested that the relationship between gratitude and better sleep was explained by more positive and less negative thoughts at bedtime (Wood et al., 2009).

The link between gratitude and better sleep is important in understanding the relationship between gratitude and physical health because a vast body of research links sleep duration and quality to psychological and physical well-being and even mortality (Cappuccio, D'Elia, Strazzullo, & Miller, 2010). As one example, in a prospective study of college students, sleep duration and quality predicted better subjective psychological and physical well-being, as well as better grades, even after controlling for demographics and daytime functioning at baseline (Wong et al., 2013). Of course, many factors are related to sleep quality and duration, such as age, socioeconomic status, alcohol consumption, and weight, but if increasing grateful feelings before bed could improve sleep relative to one's baseline levels, gratitude could indirectly improve physical health. Indeed, one experiment found that patients with neuromuscular disorders who were prompted to list what they were thankful for once per day for 3 weeks saw improvements in sleep duration and felt more refreshed upon waking than patients in a control group who did not complete the gratitude activity (Emmons & McCullough, 2003, Study 3).

Experimental evidence linking gratitude directly to physical health and health behaviors is currently thin, but two other studies are relevant (in addition to Emmons & McCullough, 2003, Study 3 just listed). In one experiment, college students were randomly assigned to either list their blessings (the gratitude condition), list their hassles, or list life events once per week for 10 weeks. Those assigned to the gratitude group reported fewer physical health symptoms than either comparison group and more hours of exercise than the hassles group (Emmons & McCullough, 2003, Study 1). Additionally, hypertensive African Americans who were randomly assigned to list their blessings for 10 weeks (the gratitude condition) decreased in systolic blood pressure over time (Shipon, 2007).

All three of the abovementioned experiments showed significant increases in trait gratitude among people in gratitude versus comparison conditions; however, the first two experiments did not test whether these increases in gratitude mediated the relationship between the expression of gratitude and the changes in physical health (Emmons & McCullough, 2003, Study 1 & Study 3), and the second experiment tested the relationship but found that changes in gratitude were not related to changes in blood pressure (Shipon, 2007), leaving the mechanisms of the change up for debate. Future research would do well to test the mechanisms through which gratitude interventions improve physical health to inform a causal model. Furthermore, to address the overlap between self-reported health and psychological well-being, future studies of gratitude and gratitude interventions should strive to include objective measures of physical health that could disentangle gratitude's influence on psychological health from its influence on physical health.

Moderators of the Link Between Gratitude and Health

An important caveat is that trait gratitude may show different patterns in different people, and similarly, gratitude interventions may have different effects on different people (see Lyubomirsky & Layous, 2013). For example, the relationship between gratitude and self-reported physical health increases with age (Hill et al., 2013), and evidence suggests that the effects of psychological well-being interventions (including gratitude) are stronger in older adults (Sin & Lyubomirsky, 2009). Regarding gender differences, one study found that men were less likely to feel and express gratitude and received fewer benefits from gratitude (Kashdan, Mishra, Breen, & Froh, 2009). Another study in adolescents also found that girls report marginally more trait gratitude than boys, but largely did not find gender differences in how much girls or boys benefit from gratitude (Froh et al., 2009). Thus, some evidence suggests that women may feel and express gratitude more than men and may receive more benefits from gratitude, but further investigation is necessary. Some evidence suggests that gratitude interventions are particularly successful in raising psychological well-being among people low in trait gratitude (e.g., Harbaugh & Vasey, 2014), suggesting that if men are lower in trait gratitude, they may be particularly primed to benefit from a gratitude intervention.

Lastly, one quasi-experiment found that writing gratitude letters once per week for 6 weeks (versus engaging in a neutral writing activity) raised psychological well-being in a sample of US college students but trended toward decreasing well-being in a sample of South Korean college students (Layous, Lee, Choi, & Lyubomirsky, 2013). The authors thought the difference between cultures may be due to South Koreans' feeling less comfortable receiving social support than their US counterparts. Another possibility is that Asian cultures already emphasize gratitude and therefore may be approaching an upper limit, such that expressing yet more gratitude does not confer additional benefits. This and other potential moderators of the effect of gratitude on various types of health should continue to be explored.

Conclusion

In sum, the research linking gratitude to psychological well-being and positive social relationships is strong and even causal, whereas the research linking gratitude and physical health and health behaviors is thus far limited but suggestive. A review of all articles published in the three leading health psychology journals found that only 3% of all articles published included "positive psychological constructs" such as optimism, happiness, and emotion-focused coping (Schmidt, Raque-Bogdan, Piontkowski, & Schaefer, 2011). That percentage seems small in and of itself, but another telling fact is that gratitude was not even on their list of searched terms, speaking to its relative lack of consideration thus far in the health psychology field.

Future research should include prospective studies of trait gratitude and physical health, as well as randomized controlled studies of gratitude interventions that explore the mechanisms that drive changes in physical health. Because of gratitude's well-documented effects on psychological well-being and relationships, and because of the well-documented association between psychological well-being, relationships, and physical health, increasing gratitude has the potential to affect physical health, once again supporting Cicero's contention that "gratitude is not only the greatest of virtues, but the parent of all others."

Author Biography

Kristin Layous (PhD, University of California, Riverside; MA, Ohio State University; BA, University of California, Santa Barbara) is an assistant professor of psychology at California State University, East Bay. Her research explores the processes by which people can become happier and healthier through practicing simple positive activities (e.g., expressing gratitude or performing kind acts). During a postdoc at Stanford University, she also investigated how psychological interventions can enhance weight-loss efforts and reduce negative stereotypes surrounding obesity.

The Health Implications of Resilience

Kristen L. Rudd and Tuppett M. Yates

Department of Psychology, University of California, Riverside, , CA, USA

Introduction

Resilience is a developmental process that supports positive or better-than-expected adjustment despite exposure to incontrovertible adversity (Masten, 2014). Two pieces of information are necessary to "diagnose" resilience: (a) the individual must have encountered a clear threat to typical development, and (b) the individual must evidence competent adaptation as evaluated with respect to developmental and cultural expectations. In addition to *resilience* (i.e., positive adjustment in the context of high adversity), development can be characterized by *maladaptation* (i.e., negative adjustment in the context of high adversity), *competence* (i.e., positive adjustment in the context of low adversity), or, somewhat less commonly, *vulnerability* (i.e., negative adjustment in the context of low adversity). However, given that an estimated 64% of adults report exposure to at least one clear and pronounced adverse experience prior to age 18 (Anda et al., 2006), efforts to identify processes that promote positive adaptation in contexts of adversity (i.e., resilience) have significant implications for supporting human health and well-being in childhood and beyond.

Once thought to be an individual capacity for "invincibility" (Werner & Smith, 1982), current theories conceptualize resilience as a process of "ordinary magic" (Masten, 2014). In this view, normative developmental support systems enable individuals to function in developmentally and culturally expected ways despite the disruptive influences of adverse life experiences. Thus, resilience is no longer viewed as an extraordinary capacity of an individual, but rather as the natural expression of ordinary adaptive systems despite extraordinary experiences. Capacities for self-regulation, attachment, and cognitive reasoning comprise core systems that influence human development and adaptation. When these basic adaptive systems fail, negative adjustment will follow (i.e., *maladaptation* in the context of adversity and *vulnerability* in the absence of adversity). Thus, the quest to understand and promote resilience must advance beyond individual traits and characteristics, to encompass the entire system of dynamic developmental influences (Luthar & Cicchetti, 2000).

This entry provides an introduction to the construct of resilience with an explicit emphasis on its relevance for understanding and promoting health and wellness. First, we conceptualize resilience within a developmental framework wherein culturally and developmentally appropriate adaptation in the context of prior or ongoing adversity reflects a developmental process that may vary over time and contexts. Second, we explicate factors that contribute to resilience generally (i.e., main effects of risks and assets), as well as those that take on disproportionate salience in contexts of adversity exposure (i.e., moderating effects of vulnerability and protective factors). Third, we review mechanisms at biological, psychological, and social levels of analysis that may influence individual differences in the expression of resilience over time and across contexts. Finally, we consider the implications of resilience theory for health psychology and for specific efforts to bolster positive health outcomes, particularly in contexts of adversity.

Resilience as a Developmental Process

Although resilience can characterize a range of living systems, including schools, neighborhoods, and ecosystems, it is most often used to describe a pattern of individual development that proceeds in a (culturally) desired fashion despite encountering challenges and threats to positive development that go beyond the bounds of typical human experience (i.e., adversity). Contemporary models recognize that resilience is a process that may characterize the development of an individual but nevertheless reflects a range of influences beyond the individual. In this view, human resilience is not an expression of a singular trait or characteristic, but rather reflects a process of transactional exchanges among multiple systems within and beyond the individual (Luthar & Cicchetti, 2000). Together, these systems enable the individual to adapt effectively despite the presence of clear and present threats to their doing so (i.e., adversity).

Resilience is not about those who *have* or do not *have* resilience, or those who *are* or *are not* resilient; it is a description, rather than a causal agent. Resilience describes a developmental process by which core adaptive systems continue to operate in a healthy and desirable manner despite threats to their doing so. As described in the next section, resilience may be supported or thwarted by a range of factors. As these influences change over time, so, too, will the expression of resilience wax or wane across development. Likewise, expressions of resilience may vary over contexts within time, and individuals may have the resources to navigate one type of adverse experience, but not another. Resilience embodies a dynamic developmental process that rests neither in the individual nor in the context but rather in the transactional relation between individuals and their contexts.

Influences on the Process of Resilience

Resilience is a dynamic developmental process that emerges out of broader contexts of risk and protection. Across multiple levels of developmental influence, there are factors that are universally good or bad for everyone (i.e., main effects), and there are factors that change the impact of specific events and experiences for better and/or for worse (i.e., moderating effects). Resilience is multiply determined by the influence of main and moderating effects on the individual's capacity to adapt effectively despite adversity exposure.

Asset and *risk* factors exert main or uniform effects on development for better or worse, respectively. Indeed, the expression of resilience is, in part, a reflection of cumulative or net risk, namely, the compilation of factors that are known to threaten positive adaptation (i.e., risks) as they operate concurrently with factors that are known to support positive adaptation (i.e., assets). Some examples of common assets or resources that support health and wellness for *all* individuals include perinatal care, high-quality schools, regular health checkups, a safe and cohesive family environment, and strong cognitive and problem-solving skills. Risk factors that are statistically associated with negative human health outcomes include premature birth, family history of heritable illness, obesity, and smoking. Importantly, assets and risks rarely occur in isolation and tend to accumulate such that strength engenders strength and risk engenders risk. Unfortunately, as risks accumulate in number and severity, assets typically wane yielding high *net risk* and an increased probability of maladaptive outcomes (Appleyard, Egeland, Van Dulmen, & Sroufe, 2005).

Whereas assets and risks affect all individuals to a similar degree regardless of individual differences in adversity exposure, other developmental influences take on special significance when they occur in contexts of adversity. *Protective* and *vulnerability* factors are characterized by neutral or modest effects in contexts of low adversity but evidence stronger developmental effects as risks increase, assets decrease, and adversity becomes prominent. Protective factors moderate the impact of adversity on development by reducing its negative effects. For example, recent efforts to develop disaster-proof hospitals in high-risk areas will have neutral effects on patient health, except in the case of a natural disaster when such efforts will take on special significance to promote resilience to the negative impact of disaster on health service provisions. Much like an airbag takes its protective function from its ability to buffer the blow of an accident, protective factors are particularly important for understanding when and how individuals adapt effectively in the context of concomitant adversity. In contrast to the buffering effect of protective factors, vulnerability factors moderate the impact of adversity on development by magnifying its negative effects. For example, a person with an immune deficiency is vulnerable to negative health outcomes when challenged by toxins in the environment or disease processes in the body, but this vulnerability factor has a relatively neutral effect on health in the absence of such exposures.

Protective and vulnerability processes influence adaptation in many different ways. They may open or close avenues of opportunity, stop or initiate cascades of negative events, or interact with other developmental influences to foment or mitigate negative adjustment in contexts of adversity (i.e., maladaptation). Importantly, some factors may serve multiple moderating functions, thereby influencing the impact of adversity for better or worse. A classic example of this differential effect can be seen in research on how individuals' genes can interact with the environment to influence emotional adjustment. The serotonin transporter gene is responsible for helping the brain regulate the amount of the serotonin neurotransmitter, which is strongly implicated in various forms of psychopathology, including depression. The gene comes in two primary forms, short and long. On the one hand, a short serotonin transporter genotype is a vulnerability factor, which has the potential to magnify risks for depression in the context of clear adversity exposure, such as child maltreatment (Caspi et al., 2003). On the other hand, the long allele genotype serves as a protective factor that mitigates against this same negative outcome but only in the context of maltreatment. Operating as a vulnerability and protective process, the serotonin transporter genotype does not influence adjustment in all situations uniformly, but rather the meaning of this genotype takes its significance from the surrounding context of relative adversity, serving to moderate the impact of child maltreatment on emotional health outcomes for better and for worse.

Just as the short and long serotonin transporter genotypes may magnify or mitigate the impact of adversity on emotional health, respectively, other factors may moderate the contributions of both positive and negative environmental factors on human health and well-being. For example, contemporary research on physiologic stress reactivity points to a biological sensitivity to context effect, wherein the organism is rendered more sensitive to both positive and negative environmental influences. In a now-classic study of psychobiologic stress reactivity and illness, Boyce et al. (1995) demonstrated that children with sensitive stress response systems (i.e., children who exhibit higher cardiac reactivity in response to challenge) developed more respiratory health problems in the context of high environmental stress (i.e., family and childcare setting stressors) but actually developed fewer respiratory illnesses in the absence of such exposure.

Taken together, the main effects of assets and risks, the moderating effects of protective and vulnerability factors, and the differential effects illustrated in recent research on biological models of contextual sensitivity and impact illustrate that resilience is multiply determined. The impact of a given factor on adjustment may vary across time, across contexts, and in tandem with other factors to engender or undermine resilience processes in development. In addition to identifying these factors, efforts to clarify the mechanisms by which they influence resilience have significant implications for developing the most efficacious interventions to prevent maladaptation and promote resilience in contexts of adversity.

Explanatory Mechanisms

Multiple mechanisms underlie the main, moderating, and differential effects of various influences on resilience. Although classical theories of risk and protection favored psychosocial conceptualizations, recent years have witnessed a complementary rise in the consideration of resilience (and the factors that promote or thwart it) in biobehavioral models of health and wellness. Clarifying *how* processes of resilience emerge and diverge at multiple levels of analysis will reveal opportune moments and sites for interventions to promote human health and well-being (Cicchetti, 2010). A range of biological, psychological, and social processes may explain the impact of varied risks and assets, or protective and vulnerability factors on health and health behaviors in contexts of adversity.

The primary biological mechanism by which organisms adjust to environmental variation and stress is allostasis. *Allostasis* is the process by which individuals mobilize physiologic responses to manage challenge and return to a homeostatic condition that promotes health and restoration (McEwen, 1998). Multiple systems mediate this process, particularly the neuroendocrine hypothalamic–pituitary–adrenal (HPA) axis and the parasympathetic and sympathetic branches of the autonomic nervous system. With exposure to chronic stress (e.g., disease, malnutrition, violence), allostatic capacities may become overloaded. *Allostatic load* refers to the excessive demand placed on psychobiologic systems in contexts of chronic stress and adversity, which, in turn, may contribute to negative health outcomes (McEwen, 1998). At the level of biology, assets and risks, as well as protective and vulnerability factors, may operate to increase or decrease the allostatic demand on the organism. For example, assets may reduce the need for allostatic adjustment directly and/or provide additional support if allostatic adjustment is needed (e.g., medication to reduce the physiologic demands of illness; food, blankets, and shelter to offset the physiologic demands of homelessness).

Influences on resilience may also operate via psychological mechanisms. For example, a sense of personal coherence supports one's ability to understand the world and one's experiences in it (particularly difficult life experiences) and is thought to be an important process for coping with stress and managing health (Amirkhan & Greaves, 2003). Various factors may influence the capacity for coherence and meaning making and, by extension, for resilience. For example, individuals living in contexts of increased mortality risk (e.g., life-threatening illness, active military service) may have a foreshortened sense of time such that they struggle to project themselves into the future. By undermining the psychological sense of continuity across past, present, and future that defines a person's sense of coherence, these factors may negatively impact the individual's use of healthcare and/or health-related activities, such as healthy eating, exercise, or risk-taking. In a recent study of natural disaster preparation, investigators showed that a sense of personal agency (i.e., the belief that one's action will have an effect on one's outcome) facilitated positive and preventive action (Paton, Parkes, Daly, & Smith, 2008). In contrast, influences that confer a sense of helplessness, fatalism, and limited opportunity (e.g., poverty, racism) can jeopardize a sense of personal coherence and, by extension, undermine the capacity to express resilient adaptation.

Finally, main and interactive influences on resilience can operate via social mechanisms. For example, social capital refers to knowledge and resources that derive from the interdependence of social networks (Caughy, O'Campo, & Muntaner, 2003). In times of need, access to and inclusion in social networks can provide necessary resources to navigate life's difficulties. Influences on resilience may operate by providing connections with positive networks and/or blocking engagement with negative networks. With regard to health, assets and protective factors on the one hand and risks and vulnerability factors on the other hand may provide or hinder the social capital (e.g., relevant connections) to successfully navigate the healthcare system. For example, in the context of a life-threatening illness, these factors may influence the patient's ability to advocate for a second opinion, locate an expert physician, and/or martial support for care and recovery.

Multiple mechanisms underlie resilience and may work together at any given time to produce various outcomes. For example, studies of post-traumatic stress disorder (PTSD) show that the presence of a supportive other can reduce the *biological* hyperarousal that characterizes the trauma response and other features prominent in the onset of PTSD (Ozbay, Fitterling, Charney, & Southwick, 2008). Through conversation and empathic exchange, a supportive other may also buffer, engender, or restore the individual's *psychological* sense of coherence in the wake of a traumatizing experience. Finally, a supportive *social* connection may provide access to tangible resources, such as a therapist referral or a safe place to stay, that may foster resilience to the impact of traumatic experiences.

The fundamental adaptive systems thought to most strongly support the "ordinary magic" of resilience likely operate across biological, psychological, *and* social levels of analysis and action. As yet another example, attachment processes promote adaptive stress modulation at the biological level (Gunnar & Quevedo, 2007), a sense of coherence at the psychological level (Sroufe, 1979), and connections to support networks at the social level (Kawachi & Berkman, 2001). Additional core systems of adaptation, such as self-regulation and cognitive processing, likely operate across multiple levels of developmental influence as well. In a complementary fashion, the most potent risks to development also undermine adjustment across multiple systems. For example, poverty likely taxes allostatic capacities (Blair, Raver, Granger, Mills-Koonce, & Hibel, 2011), distorts an individual's sense of coherence (Amirkhan & Greaves, 2003), and limits social capital (Caughy et al., 2003). In future research, it will be important to elucidate whether and how specific mechanisms take on differential salience as a function of the kind of adversity exposure (e.g., illness, poverty, maltreatment), the specific type of adjustment outcome (e.g., immune function, behavior, mood), and the period of development in question (e.g., infancy, adulthood, old age).

Implications for Health and Health Resilience

A developmental process framework adopts a systems view in which resilience is conceptualized as a pattern of individual adaptation in a given context and over time. Moreover, this process may be engendered or compromised by the operation of multiple factors working at biological, psychological, and social levels of action. This view has significant implications for how we understand and promote health and health resilience.

Time is of central importance in a developmental model of resilience. Development is cumulative such that early adaptations provide a foundation for subsequent adjustment. In some instances, the health consequences of adversity exposure may be readily apparent (e.g., if you bump your head, a bruise will appear immediately), yet in others the effects may be quite delayed (e.g., maintaining homeostasis despite childhood stress exposure may lead to a range of physical ailments in middle adulthood; Brody et al., 2013). Moreover, the impact of these influences may vary over time (e.g., breaking a growth plate in childhood may result in a shortened limb, whereas the same break would not stymie growth in later development). Likewise, some traumatic experiences are especially pernicious when they occur early in life, whereas the same events may have less impact in later life if previous experiences have provided necessary skills to better navigate that adversity. For example, being in a rare natural disaster in childhood may lead to increased anxiety of another occurrence, while the same experience in adulthood would be accompanied with the knowledge of its rarity. In other ways, such events may be less consequential for early development relative to later development. For example, experiencing a hurricane and losing one's possessions in infancy is perhaps less detrimental than in adolescence when youth place greater importance on material markers of status and identity. Finally, the expression of resilience itself may vary over time amidst shifts in the balance of assets and risks, of protective and vulnerability factors.

Greater consideration of the individual's developmental status and the timing of factors influencing resilience will inform future prevention and intervention efforts. Identifying periods of marked vulnerability to subsequent maladaptation may provide information about the most opportune times to intervene. For example, because smoking behaviors most often begin in adolescence, prevention efforts should target this developmental epoch. In addition, a developmental perspective emphasizes the cumulative nature of both adversity and resilience. For example, individuals who have had positive health encounters in the past will be more likely to negotiate future health challenges in an effective fashion, both because the developmental system itself is healthier and because the individual is able to mobilize adaptive resources within and outside the self to engage positive health change.

A comprehensive model of health resilience must consider the simultaneous operation of multiple influences at multiple levels of action over time. The roots of individual health and health resilience extend well beyond the individual. In a study of patients with diabetes, Yi, Vitaliano, Smith, Yi, and Weinger (2008) found that stable glycemic control and fewer diabetes-related health problems reflected the simultaneous operation of both individual processes (e.g., self-efficacy and self-esteem) and systems external to the patient (e.g., social support and health education resources). Extending to the community, access to medical facilities, professional guidance, and effective treatments can increase the likelihood that a person may resist or recover from the negative impact of adverse health events. At the broadest level, health welfare and insurance policies influence individuals' access to affordable, reliable, and immediate healthcare. Together, these factors transact to influence individuals' relative risk or resilience to negative health outcomes.

The emphases on time and multiple levels of influence in a developmental model of resilience suggest that efforts to promote health may operate in various periods of development and at different levels (see Yates & Masten, 2004 for discussion). When risks are identifiable and modifiable, risk-focused interventions can eradicate threats to development. For example, given that adolescence is a period of heightened risk for smoking, we can strive to decrease risk by preventing youth from purchasing nicotine products prior to age 18. However, in cases where the source of risk is unclear or intractable, asset-focused interventions can combat threats to development. For example, genetic vulnerabilities to illness resist modification, but we can ensure access to basic healthcare and preventive screening to increase the possibility of a positive health outcome in the event of disease expression. Preventing risks and increasing assets are important intervention initiatives in their own right, but their impact will be magnified by process-focused approaches that aim to increase individuals' capacities to make use of a new resource context and/or to navigate ongoing risks. Such process-focused interventions can target basic systems known to promote resilience (e.g., attachment, self-regulation) to protect them from harm and/or to promote or reactivate their optimal functioning.

Just as the most pernicious threats to development undermine multiple systems, the most efficacious interventions incorporate multiple avenues to health and wellness (Wyman, Sandler, Wolchik, & Nelson, 2000). For example, obesity is a prominent health concern with negative and enduring health ramifications. Soda bans in various states constitute a *risk-focused* intervention that decreases exposure to a known risk for obesity, namely, excess sugar consumption. At the same time, *asset-focused* interventions may provide nutritional education or low-cost opportunities for health and fitness to combat obesity. Finally, a *process-focused* model could target core systems of self-worth and self-efficacy to activate individuals' motivation to take responsibility for their health and promote their agency to enact a healthy lifestyle. In combination, these approaches have the potential to combat cumulative sources of risk and vulnerability associated with obesity.

Closing Comments

Resilience is a prominent area of interest for psychologists and health researchers alike. Amidst contemporary debates about vaccinations and struggles with infectious diseases, meeting the need to understand why and how people are differentially susceptible to risk and achieving the challenge to elucidate mechanisms by which we can bolster health and wellness are of increasing importance. Resilience theory and research have the potential to guide these efforts. However, opportunities for translation from resilience science to practice may be limited by barriers among research, practice, and policy. Moving resilience ideas forward into the lived experiences of individuals and communities will require open minds and new collaborations. In this chapter, we explicate the multitude of factors and processes that support or undermine positive adaptation in contexts of adversity. We encourage and guide the application of a developmental view of resilience to the fields of health and health psychology with the hope of advancing and informing ongoing and collaborative efforts to promote positive health trajectories for all people.

Author Biographies

Kristen L. Rudd, MA, is a doctoral student at the University of California, Riverside. Her research focuses on early childhood experiences of stress and adversity and the influence of the physiologic stress response on adjustment outcomes.

Tuppett M. Yates, PhD, is an associate professor of psychology and director of the Adversity and Adaptation Laboratory (www.adlab.ucr.edu) at the University of California, Riverside. Her research examines the impact of childhood adversity on developmental pathways toward psychopathology and competence with particular emphases on relational and regulatory developmental processes.

Health Information Avoidance

Jennifer L. Howell[1], Nikolette P. Lipsey[2],
and James A. Shepperd[2]

[1]*Psychology Department, Ohio University, Athens, OH, USA*
[2]*Psychology Department, University of Florida, Gainesville, FL, USA*

In the modern era, people can learn their disease risk, receive diagnoses, track their physical activity, share health information with their physician, and receive direct-to-consumer genetic testing all from the comfort of home. Nevertheless, people are sometimes reticent to learn information about themselves (Shepperd & Howell, 2015; Sweeny, Melnyk, Miller, & Shepperd, 2010).

We review research on *health information avoidance*, the motivated decision to avoid learning information about one's physical health (Shepperd & Howell, 2015). In this entry, we define health information avoidance and discuss its prevalence. We also discuss individual differences in health information avoidance, explore its causes, and examine interventions that can reduce it.

Defining Health Information Avoidance

Information avoidance is "any behavior designed to prevent or delay the acquisition of available but potentially unwanted information" (Sweeny et al., 2010, p. 314). Information avoidance is distinct from failing to seek information in that the former represents a motivated decision to avoid information that threatens how one wishes to think, feel, or behave. For example, a woman who does not seek articles about oral cancer because she has never heard of oral cancer or because she simply does not care is not actively avoiding that information.

Health information avoidance encompasses a variety of behaviors. Moreover, it subsumes several other information-related psychological phenomena including selective exposure (avoiding attitude inconsistent information), blunting (ignoring information about a disease after diagnosis with that disease), preferences for information (patients' desire to know about their medical status and care), and other forms of defensiveness and avoidance (e.g., ignoring

stimuli that might indicate risk; see Howell & Shepperd, 2016). These other psychological phenomena represent special cases of information avoidance (Sweeny et al., 2010).

The Problem of Health Information Avoidance

Although information avoidance can protect people from threatening information, it can also be problematic. For instance, delaying diagnosis can have dire health consequences for diseases such as cancer or HIV, for which early initiation of treatment can substantially prolong life. Thus, to the extent that late diagnosis reflects health information avoidance, such avoidance can prove deadly.

Prevalence of Health Information Avoidance

How prevalent is health information avoidance? In one study, 37% of university students and 31% of general-population adults indicated that they had at some point done something to "avoid getting information about a health topic" (Barbour, Rintamaki, Ramsey, & Brashers, 2012, p. 215). In another study, 25% of a nationally representative sample of US adults agreed or strongly agreed with the statement "I can think of situations in which I would rather not know everything about my health" (Howell, Crosier, & Shepperd, 2014).

Evidence suggests that the prevalence of health information varies widely based on the type of information avoidance examined and the population evaluated. For instance, 39% of a nationally representative sample of US adults agreed with the statement "I would rather not know my risk for cancer" (Emanuel et al., 2015). Nevertheless, only 13% of a sample of Black adults living in rural north Florida agreed with the statement "I would rather not know my risk for mouth and throat cancer" (Shepperd, Howell, & Logan, 2014).

The prevalence of information avoidance also varies based on how one defines avoidance. Rates of avoidance are typically much lower when one assesses avoidance in terms of intentions to avoid information versus actual avoidance behavior. Indeed, although almost 88% of rural black adults in one study signed up to attend an oral cancer examination, only 40.1% of the study participants who signed up actually attended their screening appointment (Shepperd, Emanuel, Howell, & Logan, 2015). In this case assessing avoidance via intentions rather than behavior resulted in a lower prevalence of information avoidance.

Predictors of Health Information Avoidance

A number of studies have examined individual differences in information avoidance and found that some people are more inclined than others to avoid information. Researchers have identified both demographic and personality predictors of avoidance.

Demographic Predictors of Avoidance

The findings regarding demographic predictors of health information avoidance are inconsistent. Whereas some studies find greater health information avoidance among younger adults than among older adults (e.g., Persoskie, Ferrer, & Klein, 2013), others find the opposite pattern (e.g., Emanuel et al., 2015), or no relationship (e.g., Shepperd et al., 2015). The findings for gender are also mixed, with some studies finding the greatest health information avoidance among men (e.g., Kelly et al., 2010) and others finding the greatest health information avoidance among women (e.g., Emanuel et al., 2015).

In contrast to age and gender, education consistently predicts avoidance. Research links lower education to greater avoidance of general health information (Shepperd & Howell, 2015) and cancer risk feedback (Emanuel et al., 2015), greater avoidance of doctors (Persoskie et al., 2013), and lower health information seeking (Kelly et al., 2010).

Of course, demographic variables are not psychological variables per se but rather are proxies for one or more psychological constructs. For example, education is likely a proxy for dispositional curiosity or perhaps psychosocial resources. As we discuss presently, both greater coping resources and greater curiosity correspond with less information avoidance.

Personality Measures

Studies examining personality and information avoidance reveal two general predictors of avoidance: orientation toward information and personal and interpersonal resources. First, several studies offer evidence that people who are dispositionally open to information display less information avoidance. For example, one study that followed 316 undergraduate students over 4 months included several measures assessing orientation to information (e.g., dispositional curiosity, tolerance of uncertainty) as well a general measure of avoidance of health information. On every measure of openness to information, participants who were dispositionally open to new information reported less inclination to avoid health information (Shepperd & Howell, 2015).

Second, dealing with psychosocial threats demands psychosocial resources (Howell et al., 2014). Not surprisingly, several studies find that having fewer personal and interpersonal resources (e.g., coping resources, social support) corresponds with greater information avoidance (Howell et al., 2014). For example, in one study students who reported having more coping resources were less likely to avoid viewing a personal UV photo depicting sun damage (Dwyer, Shepperd, & Stock, 2015). In a second study, having more threat-management resources (i.e., being more optimistic, spontaneously self-affirming) corresponded with less avoidance of genetic screening results (Taber et al., 2014), and a third study found that reports of greater coping ability and having a network of close friends that one can talk to about one's health corresponded with less avoidance of health risk feedback (Howell et al., 2014). These studies confirm findings from experimental studies showing that making people feel socially isolated (via social exclusion) increases their avoidance of health risk feedback (Howell & Shepperd, 2017), whereas bolstering people's ability to manage bad news by affirming their personal worth reduces avoidance (Howell & Shepperd, 2012).

Causes of Health Information Avoidance

People avoid information for three broad reasons: The information potentially threatens how they wish to feel, think, or behave (Sweeny et al., 2010).

Affective Concerns

People are motivated to create and maintain positive affect and sometimes avoid heath information to maximize positive emotions and minimize negative emotions (Sweeny et al., 2010).

Unfavorable health information can evoke a variety of negative emotions including sadness, fear, anger, regret, disappointment, and guilt. Numerous studies document that people avoid health information to avoid these unpleasant emotions. For instance, studies find that concerns over negative emotions prompt avoidance of doctors (Persoskie et al., 2013).

Of course, people also avoid information to preserve or enhance positive emotions. For example, people cite a desire to preserve hope as a motive for avoiding health information (Barbour et al., 2012). Importantly, people are more likely to avoid information if they anticipate the information will make them feel bad. By contrast, currently feeling bad does not appear to influence information avoidance (Persoskie et al., 2013).

Challenge to Self- or Worldview

Because people are motivated to create and maintain consistent and positive views of themselves and their worlds, they will avoid information that threatens their beliefs (Earl et al., 2009). Although few studies examine health information avoidance, theorizing and research on selective exposure—a type of information avoidance—suggests that people will avoid learning health information that challenges their beliefs. In one study, participants were less likely to enroll in a HIV-prevention counseling session to the extent that they had not used condoms in the past (Earl et al., 2009). By so doing, they avoided information that might challenge their belief that they are healthy and make good decisions.

Finally, people report that they sometimes avoid health information to maintain the belief that they are healthy (Barbour et al., 2012). For example, participants were more likely to avoid a UV photo to the extent that they thought it might reveal skin damage (including showing them to be “ugly”), particularly if they did not regularly engage in sun-protective behavior (Dwyer et al., 2015). Together, these findings suggest that just as people will avoid belief-inconsistent information generally, people avoid health information that might threaten desired beliefs about themselves or their health.

Challenge to Behavior

People are prone to avoid information that they believe might constrain them from behaving as they wish (Howell & Shepperd, 2013a). For example, several studies demonstrate that people are more likely to avoid learning their risk for a disease if they believe it will obligate them to take an unpleasant or disgusting definitive test (e.g., a cervical exam) than if they believed it would obligate a less invasive test (e.g., a cheek swab; Howell & Shepperd, 2013a). Similarly, study participants are more likely to avoid learning their risk for a disease if having the disease requires that they take a pill for the rest of their lives versus for a week (Howell & Shepperd, 2013a). Together, the evidence suggests that people avoid health information to the extent that the information obligates undesired action.

Interpersonal Motives

The three motives discussed thus far represent personal motives: People avoid information that threatens how they wish to think, feel, or behave. Yet researchers have long known that interpersonal motives also influence behavior. As such, if health information might become available to others, and that information might negatively influence how others think about them, feel about them, or behave toward them, people may avoid learning the information.

We know of no experimental research demonstrating that people avoid health information for interpersonal reasons. However, correlational evidence suggests that people may avoid information for interpersonal reasons. For instance, in a study of genetic screening, participants often report that receiving and sharing an undesirable diagnosis with close others might cause others to perceive them as a burden or desert them (Yaniv, Benador, & Sagi, 2004). Similarly, in a study on Alzheimer's genetic testing decisions, more than 50% of the people who chose to avoid Alzheimer's genetic testing cited concern about loved ones' reactions as an important reason not to get tested. These findings suggest that concerns with the role others play in health decisions may prompt avoidance.

Reducing Health Information Avoidance

Given that health information avoidance can lead to problematic health outcomes (e.g., delayed diagnosis and treatment, disease spread), it is important to understand how to reduce it. Here we review three interventions to reduce health information avoidance: self-affirmation, motives contemplation, and increasing perceptions of control.

Self-Affirmation

Self-affirmation involves prompting people to consider their personal values and strengths (see Sherman, 2013 for a review). When people facing threats self-affirm (typically by writing or thinking about a recent demonstration of an important value), they are better able to focus on aspects of themselves that are not under threat and to draw on the psychological resources necessary to manage threat (Sherman, 2013). Similarly, affirmation should reduce information avoidance because it reduces perceptions of the resources required and increases perceptions of resources available to deal with threatening information. Consistent with this reasoning, people who are affirmed are more likely to view the results of online health risk calculators even when the information might obligate unwanted action (Howell & Shepperd, 2012).

Motives Contemplation

Contemplation involves prompting people to evaluate the pros and cons of seeking versus avoiding information. One approach to prompting contemplation is to have people list their reasons for seeking and their reasons for avoiding threatening information and then having them evaluate the strength of each reason. This intervention has successfully reduced avoidance of health risk feedback for a variety of diseases including cardiovascular disease and melanoma (Howell, Ratliff, & Shepperd, 2016). The mechanisms underlying the effectiveness of contemplation remain unclear. Some research suggests that contemplation encourages rational decision making (Howell & Shepperd, 2013b). Other research suggests that it prompts people to justify intuitive reactions (Howell et al., 2016). Regardless of the mechanism, contemplation reduces avoidance only when people view seeking as the prudent course of action (e.g., when disease is controllable), but not in situations in which people view avoiding as the prudent course of action (e.g., when disease is uncontrollable; Howell & Shepperd, 2013b). As such, interventionists must exercise caution in using contemplation as a remedy for avoidance.

Increasing Perceived Control

We noted earlier that obligating behavior can prompt information avoidance (Howell & Shepperd, 2013a). In the health context, uncontrollable diseases represent a threat to people's ability to control their worlds, and people are often more inclined to avoid information about uncontrollable diseases than controllable diseases (Melnyk & Shepperd, 2012; Yaniv et al., 2004). Importantly, emphasizing the controllable aspects of disease can reduce avoidance. For example, women in one study were more likely to choose to learn their breast cancer risk from an online risk calculator if they read about the controllable predictors of breast cancer (e.g., diet, exercise) than if they read about uncontrollable predictors of breast cancer (e.g., genetics; Melnyk & Shepperd, 2012).

Summary

As people's access to health information grows, and interventionists try to promote healthy behavior through personal feedback and data, understanding people's reticence to receive health feedback becomes increasingly informative and important. Health information avoidance is the motivated avoidance of available health information and can be problematic, especially when it leads to delayed diagnosis. The prevalence of health information avoidance is highly variable, but avoidance seems to occur least among people who are dispositionally open to new information and most among people who lack psychosocial resources. Evidence suggests that information avoidance is a defensive behavior motivated by a desire to protect affect, cognition, and behavior. Interventions that reduce threat (e.g., affirmation), require people to contemplate the pros and cons of avoidance (e.g., motives contemplation), or increase personal control (e.g., emphasizing controllability) are effective in reducing health information avoidance. Although research on health information avoidance has answered several important questions, many more questions remain unanswered. The field would benefit from systematic examination information avoidance in a variety of health contexts. Moreover, additional research is needed on potential interventions to reduce harmful avoidance and to determine when (and for whom) intervention strategies are most effective. Finally, more research is needed to understand the downstream consequences of avoidance for health.

Author Biographies

Jennifer L. Howell, PhD, is an assistant professor at Ohio University. Her research focuses primarily on psychological threat management and health. She seeks to understand the proactive and reactive strategies people use to manage bad news, particularly about their health. This broad umbrella encompasses work on decision making, responses to feedback, defensiveness, physical health behaviors, risk, coping, individual differences, social cognition, attitudes, and communication.

Nikolette P. Lipsey is a graduate student at the University of Florida. She studies information avoidance and impression management. With an emphasis on health-related contexts, her research examines how perceptions of audiences influence information avoidance.

James A. Shepperd, PhD, is the R. David Thomas Endowed Professor of Psychology at the University of Florida and the research director for the Southeast Center for Research to

Disparities in Oral Health. Most of his research examines how people manage threatening information, which includes topics such as optimism, maintaining desired self-views, and information avoidance. Much of his work involves applying psychological theory to addressing health concerns such as screening for cancer.

Health Literacy

Amber S. Emanuel[1] and Kristel M. Gallagher[2]

[1]Psychology Department, University of Florida, Gainesville, FL, USA
[2]Thiel College, Greenville, PA, USA

In a world where we seem to have access to a wealth of health knowledge and expertise at our fingertips, it may be difficult to imagine that the strongest predictor of an individual's health status is literacy skills (World Health Organization, 2013). Age, income, employment status, education level, and race—each of these factors certainly has a place in the equation, but literacy skills, and specifically *health literacy* skills, are a driving force in the promotion of optimal health. As an invisible factor in health, health literacy skills tend to be both overlooked and misunderstood by the medical community and general population alike. However, two out of every five people in the United States suffer from low health literacy (Kutner, Greenberg, Jin, & Paulsen, 2006), greatly putting their health at risk.

The National Institute of Health defines health literacy as the "degree to which individuals have the capacity to obtain, process and understand basic health information and services needed to make appropriate health decisions" (Institute of Medicine, 2004). In this definition, there are four key verbs that are important to note when studying health literacy: obtain, process, understand, and decide. The ability to *obtain* health information is the piece of health literacy with which most people are familiar because it is most associated with reading and writing skills. Since obtaining basic health information in the age of digital media is often as simple and quick as an Internet search, it is easy to overlook health literacy as a real problem. However, being able to gather health information is only a small part of having adequate health literacy skills. Including the ability to *process* and ultimately *understand* health information in the definition means that health literacy skills are rooted in deeper cognition, rather than surface level processing. Yet the most integral term in the definition of health literacy is *decide*. Individuals must not only have the ability to obtain, process, and understand health information and services, but they must also be able to use that information to make appropriate decisions regarding medical care. It is here that the real value of health literacy skills can be recognized.

Health literacy, then, is a functional type of literacy that goes far beyond the mere level of one's reading and writing skills. There are some clear similarities between health literacy and

---

General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

literacy, such that both need an ability to recognize and understand words, search texts, and make text-based inferences. However, there are also some important differences. Consider the following example: "A two-year old is diagnosed with an inner ear infection and prescribed an antibiotic. Her mother understands that her daughter should take the prescribed medication twice a day. After carefully studying the label on the bottle and deciding that it doesn't tell her how to take the medicine, she fills a teaspoon and pours the antibiotic into her daughter's painful ear" (Parker, Ratzan, & Lurie, 2003). Here, the mother likely possesses adequate literacy skills—she recognized and understood the words on the label, knew to search the text on the label for instructions, and made a judgment on how to best proceed with the treatment given the location of the infection. However, she did not fully understand the relationship between the infection and the antibiotic, suggesting a low level of health literacy.

As highlighted in the above example, literacy and health literacy are not always connected. The focus of health literacy is narrower than general literacy. Unsurprisingly, health literacy focuses on health, being able to understand common health-related vocabulary and the health-care system (Vernon, Trujillo, Rosenbaum, & DeBuono, 2007). Health literacy also encompasses knowledge of the basic operation of the human body: how medications work, what causes diseases, and the relationship between lifestyle factors and health-related outcomes. Thus, health literacy is distinct from literacy.

Measures of Health Literacy

Since health literacy skills are unique, standardized measures of overall literacy are not equipped to accurately gauge an individual's level of health literacy. Thus, there are a number of scales that specifically measure health literacy. Some are lengthier and provide a more in-depth picture of an individual's level of health literacy, used mainly in the research domain, while others have been designed for ease of implementation in clinical settings. Many of these measures (e.g., Test of Functional Health Literacy [TOFHLA], Short Assessment of Health Literacy, Newest Vital Sign) are available in both English and Spanish. See further readings for a review of health literacy measures and their sources (Agency for Health Research and Quality, 2016).

The *TOFHLA* is a 50-item reading comprehension test and a 17-item numerical ability test that takes 22 min to administer. A shortened version of the TOFHLA (s-TOFHLA) takes approximately 12 min to administer. The 14-item *All Aspects of Health Literacy Scale* is a self-report measure with three subscales: functional health literacy, communicative health literacy, and critical health literacy. A slightly shorter questionnaire is the *Rapid Estimate of Adult Literacy in Medicine*, for which participants are asked to verbalize health-related words (e.g., allergic, jaundice, anemia), and a score of six or less puts them at risk for low health literacy. Similarly, the *Short Assessment of Health Literacy* is an 18-item measure of comprehension and pronunciation of health-related items. For example, participants are shown a stem (such as "infection") and asked to say the word and then say which of two words ("plant or virus") are most similar to the stem word.

Shorter measures include the 6-item *Newest Vital Sign* and the 3-item *Set of Brief Screening Questions* (SBSQ). The *Newest Vital Sign* uses a fictitious nutrition label from a carton of ice cream as the stimulus for the question prompts, involving both comprehension and numeracy problem-solving skills. A variation of the SBSQ is the *Single-Item Literacy Screener*, which uses the question, "How often do you need to have someone help you when you read instructions, pamphlets, or other written material from your doctor or pharmacy?" There are also some disease-specific scales, such as the *Diabetes Numeracy Test* and the *Breast Cancer Literacy Assessment Tool.*

Regardless of the scale used to measure health literacy, simply asking whether the person understands the given health information is insufficient. Individuals are often reluctant to admit that they do not understand health information, especially if they have limited overall literacy as well. Further, as with overall literacy and most cognitive tasks, it is unreasonable to expect individuals to “know what they don’t know” when it comes to health information. One way providers have managed to avoid these issues is to use an indicator of health literacy that is short and practical, such as asking patients to read a prescription label.

Rates of Health Literacy

Unfortunately, health literacy is a common problem for many individuals. Commonly characterized as the health literacy “crisis,” up to two-thirds of patients may not be able to comprehend key health information essential to navigating the healthcare system, such as how to take medication or schedule a follow-up appointment (Williams, Davis, Parker, & Weiss, 2002). In 2003, the National Assessment of Adult Literacy (NAAL) measured health literacy in their large-scale national assessment of 20,000 adults. Importantly, the 2003 NAAL was the first large-scale assessment of literacy that included a specific measure of health literacy. Health literacy was characterized in the NAAL by participants’ responses to a series of 28 assessment tasks, such as reading health-related materials and answering questions to demonstrate comprehension of the material. Based on correct answers to these questions, respondents were divided into either Below Basic, Basic, Intermediate, or Proficient levels of health literacy. Participants in the “Proficient” level could perform tasks such as finding the definition of a medical term by searching a complex document and calculating health insurance costs for a year using only a monthly cost table. Only 12% of American adults possessed these proficient health literacy skills, while 36% had inadequate skills to make appropriate health decisions, falling into the bottom categories of “Basic” and “Below Basic.” The remaining participants performed at an “Intermediate” level, possessing the skills necessary to read a prescription label and decide on the appropriate times to take the medication.

Individuals in the “Basic” and “Below Basic” levels, approximately 77 million Americans, are at a particular disadvantage in the healthcare system. Having low levels of health literacy means that they may not be able to perform even the most basic of health activities necessary to take care of themselves and loved ones. These activities include circling the date of a medical appointment on a hospital appointment slip, following directions on a prescription drug label, or using a chart to adhere to a childhood immunization schedule, among others (Kutner et al., 2006)

Predictors of Health Literacy

Given the many problems associated with low levels of health literacy, can researchers identify its predictors? Several sociodemographic factors are associated with low health literacy. Most studies suggest an association between lower educational attainment and low health literacy (e.g., Baker, Gazmararian, Sudano, & Patterson, 2000). Lower socioeconomic status, measured using income, has also been linked to lower health literacy (Baker et al., 2000), though not all studies have found a significant association (Williams et al., 2002). Older adults are also more likely to have low health literacy (e.g., Morrow et al., 2006), though this relationship may be explained by cognitive ability (Baker et al., 2000; Morrow et al., 2006).

Ethnicity may also be a predictor of health literacy. Most studies have compared the health literacy of Black and White individuals and found that, on average, Blacks have lower health literacy than Whites (e.g., Baker et al., 2002). Race may also interact with other sociodemographic variables. For instance, in a survey of American veterans, Black veterans had lower health literacy than White veterans, and low health literacy was especially pronounced in younger Black veterans (Rodríguez et al., 2013).

Other studies have concentrated on whether health literacy may partially explain health disparities (e.g., Sentell & Haplin, 2006). In some studies, health literacy mediates disparities between White and Black participants. For example, health literacy explains race differences in nonadherence to HIV regimes, misinterpretation of medication labels, prostate-specific antigen (PSA) levels among newly diagnosed prostate cancer patients, lack of health insurance in children, and quality of life among Medicare enrollees (Berkman, Sheridan, Donahue, Halpern, & Crotty, 2011). Similarly, in a sample in which 29% of older-aged participant had below-basic health literacy skills, health literacy mediated race disparities and education-related disparities in self-reported health status (Bennett, Chen, Soroui, & White, 2009). Thus, health literacy seems to explain some well-known health disparities.

In sum, the most consistent predictors of low health literacy seem to be low educational attainment, low socioeconomic status, and older age. However, many studies have also found that these sociodemographic predictors interact with each other or mediate each other, so these relationships are complex.

Monetary Cost of Low Health Literacy

One reason health literacy has started to garner attention in both the research and clinical realms is that low health literacy is expensive. The estimated cost of low health literacy to the US economy is between 106 and 236 billion dollars annually (Vernon et al., 2007). In a report about these issues, Vernon et al. (2007) estimated that the economic savings of improving health literacy in the United States could translate into enough funds to insure 47 million Americans—that is, every uninsured person in the United States, according to the 2006 Census Bureau.

Additionally, Medicaid patients with third grade or below reading levels cost $7,500 more per year to insure than Medicaid patients with reading skills above the third grade level (see Nielsen-Bohlman, Panzer, & Kindig, 2004). Individuals with low health literacy are hospitalized more often, up to twice as likely to be admitted to the hospital than individuals with adequate health literacy (Baker, Parker, Williams, & Clark, 1998). This increase in hospitalization is also prevalent in Medicare patients (Baker et al., 2002), further placing a burden on the economic system. Thus, low health literacy is a serious concern for many facets of the healthcare system.

Medical Decision Making and Health Literacy

Health literacy is an important predictor of patients' medical decisions. For example, low health literacy predicted wanting more aggressive treatment at end of life, independently of education and race (Volandes et al., 2008). If the researchers had not measured health literacy, they may have concluded that race and education uniquely predicted end-of-life decisions. Similarly, health literacy is a significant predictor of adherence to HIV medication regime, and including health literacy levels eliminated the health disparity that Blacks were more likely to be nonadherent (Osborn, Paasche-Orlow, Davis, & Wolf, 2007). Among the elderly, low health literacy is associated with poor self-care of chronic diseases, excess use of emergency care services, low use of preventative health services, and an increased risk for mortality (Baker et al., 2007; Berkman et al., 2011). In a recent meta-analysis of health literacy (Berkman et al., 2011), low health literacy was associated with poor ability to adhere to a medication regime, lower use of preventative services (mammography screening, influenza immunizations), greater use of emergency care, more hospitalization, and lower overall physical health status.

It should be noted that several potential mediators and moderators help to explain these relationships. For instance, knowledge, patient self-efficacy, norms, and stigma may be mediators, helping to explain the strong relationship between health literacy and medical decision making. Potential moderators may be social support and characteristics of the healthcare system (Berkman et al., 2011).

Physical health outcomes have also been linked to low levels of health literacy. In a British sample, low health literacy was associated with worse general physical fitness, greater body mass index (BMI), and fewer natural teeth. Health literacy skills are correlated with both adult and childhood cognitive ability, suggesting that health literacy may be an aspect of general cognition. Also, in this particular sample, education was a strong predictor of health literacy. The link between education and health literacy in this sample as compared with US samples may be due to differences between the UK and US education systems (Mõttus et al., 2014).

While health literacy is related to BMI overall, it is also specifically related to obesity. Remarkably, obesity in school-aged children has been found to be associated with not just parental obesity, but also with their parents' health literacy. Further, obesity in adolescents is associated with the adolescents' own health literacy (Chari, Warsh, Ketterer, Hossain, & Sharif, 2014). Thus, physical health is influenced not only by one's own health literacy but also by parents' health literacy skills in childhood and early adolescence. Based on these findings, interventions to improve health literacy skills may be effective at improving the physical health of multiple generations.

Interventions Improving Health Literacy

Like general literacy, individuals can become more literate in the domain of health. However, much of the focus in this area has been on the healthcare provider rather than the healthcare recipient. Removing literacy-related barriers to health by increasing providers' abilities to communicate effectively and properly with low health literacy individuals has been where the most significant attention has been placed. Indeed, the need for healthcare providers to increase their ability to effectively communicate health information is critical, as many patients understand as little as 50% of what is communicated during healthcare visits (Ong, De Haes, Hoos, & Lammes, 1995).

A popular method that has been introduced to healthcare providers is the "teach-back" or "teach-to-goal" method (Batterham, Hawkins, Collins, Buchbinder, & Osborne, 2016; DeWalt et al., 2011). This method is used after a healthcare provider has explained some form of health information to the patient. The provider will ask the patient to explain—in his or her own words—the information as he or she understood it. As part of this approach, providers are taught to ask open-ended questions, avoid the use of yes-or-no questions, and take responsibility for any misunderstanding that the patient has (DeWalt et al., 2011). Along with the "teach-back" method, another way providers can increase patients' understanding is to use "living room language," avoiding medical jargon, abbreviations, or complicated words (DeWalt et al., 2011). Using visual aids or images instead of relying solely on words may be another way to supplement information for low-literate individuals (Murphy, Chesson, Walker, Arnold, & Chessen, 2000).

Importantly, adequate health literacy is often seen as the exception rather than the rule, and both healthcare providers and health researchers need to remember to communicate in a manner that is understandable to all. Health professionals often overestimate patients' health literacy abilities and fail to recognize that a problem exists. Because of this gap in the communication process, healthcare providers need to learn a set of communication skills that are conducive to increasing patients' understanding. Addressing the obvious challenge of working with patients who have low health literacy, many clinicians and researchers alike have put forth guidelines to enhance the interaction between providers and patients (e.g., Parker, 2000).

Much overlap exists in these guidelines, but based on the research presented, several key components are worth note. First, healthcare providers (and researchers) need simply to be aware that low health literacy is a serious barrier for many patients and take the time to assess patients' health literacy skills. Being sensitive to the fact that this problem exists in two out of five Americans and taking the time to cue into patient speech and behavior patterns can smooth the patient–provider interaction and be more beneficial for the patient. Second, the use of medical language should be kept to a minimum amount necessary to convey adequate and appropriate information. Instead, "living room" language is simpler and creates less confusion for a low health literate patient who may be unfamiliar with even basic medical terminology. Third, the amount of information a patient receives during each interaction should be limited and repeated throughout the visit. Because patients forget more as the amount of information increases, information for retention is best presented in small chunks. Interactive approaches, such as the "teach-back" method, can simultaneously increase patient retention of information and confirm to the provider that the patient understands what is being asked of him or her. For example, a patient can teach the doctor how to take his or her medication according to what has been discussed in the visit. Lastly, because many low health literate patients are reluctant to ask questions, providers should help their patients ask questions and even encourage them to write down any questions before an appointment or bring a spouse or family member who may overhear information the patient misses.

In addition to communicating orally with patients, it is important to design health-related materials, so all individuals can understand the health information. With the increasing complexity of the healthcare system, patient education materials are following suit, and healthcare providers are relying more and more on written materials to educate patients about disease and treatment options. Yet a large number of studies have shown that the majority of standard education materials are written at levels far exceeding the reading and comprehension abilities of most Americans (Williams et al., 2002). While the average reading skill of Americans is around the eighth grade level, one study found that only 19% of health education pamphlets for parents with infants were written below a ninth grade level—making nearly 81% of materials inaccessible for the majority of parents (Davis et al., 1994). In terms of health promotion, many public health messages may also be inaccessible for individuals with low health literacy. Health messages in magazines, on billboards, or on clinic posters informing patients about the value of preventive behaviors like flu shots or regular mammograms may be problematic for those with low health literacy because they often require some understanding of medical knowledge (Parker, 2000).

One way to address these communication issues is by presenting only the most essential information, or presenting essential information first, which has been show to help low-numeracy individuals to better understand information (e.g., Peters, Hibbard, Slovic, & Dieckmann, 2007). Other suggestions include receiving input or feedback from target groups to ensure the information is clearly conveyed and culturally appropriate (Batterham et al., 2016), as well as using more pictures and less text. As an example, presenting comparable information about the harms and benefits of two drugs in tables rather than in narrative text improved understanding in one study (Tait, Voepel-Lewis, Zikmund-Fisher, & Fagerlin, 2010; though see Peters et al., 2007).

Adding video to a verbal narrative may also help low health literate individuals understand materials (Volandes et al., 2009). A meta-analysis of interventions for individuals with low health literacy found that the same intervention may have opposite effects depending on an individual's health literacy level (Sheriden et al., 2011). For example, adding traffic light signage to information aided the understanding of those with high literacy but decreased the understanding of those with low literacy. Thus, healthcare communication and messages aimed at making it easier to understand health information may not be "one size fits all."

Future Directions in Health Literacy

Health literacy is now recognized as a dynamic, multifaceted skill set (Berkman et al., 2011; Chin et al., 2011), and the US government is placing importance on increasing health literacy. Health literacy is part of the Affordable Care Act in the United States and is outlined as an objective in Healthy People 2020, and the US Department of Health and Human Services has written a "National Action Plan to Improve Health Literacy."

In the Affordable Care Act, the law required the enrollment process to be streamlined for Medicaid, the Children's Health Insurance Program, and state-based insurance exchanges that clear information be presented about insurance plans and benefits and for health literacy to be incorporated into professional training (Koh et al., 2012). In Healthy People 2020, objectives under the category of "Health Communication and Health Information Technology" related to health literacy are to improve the health literacy of the population and increase the proportion of persons who report that their healthcare providers have satisfactory communication skills. The US Department of Health and Human Services' National Action Plan to Improve Health Literacy includes seven goals to improve health literacy. These goals include promoting healthcare system changes that improve health information and communication, supporting and expanding efforts to provide culturally and linguistically appropriate health information services, and increasing basic research and evaluation of practices and interventions to improve health literacy.

Thus, the current focus in the field of health literacy is not so much on individual-level interventions aimed at increasing a single person's health literacy skills but rather system-level changes to improve how healthcare providers communicate, how healthcare systems are set up and managed, and how health communication materials are constructed. These changes are not easy to implement, nor will they provide an immediate fix for the health literacy "crisis," but they are a necessary step forward to promote and maintain optimal health for the most vulnerable patients. As one of the strongest predictor of an individual's health status is health literacy, the conversations surrounding the health literacy "crisis" should progress in the coming years, no longer overlooked and misunderstood, but evolving and expanding to improve the lives of many.

Author Biographies

Amber S. Emanuel, PhD is a lecturer in the Department of Health Education and Behavior at the University of Florida. Her research focuses on using social psychological theories to formulate and study effective health messages for eliciting health behavior change.

Kristel M. Gallagher, PhD is an assistant professor of psychology at Thiel College where she oversees the undergraduate psychology specialization in social psychology, focusing her research on the application of social psychology to health. Her research centers around the study of health behavior change, examining both theoretical and practices approach to motivation and health-related decision making. Past research includes the study of health message framing, including a meta-analysis published in the *Annals of Behavioral Medicine*.

> It is health that is real wealth and not pieces of gold and silver.
>
> —Mahatma Gandhi

Given the defining impact of mental and physical health on well-being, effective healthcare is a crucial aspect of human life. Beyond its direct impact within the personal and public domains, healthcare also plays a central economic role in society, representing over $4 trillion of spending within the United States in 2015 (Munro, 2014).

In light of the above, even the most advanced, comprehensive healthcare system is only effective to the extent that it is utilized, for when people fail to seek—or actively avoid—needed treatment, they not only threaten their own health but also increase health risks (and costs) to the broader public. It is thus crucial to understand treatment seeking and avoidance, including how they are developed and maintained, and their influence on individuals and society as a whole. To that end, this entry examines the following fundamental questions: (a) What constitutes healthcare treatment seeking and avoidance? (b) What factors influence seeking and avoidance? (c) What are their effects? (d) How can we understand treatment seeking and avoidance in the context of our current social and healthcare systems? (e) How can we improve treatment seeking and the corresponding outcomes?

Defining Treatment Seeking and Avoidance

Because treatment seeking and avoidance come in many forms, it is important to define them in the current context. For the purposes of this chapter, we are defining healthcare *treatment*

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

seeking as the active pursuit of healthcare resources for a health concern, including the following levels: (a) awareness (a necessary precursor), (b) information seeking (either independently or via professional consultation), (c) diagnosis, and, if necessary, (d) intervention (e.g., medication, equipment, exercise, and/or invasive procedures). We are defining *treatment avoidance* as a volitional forestalling of treatment for a recognized health problem, which includes a continuum of behavior from passive resistance (e.g., psychological denial) to delaying treatment and active refusal of care.

Factors Influencing Treatment Seeking and Avoidance

Demographic Factors

Individuals in poverty tend to have a general distrust of medical services, perceive these services as risky, and often express fears of being judged, losing resources, losing their children, and not receiving proper care (Canvin, Jones, Marttila, Burström, & Whitehead, 2007). Within these contexts, some physicians err on the side of overly vigilant treatment by sending individuals with reported chest pain to an intensive care unit—an action that can be unnecessarily dangerous if those individuals are not severely ill (Gigerenzer, 2007). Even in cases when medical services are extremely inexpensive or free of charge (e.g., in Montreal, Canada), avoidance can occur with people who have limited financial resources, such that aside from typical accessibility issues, avoidance has been linked with difficulties in gauging the seriousness of an issue and pride in one's masculinity (Dupéré, O'Neill, & Koninck, 2012). Individuals in poverty are also more likely to use an emergency department as their primary source of care, and this choice can lead to added expense, exposure to illness, and an increased length of stay (Lucas et al., 2009).

The highest levels of avoidance have been primarily found among individuals living in rural areas, younger men (18–35), and the uninsured, along with those reporting low trust in physicians, low confidence in personal health, and no consistently regular physician (Spleen, Lengerich, Camacho, & Vanderpool, 2014).

Psychosocial Factors

The results of a qualitative study in which individuals were interviewed to explain why they declined treatment highlighted the following reasons for avoidance: self-efficacy, threat minimization, fatalism and faith, distrust, need for additional information, desire to not know the diagnosis, futility, postponing intentions, physical discomfort from treatment, and quality of life (Sharf, Stelljes, & Gordon, 2005). Other reasons for avoiding care have included anticipating long wait times, believing that one can self-treat, expecting difficulty with obtaining an appointment, and fearing immigration issues (Asch, Leake, Anderson, & Gelberg, 1998).

A meta-analysis of compliance studies revealed that there are *hard* factors (e.g., duration of treatment, accessibility) and *soft* factors (e.g., beliefs, attitudes) that influence compliance, and chronic patients go through a cost–benefit analysis to determine if they would like to continue with treatment (Jin, Sklar, Min Sen Oh, & Chuen Li, 2008). A second meta-analysis revealed that men often avoid seeking medical care because they may prefer to avoid expressing emotions and because of health-based concerns, in some cases due to poor communication with healthcare providers, as well as fear, anxiety, and embarrassment (Yousaf, Grunfeld, & Hunter, 2015).

Those who felt their physicians were listening to them were less likely to avoid treatment (of the physical and psychological variety) during the following year, and certain individual differences (degree of distress and health status) were associated with avoidance level (Moore et al., 2004). Trust is particularly salient when it comes to protocol adherence and patients' reuse intentions, such that patients' trust in physicians has been linked with medical outcomes, physicians' medical training, physicians' prioritization of patients' treatment, and the extent to which physicians treat patients in a polite, friendly, and respectful manner (Olsen, Lind, Kennedy, & Chrabaszcz, 2008).

Additionally, physical embarrassment and concerns with being judged have been associated with avoidance behaviors (Consedine, Krivoshekova, & Harris, 2007), and others have further supported links between fear of embarrassment and avoidance, along with not having enough time to worry about oneself, minimizing health problems, and viewing health issues as normal (Hägglund & Wadensten, 2007).

Personality

Within the personality realm, help seeking has been linked to neuroticism, openness, agreeableness, and conscientiousness. The likelihood that a person seeks periodic health screening tends to be maximized at moderate levels of neuroticism; whereas extroversion and openness were negatively associated with the seeking of medical care, conscientiousness was positively correlated with care (Armon & Toker, 2013).

Type and Intensity of Health Problem

A study of 50 years of variations in patients' adherence to medical recommendations demonstrated that adherence levels can vary by disease (e.g., high for HIV, low for diabetes) and that in select (rare) instances, nonadherence may actually be adaptive (DiMatteo, 2004). Distrust in, and fear of, the medical community (whether warranted or not) can lead one to avoid medical care. For example, when it comes to colorectal cancer screenings within an ethnically diverse sample of adults, a fear of pain was associated with avoiding treatment and/or screenings (Bynum, Davis, Green, & Katz, 2012).

A meta-analysis of health beliefs, disease severity, and patient adherence revealed a possible curvilinear relationship between illness severity and propensity to secure care (DiMatteo, Haskard, & Williams, 2007), such that the seeking of care is highest in individuals with *moderately* severe illnesses.

Dynamic assessments of disease screenings have revealed that when a disease is serious and treatable, people tend to seek screens; however, when a disease is serious and untreatable, people tend to avoid them (Dawson, Savitsky, & Dunning, 2006). Perceived likelihood that a specific fear might be confirmed can also determine how individuals behave. For example, individuals who thought a cancer was incurable were less likely to seek medical care (Persoskie, Ferrer, & Klein, 2013).

Type and Source of Medical Treatment

People have been found to react defensively to threatening health-promoting information if it is relevant to them (van 't Riet & Ruiter, 2013). When seeking information, accessibility can override credibility, as health information is gleaned from multiple sources (Johnson, 2014). On the proactive front, and when considering vaccinations, the perceived likelihood of, susceptibility to, and severity of possible illnesses were all positively correlated with seeking vaccinations (Brewer et al., 2007). Intention to vaccinate, on the other hand, has been found to be negatively correlated with the perceived risk of vaccinating—particularly via information gathered from vaccine-critical websites (Betsch, Renkewitz, Betsch, & Ulshöfer, 2010).

Impact of Treatment Seeking and Avoidance

Outcomes related to the seeking and avoidance of medical treatment include quality of life, medical costs (e.g., emergency department care, end of life), vaccination, diagnoses (e.g., identifying cancer at stage 1 vs. stage 4), script writing (prescribing), and testing. Of course, issues of overdiagnosis can surface, such that sometimes even a correct diagnosis does not necessarily lead to better health. In other cases, seeking medical care can lead to patterns of overmedicating. For example, while acute upper respiratory tract infection is considered to be one of the most common illnesses that physicians report in emergency departments, and given that it is generally not a serious condition, physicians tend to overprescribe antibiotics for patients in many of these cases (Xu et al., 2013).

Treatment Seeking and Avoidance in the Healthcare Context

Federman et al. (2001) sampled nearly 3,000 primary care patients, and after controlling for patient demographics, health status, technical satisfaction, and site of care, patients' avoidance of medical care was found to be explained by 2 predictors: dissatisfaction with time spent with physicians and perceptions that physicians were not listening to patients (as cited in Moore et al., 2004). Moore et al. (2004) sampled over 1,000 adults to measure the impact of physician–patient relationships as a driver of treatment avoidance for a confirmed medical or psychological issue. Of the five key dimensions that Moore et al. (2004) explored (time waiting, time with physicians, respect displayed by physicians, physicians' confirmation of patients' understanding, and physicians listening to patients' concerns), all five dimensions were correlated with each other, and all but *time waiting for physician* were significantly correlated with *avoidance* of medical and psychological treatment. Further, when the four dimensions correlated with avoidance were combined, the more patients perceived that physicians were *listening to them*, the less likely they avoided treatment for medical or psychological issues (Moore et al., 2004). Thus, according to Moore et al. (2004), patients' relationships with physicians significantly determined the extent to which they sought medical treatment, and the inclusion of patients' preferences was critical to developing and maintaining a shared-decision treatment strategy—all of which helped to reduce patient ambiguity, adherence issues, and avoidance of medical care (Sieber & Kaplan, 2000).

Is Seeking Always Positive and Avoidance Always Negative?

Certainly there are instances in which one's seeking of medical treatment is so vigilant that it approaches an excessive level (e.g., one can envision a positive correlation between obsessive–compulsive disorder and treatment seeking). There are likewise instances when avoiding treatment can have a positive impact. For example, when seeking treatment for a cancer with a timeline that exceeds a person's expected lifespan, or if relative to a much less invasive, more conservative therapy, one must consider surgery that includes risks of infection, physical complications, medical errors, and even death, in these circumstances, it may (depending on the patient) be optimal to avoid immediate treatment.

Summary, Conclusions, and Recommendations

It appears that treatment accessibility, irrational fear assessment, and proactive vigilance on the part of individuals seeking care are just a few of the factors explaining a highly dynamic and complex relationship between individuals seeking medical treatment and those providing it. It is also true that patients can optimize their outcomes by taking an active role in the maintenance and treatment of their health.

Incentive Programs

El-Sadr and Branson (2015) examined the 2-year impact of financial incentives on patients' willingness to seek care and adhere to HIV medication protocols. To motivate patients along the lines of follow-up testing and appointments, patients identified as HIV+ received $25 per lab test and $100 per clinical appointment. Low viral counts signaled patients' adherence to their HIV medication protocols, and if patients' blood tests registered low HIV levels, patients could receive a $70 gift card every 3 months. The results were, in some ways, counterintuitive. Despite the opportunity to receive a $125 voucher for labs and follow-up care at sites offering incentives, patients in *both* the incentive and non-incentive conditions improved their follow-up with lab tests and appointments (i.e., no outcome differences). Ultimately, patients receiving financial incentives at sites with higher pre-study HIV showed the greatest HIV infection control (El-Sadr & Branson, 2015).

One possible explanation for treatment avoidance is that the traditional (paternalistic) approach of physicians as expert advisors does not always lead to optimal patient outcomes (Tefera & Olsen, 2015). When it comes to avoiding negative health behaviors (e.g., smoking) or approaching positive ones (e.g., HIV medication adherence), it has become increasingly important for architects of incentive programs—designed to improve patients' outcomes and quality of life—to consider dynamic approaches that include research from the medical, psychological, and behavioral economics literatures. Such an interdisciplinary marriage of data could better inform healthcare practitioners and policy makers alike, as they strive toward exceptional patient care and as patients look to make optimal healthcare decisions (Tefera & Olsen, 2015).

Wearable Technology: Putting Patients in the Driver's Seat

With the onset of an industry geared toward wearable health tracking devices, recent developments include the following technologies: accelerometers, consumable pills, biosensors embedded within a patch, and crystals inserted into a wearable skin-like attachment—all of which can track and transmit data to a corresponding application or companion software (e.g., heart rate, temperature, breathing rate, smoking covariates, tissue pressurization, steps taken, body position; Kosir, 2015). There are even reports of a smart bra that monitors the condition and rhythm of breast tissue to alert the wearer of possible breast cancers and smart contact lenses that utilize the user's natural tears to measure glucose levels (e.g., for diabetes care; Kosir, 2015).

Health Treatment and Health Maintenance

As important as maintaining one's medical treatments has become, the maintenance of one's health is also crucial. From diet to exercise to stress mitigation, balancing one's opportunities for health promotion with a dynamic lifestyle is critical in today's fast-paced environment. Perhaps as the availability of interactive wearable health technology increases, individuals can continue to monitor their own health in real time and present detailed and dynamic data to healthcare providers. It is with this potential trend in place that individuals can focus not only on maximizing the quality of their healthcare but also on (proactively) optimizing the quality of their health.

À votre santé.

Author Biographies

Nils Olsen (PhD, Social Psychology, University of North Carolina–Chapel Hill) is an assistant professor of organizational sciences at the George Washington University and conducts research within the following domains—(a) individual decision making (e.g., medical), (b) strategic decision making (e.g., Olympic Games), and (c) procedural justice (e.g., physician–patient, lawyer–client)—and has publications appearing in the *Journal of Personality and Social Psychology*, *Academic Emergency Medicine*, and *Handbook of the London 2012 Olympic and Paralympic Games.*

Phillip J. Moore (PhD, Social Psychology, University of California–San Diego) is an associate professor of applied social psychology at the George Washington University and conducts research that is designed to explore how psychological, environmental, and biological factors combine to influence important health-related decisions, behaviors, and conditions (e.g., obesity-related outcomes, terrorism and other emergencies, stressful events) and has publications appearing in the *Journal of Personality and Social Psychology*, *Cognition and Emotion*, and *Health Psychology.*

Steven Hyde (PhD student, Organizational Behavior, University of Texas–San Antonio). He received his master's degree, in 2015, in organizational management from the George Washington University and his bachelor's degree in psychology in 2013 from Southern Utah University. Steven's primary researcher interests are in decision making and behavioral strategy.

Lauren A. Fowler (PhD student, Applied Social Psychology, The George Washington University) received her BS in psychology and mathematics with a concentration in statistics from Eastern Michigan University. Her research focuses on the biological, psychological, and social determinants of weight-related health behaviors.

Health-Related Uncertainty

Jada G. Hamilton[1], Margaux C. Genoff[1], and Paul K. J. Han[2]

[1]Department of Psychiatry and Behavioral Sciences, Memorial Sloan Kettering Cancer Center, New York, NY, USA
[2]Center for Outcomes Research and Evaluation, Maine Medical Center Research Institute, Portland, ME, USA

Uncertainty is the subjective perception of ignorance, a state of knowing that there is something that one does not know (Han, Klein, & Arora, 2011). In medicine and healthcare, people are frequently confronted with uncertainty. For example, uncertainty can be perceived when a patient becomes aware of the probabilities of medication side effects, when a person hears a news report on how expert panels disagree about cancer screening recommendations, when parents consider whether their child should have a new vaccine that has a limited and evolving evidence base, or when a physician is deciding between multiple diagnoses that fit a patient's nonspecific set of symptoms.

These and myriad other instances of health-related uncertainty present significant challenges for laypeople, patients, healthcare providers, and health policy makers. For instance, uncertainty is a substantial source of stress for patients and families in acute and chronic disease contexts (e.g., Mishel, 1997). Research indicates that health-related uncertainty has implications for people's emotional well-being, decision making, and health behaviors, and investigating these diverse responses will allow researchers and clinicians to develop strategies to facilitate people's understanding of and adaptation to uncertainty. This chapter provides a concise overview of different types of uncertainty present in healthcare, ways in which people respond to uncertainty, and approaches to managing uncertainty, illustrated with examples and data from the cancer prevention and control context.

Defining Uncertainty

Establishing a clear definition of health-related uncertainty is important for promoting research and improving understanding of this phenomenon, and scholars from disciplines including

communication, decision sciences, engineering, health services, nursing, and psychology have presented various descriptions of this construct (e.g., Babrow, Kasch, & Ford, 1998; Brashers, 2001; Mishel, 1997). Here we focus on a conceptualization developed by Han et al. (2011), which integrates these perspectives into a multidimensional taxonomy of uncertainty in healthcare. This taxonomy provides a comprehensive tool for categorizing the varieties of uncertainty in healthcare by specifying three distinct dimensions of uncertainty: source, issue, and locus.

Source, the type of uncertainty, includes probability (uncertainty about the likelihood or risk of an event arising from the randomness or indeterminacy of the future), ambiguity (uncertainty regarding the strength, validity, consistency, or adequacy of risk estimates or risk information), and complexity (aspects of an event that make it difficult to understand, such as multiple possible causes or outcomes; Han et al., 2011). Delineating the different sources of health-related uncertainty underscores the fact that uncertainty is not entirely synonymous with a lack of knowledge, but rather can arise due to the characteristics and quality of available information. For example, uncertainty due to probability reflects in part the conceptual challenges inherent to translating risk estimates derived from a population to the level of the individual, and uncertainty due to ambiguity can be present in situations where a large body of evidence exists yet is conflicting in nature.

The second dimension is *issue*, or the substantive content of the uncertainty, which includes scientific uncertainty (disease centered, regarding aspects such as diagnosis or prognosis), practical uncertainty (healthcare system centered, regarding the structure or process of healthcare such as procedures to access care), and personal uncertainty (patient centered, regarding psychosocial or existential aspects such as implications of disease for one's personal relationships; Han et al., 2011). The dimension of issue reflects the multiple contexts and challenges that span the trajectories of acute and chronic diseases. Furthermore, the conceptualization of practical and personal uncertainty incorporates issues of great interest to individuals facing a health threat, consistent with the current emphasis on patient-related outcomes in health.

The third dimension of uncertainty is *locus*, or where the perception of uncertainty resides. Uncertainty can exist in the mind of the patient, the healthcare provider, neither, or both (Han et al., 2011). Dyadic exchanges between patients and providers are a fundamental aspect of medicine necessary for the diagnosis and management of disease and for the development of a shared understanding of relevant information and its associated uncertainties. By integrating the dimension of locus, the taxonomy explicitly acknowledges this relational nature of healthcare.

Responses to Uncertainty

Han et al.' (2011) taxonomy provides a useful framework for categorizing varieties of health-related uncertainty; however, it does not make predictions about how individuals will respond to uncertainty. Past work on this topic has generally focused on individual responses to different sources (e.g., probability, ambiguity) or issues (e.g., scientific, personal) of uncertainty and confirms that health-related uncertainty can have distinct effects on psychological and behavioral outcomes.

Psychological Outcomes

Most research suggests that health-related uncertainty has adverse effects on people's cognitions and emotions. Some of these challenges arise from how people process uncertain information. The cognitive demands of information that is high in volume and complex in nature can cause people to experience a sense of confusion and information overload (Babrow et al., 1998). Furthermore, people tend to utilize heuristics, or mental shortcuts, to make inferences when information about the probability of future events is limited, which can lead to systematic biases and errors in decision making and judgment. Consistent with a phenomenon known as "ambiguity aversion" (Ellsberg, 1961), people also tend to form pessimistic appraisals of risk information that is lacking in precision, reliability, credibility, or adequacy (for additional details, see chapter in this volume by Carpenter & Han). For example, study participants who were presented with an ambiguous quantitative risk estimate of the likelihood of drug side effects (operationalized as a numerical range versus a single point estimate) reported poorer comprehension, greater perceptions of risk for the side effects, and lower perceptions of creditability and trust in the individual conveying the risk estimate (Longman, Turner, King, & McCaffery, 2012).

Both scientific and personal issues of uncertainty have been associated with emotional outcomes in the cancer context. Uncertainty about one's symptoms, prognosis, and social and physical functioning can be extremely stressful for cancer patients and survivors. Cross-sectional studies have indicated that greater perceptions of cancer-related uncertainty are associated with poorer emotional well-being among cancer patients and survivors (e.g., Hall, Mishel, & Germino, 2014). Similarly, longitudinal data indicate that decreased perceptions of cancer-related uncertainty are associated with improvements in global quality of life over time among prostate cancer patients and their spouses (Song et al., 2011).

Behavioral Outcomes

In the presence of uncertainty, people can struggle to make medical decisions. For example, parents of children with Fanconi anemia (a rare inherited cancer predisposition syndrome) reported greater difficulty in making a decision about a risky medical treatment and were less likely to choose the treatment, when they perceived greater ambiguity due to conflicting expert opinions and greater uncertainty due to the probabilistic nature of treatment outcomes, respectively (Hamilton et al., 2013). Mediational analyses suggested that parents' perceived uncertainties increased their emotional concerns about the treatment, which in turn promoted these adverse decisional outcomes. Similarly, an investigation of patient–physician communication revealed that breast cancer patients experienced poorer surgical decisional satisfaction when their physicians communicated greater scientific uncertainty regarding surgical options (Politi, Clark, Ombao, Dizon, & Elwyn, 2011). However, patients' level of involvement in the decision-making process moderated this association such that dissatisfaction following the communication of scientific uncertainty was greatest among patients who were less involved in the decision.

It seems intuitive that people would seek information when confronted with uncertainty; yet in some instances people choose to actively avoid information (Brashers, 2001). Avoiding health information that is ambiguous (e.g., information perceived as untrustworthy, contradictory, or imprecise) or complex in nature can allow people to minimize feelings of confusion; in other cases, avoiding information allows people to retain a beneficial sense of uncertainty and hope about their future health.

Physical Outcomes

A small body of evidence across diverse samples suggests that health-related uncertainty may affect people's physical well-being. For instance, greater perceptions of cancer-related uncertainty have been associated with increased fatigue and insomnia among breast cancer survivors (Hall et al., 2014). Potential associations between health-related uncertainty and physical functioning warrant additional exploration, as does the extent to which such relationships may be explained by people's psychological responses to uncertainty.

Individual Differences in Responses to Uncertainty

Although people have unique reactions to health-related uncertainty, their stable traits and personality characteristics can lead to some predictable psychological and behavioral responses. Broadly speaking, these individual characteristics reflect specific tendencies for how people interpret and understand uncertain information and situations.

One relevant trait is *intolerance of uncertainty*, a dispositional characteristic involving a set of emotional, cognitive, and behavioral responses to an unknown outcome. This trait is theorized to arise from negative beliefs about uncertainty, and uncertainty-intolerant people tend to interpret uncertain situations as threatening and anxiety provoking (Koerner & Dugas, 2008). Intolerance of uncertainty has been conceptualized as both a desire for predictability and uncertainty paralysis, a tendency to avoid decision making or action in the presence of uncertainty (Bredemeier & Berenbaum, 2008). People with high desire for predictability are motivated to feel more certain about the future, require less information to feel certain, and are selective about the information they seek out (Bredemeier & Berenbaum, 2008). Uncertainty paralysis causes people to overestimate the likelihood of negative outcomes (Bredemeier & Berenbaum, 2008), which may contribute to avoidance of action in uncertain situations.

Their interpretation of uncertain health threats as unacceptable should influence uncertainty-intolerant people's information seeking and health behaviors. Consistent with this prediction, Rosen, Knauper, and Sammut (2007) study of women's HPV knowledge found that higher intolerance of uncertainty was linked to greater behaviors associated with information monitoring (such as intentions to discuss HPV with other people) and preferences for clinicians to spend more time discussing HPV test results.

Need for cognitive closure, an aversion toward uncertainty and ambiguity with a preference for stability in beliefs and expectations (Kruglanski & Webster, 1996), is another trait that influences people's responses to health-related uncertainty. Need for cognitive closure is a motivational tendency to pursue information, and this need can also fluctuate as a result of situational factors (e.g., fatigue, noise) that place demands on one's information-processing abilities (Kruglanski & Webster, 1996). Individuals with a heightened need for closure, whether due to dispositional or situational factors, are motivated to seek out information to obtain an answer that eliminates confusion and uncertainty. This need for closure may be at odds with the need for validity in information processing, triggering an urgency to resolve uncertainty at the expense of an exhaustive collection of information (Kruglanski & Webster, 1996).

Although empirical evidence is limited, this trait has been associated with cancer-related behaviors and emotions. Eiser and Cole (2002) observed that women with a higher need for cognitive closure were more likely to express intentions to have cervical cancer screening or to have undergone screening than were women with a lower need for cognitive closure. The motivational drive to obtain definitive information may prompt cancer screening among those with greater need for closure. In addition, Hamilton et al. (2012) demonstrated that the extent to which parents of children with Fanconi anemia experienced the phenomenon of ambiguity aversion (i.e., adverse psychological responses to ambiguous information; Ellsberg,

1961) was dependent on their need for cognitive closure. Specifically, among parents with a high need for cognitive closure, greater perceptions of ambiguity about their child's medical treatment were strongly associated with increased worry about the treatment; this relationship was not observed among parents with a low need for closure. Individuals with a higher need for cognitive closure may benefit from targeted efforts to manage affective implications of health-related uncertainty.

Dispositional optimism can help some people to handle uncertainty in healthcare, including the fundamentally unpredictable risk of cancer. Optimism is a generalized expectancy for positive rather than negative outcomes, and those who are optimistic either see positive outcomes in all situations or disassociate their mood from external factors (see Carver, Scheier, & Segerstrom, 2010). Dispositional optimism is associated with lower emotional distress and the use of adaptive coping strategies (Carver et al., 2010), as well as with lower perceived cancer risk (Hamilton & Lobel, 2015). Optimism may also influence how people interpret health messages. Han et al. (2012) used a web-based survey to present participants with textual and visual representations (i.e., icon arrays with varying degrees of randomness) of the risk of colorectal cancer. Those who were more optimistic perceived less uncertainly about their colorectal cancer risk overall, while those who were less optimistic experienced heightened uncertainty when risk information was presented in a random format.

A final characteristic that can affect how people react to uncertainty in healthcare is *numeracy*, the ability to understand and use numbers. Numbers are frequently used in conveying probabilistic risks because quantifying descriptors are more useful and less ambiguous than qualitative descriptors (Schwartz, Woloshin, Black, & Welch, 1997). Unfortunately, numerical presentations can be challenging for those with low numeracy to understand, limiting their risk comprehension and healthcare utilization. In a study evaluating women's abilities to assess their breast cancer risk, Schwartz et al. (1997) found that women with low numeracy inaccurately assessed their risk for breast cancer.

Managing Uncertainty

Uncertainty arising from limited access to available health information or the complex nature of a health issue may be reduced by the provision of additional, clarifying information. However, health-related uncertainty often exists because knowledge about the causes, course, and consequences of illness is evolving. When definitive evidence and scientific consensus regarding a disease or treatment are lacking, health-related uncertainty can be unavoidable and irreducible (Han et al., 2011). Such instances may necessitate the adoption of strategies for managing health-related uncertainty, as opposed to minimizing or eliminating uncertainty.

Coping With Uncertainty

As described in the transactional model of stress and coping (Lazarus & Folkman, 1984), in response to a stressor (e.g., health-related uncertainty), people perform a primary appraisal to determine the nature of the stressor and its implications for their well-being, followed by a secondary appraisal to determine which resources they have available for coping with the stressor. These primary and secondary appraisals represent processes that could be targeted to promote adaptive outcomes in the face of health-related uncertainty. Primary appraisals are critical (Babrow et al., 1998): uncertainty can be viewed as a distressing problem or, alternatively, as an opportunity for hope. Empirical evidence suggests that positive primary appraisals of uncertainty contribute to psychological adjustment. For instance, whereas some cancer patients with late-stage disease participating in clinical trials viewed uncertainty about their prognosis as a source of anxiety, others interpreted this uncertainty as reasons for hope and optimism about their future and the likelihood of receiving benefits from the clinical trial (Brown & deGraaf, 2013). Similarly, among men with prostate cancer undergoing watchful waiting (a disease management option in which an identified asymptomatic prostate cancer is monitored for progression instead of adopting immediate treatment), the appraisal of cancer-related uncertainty as a danger was associated with feelings of worry, negative mood, and decisional intolerance, whereas the appraisal of uncertainty as an opportunity contributed to perceptions of increased options and hope (Bailey, Wallace, & Mishel, 2007).

Achieving a positive primary appraisal of health-related uncertainty is not always possible. Uncertainty can also be managed through the secondary appraisal process and use of coping strategies, which are cognitive or behavioral efforts to manage demands that are perceived as stressful or as exceeding one's resources (Lazarus & Folkman, 1984). Coping strategies can be categorized as emotion focused (aimed at controlling negative emotions through efforts such as distraction or seeking comfort from others) versus problem focused (aimed at resolving or addressing a threat, such as through planning or preparation; Lazarus & Folkman, 1984). Alternatively, coping strategies can be categorized as approach oriented (approaching a stressor such as through problem solving or expressing emotions) versus avoidance oriented (avoiding a stressor such as through denial or withdrawal; Suls & Fletcher, 1985).

Which coping strategies one uses and the psychological outcomes achieved depend on numerous factors including aspects of the stressor, situation, and individual (e.g., Lazarus & Folkman, 1984; Suls & Fletcher, 1985). For instance, an individual's primary appraisal of uncertainty can shape the coping process. Mishel and Sorenson (1991) demonstrated that gynecological cancer patients' appraisal of health-related uncertainty as a danger was associated with greater use of emotion-focused coping, whereas appraisal of uncertainty as an opportunity was associated with the use of proactive problem-focused coping. There is no consensus regarding which coping strategies are most effective or adaptive in response to health-related stressors, including uncertainty. For example, although avoidance-oriented coping is commonly associated with maladaptive outcomes, empirical evidence suggests that the effectiveness of avoidance-oriented coping may depend in part on the temporal nature of health-related uncertainty. Avoidance-oriented coping can mitigate distress when the experience of uncertainty is time limited and short, such as when women are undergoing follow-up testing from an abnormal mammogram (Heckman et al., 2004). Conversely, avoidance-oriented coping can increase distress when uncertainty is unrelenting, including among cancer survivors facing the constant possibility of recurrence (Stanton, Danoff-Burg, & Huggins, 2002). Research is needed to understand how different characteristics of health-related uncertainty, including its source, temporality, and controllability, influence the selection and adaptability of various coping strategies.

Shared Decision Making

Shared and informed medical decision making can also help to manage uncertainty. Shared decision making is a process by which a healthcare provider educates patients about available options and the benefits, harms, and personal impressions of these options and elicits the patient's individual preferences and values in order to achieve a shared understanding of a given medical decision and ultimately make a decision together. Shared decision making is a critical component of patient-centered care and is particularly appropriate for "preference-sensitive" decisions in which an objectively best option is lacking (Politi, Lewis, & Frosch, 2013). For example, the US Preventive Services Task Force, an independent panel of nongovernment experts in prevention and evidence-based medicine, recommends shared and informed decision making between healthcare providers and women ages 40–49 years regarding the use of mammography due to inadequate evidence about the net benefit of this screening test for these women (U.S. Preventive Services Task Force, 2009).

As part of a shared decision-making process, providers should clearly and openly communicate the uncertainties associated with available options, such as uncertainties due to probabilities, ambiguities, or complexities of the situation. By acknowledging these uncertainties and addressing patients' confusion and emotional reactions, providers can help patients to tolerate health-related uncertainty and make a high-quality medical decision. In spite of the potential benefits of discussing uncertainty with their patients, providers infrequently disclose such information (Politi et al., 2011). For example, fewer than a quarter of American men report being informed that experts disagree about the use of prostate-specific antigen (PSA) testing to screen for prostate cancer or that no one is sure that PSA testing saves lives (Leyva et al., 2016), although professional societies recommend that providers discuss these issues due to inconsistent evidence about the net benefit of PSA testing.

Numerous barriers may prevent providers from initiating discussions of health-related uncertainty, including limited time, lack of training, and concerns about patients' reactions. Fears about adverse patient reactions may be warranted: discussions of health-related uncertainty can contribute to less decision satisfaction among patients (Politi et al., 2011), although some discomfort or anxiety may be a consequence of patients being truly engaged in the decision-making process (Politi et al., 2013). Strategies are needed for overcoming providers' barriers to the disclosure of health-related uncertainty, such as communication skills training or insurance reimbursement for shared decision-making discussions, as well as for empowering and supporting patients as they navigate complex medical decisions.

Conclusion

Uncertainty is a pervasive challenge in healthcare. To date, researchers have characterized some of the distinctive ways in which different types of health-related uncertainty influence people's cognitions, emotions, decisions, and behaviors, as well as how people's traits and personalities shape these responses. Promising approaches for managing uncertainty exist, including the promotion of adaptive coping strategies and shared and informed medical decision making; however, additional research is needed to determine for whom and in which situations these approaches are most effective and to develop strategies for helping patients and providers adopt these approaches and address the challenges of health-related uncertainty.

Author Biographies

Jada G. Hamilton, PhD, MPH is an assistant attending psychologist in the Department of Psychiatry and Behavioral Sciences at Memorial Sloan Kettering Cancer Center. She is a social and health psychologist whose work examines psychosocial issues in health and cancer prevention and control. Her program of behavioral research aims to translate advances in genetic and genomic medicine into improvements in cancer care and public health.

Margaux C. Genoff, MA, is a doctoral student in clinical psychology at the New School for Social Research. Her research interests are in the psychology of gender and the role of culture in psycho-oncology and health disparities.

Paul K. J. Han, MD, MA, MPH, is director of the Center for Outcomes Research and Evaluation at Maine Medical Center. He is a behavioral and health services researcher and a general internist and palliative medicine physician. His main research interests are in risk communication and shared decision making, and his work focuses on the communication and management of uncertainty in healthcare.

The commonsense model (CSM) was designed to describe the mechanisms underlying individuals' awareness and understanding of their current and future health and threats to health and how they plan to act or currently act and respond to feedback from their actions. The CSM is a dynamic control systems model that provides a conceptual framework for representing an individual's perceptions, expectations, and beliefs and actions about his/her body as he/she navigates daily life (Leventhal, Phillips, & Burns, 2016). It also provides a way for representing the moderating effects of cultural and individual differences. Although varying amounts of attention have been paid to the latter two topics, investigators have amassed a large body of data from a wide array of clinical and experimental settings regarding the CSM in general (Hagger, Koch, Chatzisarantis, & Orbell, 2017), and the CSM continues to suggest hypotheses for investigation.

Underlying Principles and Structure of the CSM

The CSM uses contemporary concepts from cognitive and social science to organize what people at different ages, including those who are ill and those who are well, say and do to manage ongoing and to prevent future health threats. The resulting conceptual framework proposes that all behaviors for controlling current or future health threats are generated and guided by mental models (i.e., *representations* of the threat, the *treatments or procedures for threat control,* and *action plans* for performance and evaluating outcomes). Representations

---

are generated when stimuli such as symptoms, changes in function, and the observation of illness in other individuals, and media messages activate underlying memory structures or illness *prototypes* acquired during an individual's prior health history. The factors defining the representation are generated by the particular prototypes that have been activated.

A second principle proposes that *prototypes*, *representations*, and *action plans* are multilevel, that is, they consist of concrete, perceptual experiences combined with abstract concepts. Perceptual experiences give meaning to abstract concepts and concepts give meaning in return (Brewer, Hallman, & Kipen, 2008). Understanding how representations and actions change over time requires modeling the interactions, both conscious and implicit, among concrete experiences and prototypes. A term such as "belief(s)" has a different meaning therefore, in the multilevel structure of the CSM than in the "health belief model" (Rosenstock, Strecher, & Becker, 1988) or the "theory of planned behavior" (Ajzen, 1991); these latter decision models focused on probabilities and utilities ("expectancy-value models") without specifying their relationships to experience. These frameworks can predict that an individual will seek and use medical care if she/he "believes" him or herself ill, without modeling the processes involved in how that individual *perceived* and *decided* that he or she was ill and how he or she decided that medical care was the appropriate action for self-management. The CSM provides conceptual starting points for describing interactions among the mechanisms underlying perceptions of health and illness. This deeper understanding is essential to move from prediction (which may involve widely different variables for different illnesses and populations) to developing effective interventions.

A third underlying principle is that all components of the CSM play a crucial role when predicting a specific outcome or planning an intervention to improve behavior and health outcomes. Thus, even when a particular variable predicts an outcome (e.g., painful symptoms are more likely than non-painful symptoms to lead to seeking medical care), factors that do not differ across pain levels and are not critical for making the prediction (e.g., having access to a medical practitioner) are critical for the occurrence of the behavior.

Structure and Operation of Commonsense Model

The processes involved in creating commonsense models of health and health threats are similar to that in other multifactorial control systems models (e.g., Carver & Scheier, 1982). All of these models hypothesize that health-related actions are generated by multiple interacting variables and ongoing feedback from action. The process is frequently initiated when a stimulus, for example, a headache, matches an *illness prototype* or memory structure of prior headaches, thereby activating an *illness representation* or mental model of the experience and its meaning. The process is also shaped by one of the prototypes at a "deeper, implicit level," the *acute prototype* that underlies and defines the properties of an array of specific conditions. Acute conditions are perceived as symptomatic, short lasting, with known causes, non-life threatening, and controllable. Representations for current ongoing conditions are influenced by the acute prototype; the expectations for its duration, causes, treatments, and action plans for implementing treatment are influenced by the underlying acute prototype. The differentiation between representations and prototypes is critical in commonsense modeling. Prototypes are the history of an individual's experiences of her or his physical and functional self and the history of specific conditions, the symptoms, and physical and cognitive functions associated with the illness. Prototypes form the "baseline comparisons" for deciding what is "normal health" and everyday illness. The mental models or representation of a condition that is active in mind at a given moment may contain only some of the features of an underlying prototype and can share features of more than one prototype. As active working models, representations are more flexible than prototypes; representations motivate ongoing action and respond to feedback from action. The expectations built into prototypes and expressed in representations are critical for appraising the value of responses whether self-selected or professionally prescribed.

Both automatic and deliberative, that is, reasoned processes, are involved in the activation of representations. The proportion of one or the other is a function of prior experience with the initiating stimulus. Representations of common conditions will automatically generate *action plans* for controlling a disorder, whereas representations generated by novel and/or highly threatening symptoms will activate substantial amounts of deliberative, conscious processing. The balance between automatic and deliberative responding will depend upon familiarity with the threat and contextual factors ranging from contact with ill individuals to exposure to novel environments and consumption of unusual foods. Feedback from action provides evidence for the validity of the both illness and treatment representations. Uncertain feedback can stimulate questions such as "Did my distress continue because the treatment failed to reduce stomach acid or because the discomfort was not from my stomach?" (Bunde & Martin, 2006). How feedback updates the parameters of illness and treatment representations and action plans is a critical area for theoretical development and empirical research.

Prototypes and Representations

Language can only partially describe the processes involved in the activation of representations; computer models will prove essential for representing this rapidly moving complex process (Lowe & Norman, 2017). The complexity arises as cues, for example, symptoms, can activate multiple disease-specific prototypes and more than one implicit (nonconscious) deep-level prototype, such as *acute*, *episodic* (periodic flares), and *chronic* (part of me will never go away). The prototype activated depends in part upon the eliciting information, for example, previously experienced symptoms, illness in a family member, information from a doctor, and mass media. Interactions among the prototypes of the self, diseases and treatments, generate the mental models or representations that stimulate action plans, actions, and feedback.

The self-system contains multiple prototypes of an individual's physical, cognitive, and emotional functions, systemic vulnerabilities, and prior illnesses in addition to their social roles, traits, and emotional states that are the typical focus of research in personality and social psychology. Prototypes are both conceptual (what I am, what I do) and experiential (i.e., somatic feel of self and its ongoing functions). Both the abstract and experiential levels generate expectations as to what I am when well and what I am when ill. They also link specific symptoms and functional changes to one or another illness. Prototypes are anchors against which changes in somatic sensations (symptoms) and function are experienced and evaluated as relevant or irrelevant to one's physical integrity and functional soundness.

Many of the prototypes that influence the mental representations that regulate ongoing health behaviors reside at a "deep" level. Evidence for the presence of deep-level prototypes can be found in many forms. One source of particular relevance to health psychologists is data validating the accuracy of individuals' overall sense of physical and functional health: "self-assessment of health" (SAH). SAH, rated on a five-point scale (poor, fair, good, very good, or excellent), is a consistent, valid predictor of mortality in multiple community samples (Idler & Benyamini, 1997) and has outperformed "objective" medical indicators in predicting mortality in clinical samples. In summary, a diverse, multilevel array of prototypes establish expectations regarding health and function in multiple areas, setting the stage for action and the interpretation of outcomes of self-generated behaviors and prescribed treatments. Deep-level prototypes of such self-assessed health likely influence whether symptoms and functional changes activate prototypes and representations of serious or mild chronic and acute conditions; the vigorous, "healthy" self may be more likely to attribute symptoms to minor than serious life-threatening events.

Illness Prototypes and Representations: A Multilevel Process

Illness prototypes are the repositories of experiences with prior illness in oneself, direct observations, and communications from family, friends, practitioners, Internet searches, and media. Some of these memory structures are universal; it is a rare individual who has not experienced an upset stomach or a cold one or more times. An illness representation is formed when an event, for example, a symptom or observation of someone who is ill, activates one or more prototypes. The parameters of representations, the expectations they generate, reside in one or more of five areas: *identity* (e.g., label and somatic experiences), *cause, control* (personal, doctor), *timelines* (time for onset, duration, and removal with treatment), and *consequences* (both immediate and long term). These factors affect the selection of actions and expectations for outcomes. Representations that attribute the causes and/or select the treatments of a somatic state that are inconsistent with the conditions underlying biology can generate responses that fail to ameliorate target symptoms and delay appropriate treatment.

Disease-specific prototypes are connected to or "nested in" deep-level prototypes, structures that affect the parameters of disease-specific prototypes and the mental representations that are active in the selection of treatments and appraisal of treatment outcomes. The "acute" prototype is the deep-level "default"; it defines the attributes and sets the expectations for virtually all everyday conditions including the selection of treatments and expected outcomes. For example, exposure to coughs and sneezes of someone with a bad head cold (cause) might lead one to expect a similar array of symptoms (identity) within 24 hours that will last 2–5 days (timeline), disrupt daily activities (consequence), and use various over-the-counter medications (control). The structure matches the experience of a vast array of acute conditions. Frequency of activation strengthens the acute prototype, making it the preferred model for representing particular illnesses. As the default, the acute prototype can define parameters and set expectations for conditions that are episodic and chronic, as well as those acute. Computer models suggests that the "acute prototype" may underlie the role of perceived control in connecting illness and treatment representations (Lowe & Norman, 2017).

The chronic prototype forms a distinct contrast with the acute prototype. Timelines are likely the major source of difference: chronic conditions are lifelong, though many vary over the lifespan, and the consequences are often life threatening. The two can overlap however, in the causal area, for example, life experiences and lifestyle behaviors are commonly cited as causal, though genetic causes are more commonly attributed for chronic conditions. The "acute and chronic" prototypes differ to a substantial degree for preferred treatments for control: over-the-counter medications and minor life changes are most often tried for acute conditions, while professionally prescribed treatment and/or major lifestyle changes are applied for conditions defined as chronic. Patients frequently attribute symptoms to chronic conditions that are asymptomatic, for example, hypertension, and misattribute symptoms to diseases that are highly threatening but silent during much of their developmental histories, for example, cancer.

The overlap between the acute and chronic prototype gives rise to a third deep structure, the "episodic prototype." Episodic conditions generally last a lifetime; they are chronic but have symptomatic flares that match acute conditions; asthma is a prime example.

Self-management of such conditions (chronic, with acute episodes of symptoms) can be undermined when patients focus on symptom management and fail to treat the underlying relatively asymptomatic chronic component. For example, many patients with asthma who agree that "I'll have asthma all my life" also agree they "only have it when having symptoms" (Halm, Mora, & Leventhal, 2006); these patients fail to use inhalers to control their underlying chronic inflammation. Problems also arise when the target symptoms are unrelated or poorly correlated with the underlying condition. Early-stage problems may arise when experimenting with alternative procedures (e.g., special diets, medication) delays care seeking. Later-stage problems may arise when successful symptom resolution leads to nonadherence to long-term treatment, allowing the underlying condition to worsen.

Prototypes and representations of treatments are similar in structure and content to those for illnesses. Treatment procedures are chosen on the basis of the match between their properties and those of the illness. The selection can be automatic, that is, reaching for antiseptic for an abrasion to the skin or deliberative. Deliberative decisions will be likely when an initial automatic selection fails (e.g., antiseptic did not prevent infection, so now call doctor's office) or when presenting symptoms are uncertain and/or of threatening magnitude.

Action plans are brought into play by the activation of illness and treatment representations. The concept was introduced in experimental studies examining the impact of fear-arousing messages on preventive health actions such as taking tetanus inoculations (Leventhal, 1970). These studies were the basis for the parallel framework in which one pathway involved cognitions of the threat of tetanus that led to changes in attitudes and intention immediately after the message and led to action, that is, getting an inoculation to prevent tetanus in the days or weeks following message exposure, when the threat information was combined with an action plan. A separate pathway involving the activation of fear emotion during exposure also influenced attitudes and intentions immediately post exposure to the threat message, but had essentially no effect on being inoculated, in the absence of an action plan. Reviews of studies over recent decades are consistent with the assumptions underlying the original parallel processing model and its revisions (Tannenbaum et al., 2015).

Action plans are often overlearned, implicit, and automatic, for example, a headache that disrupts sleep can move the restless sleeper to the medicine cabinet, removing and opening a bottle of aspirin or acetaminophen, removing two or three tablets, putting them into the mouth, and downing them with a glass of water. This well-structured and rehearsed action plan reflects a history of prior headache management. The expectations generated by illness and treatment representations led to performance, most of which was automatic, requiring few deliberative decisions. Forming a new or novel action plan requires considerably more mental and behavioral steps; the cognitive processes involved in planning will differ from those involved in the execution of well-learned, preexistent plans. The planner has to visualize the action, its details, the environment in which it takes place, and how best to insert the action into the environment. The third and perhaps most important set of factors is perceiving behavioral sequences—what he or she does at particular times and places that are compatible or incompatible with the proposed action. This latter step is critical for the management of chronic conditions such as diabetes, chronic reflux, and hypertension, illnesses that may require multiple medications taken more than once a day and benefit from substantial changes in lifestyle, for example, diet and physical activity. How does one integrate the taking of multiple medications into daily life, change food preferences, times and quantities eaten, locate places to walk? Specifically, how does one plan and initiate behaviors that become habitual (Phillips, Leventhal, & Leventhal, 2013)? Qualitative studies, focus groups, and intensive open-ended interviews indicate that producing effective action plans involves strategies for attending to the environmental details and behavioral patterns to identify habitual action sequences consistent with initiating and sustaining treatment (Brooks et al., 2015).

Using and Misusing the Commonsense Model

As stated in the opening, the CSM provides a conceptual framework for representing what people do and say as to how they manage ongoing and prospective illness threats. The CSM is designed to describe how things happen; it is a process-oriented conceptual framework designed to suggest new hypotheses and techniques for measurement and intervention, and it is open to modification when demanded by systematic observation and experiment. As is the case with all process models, there are problems in how it is used; we discuss the most important.

Confusing Method and Theory

A number of standardized instruments have been devised to measure the components of the CSM. Although useful, measures are not equivalent to concepts; the Illness Perception Questionnaire (IPQ and IPQ-R; Moss-Morris et al., 2002) is conflated with the concept of "illness representations" in a meta-analysis by Brandes and Mullan (2014). These measures are but one of many possible ways of assessing illness representations; they are not identical to the concepts and are not dynamic and do not describe process (Phillips, Leventhal, & Burns, 2017). The conflation of validated instruments with concepts, for example, the IPQ and IPQ-R, may lead reviewers to exclude studies using disease-specific measures to assess illness and/or treatment representations, an omission that reflects failure to understand the difference between measures and concepts. This also reflects an uncritical acceptance of a one-size-fits-allapproach for hypothesis testing as spelled out in a response to the claims made in recent meta-analysis of IPQ and related instruments (Phillips et al., 2017).

In addition, one might ask why investigators conducted studies and meta-analyses assessing the relationship of measures of illness representations to long-term adherence for chronic conditions rather than assessing treatment representations. A possible answer is that the availability of validated measures, IPQ and IPQ-R, stimulated research, reminding one of the saying, "If you have a hammer, everything looks like a nail." The CSM hypothesizes, however, that illness representations moderate, and treatment representations mediate, adherence for both chronic and acute conditions (see Horne et al., 2013). Illness representations are not irrelevant in the adherence process; they set the targets, that is, the outcome expectations for evaluating treatment efficacy. How effectively and quickly the treatment impacts symptoms or "objective" measures determines whether it can control the disturbance and whether it addresses its causes (Rottmann, 2016). The variables in the CSM do not operate independently. Useful though it may be, multiple regression modeling does not address these issues especially when used blindly.

When to Assess Specific Components of the CSM

The confusion of concepts and measures reflects a deeper misunderstanding of control systems models; no single variable operates without the contribution of the others. By contrast, regression modeling often leads investigators to conclude incorrectly that a predictor is responsible by itself for variance in an outcome. Illness representations are important for motivating action at symptom onset (typical for acute conditions), setting criteria for evaluating treatment efficacy, and understanding complex conditions that combine acute and chronic features. Continuing treatment after the initiation of treatment will involve satisfying expectations of both the illness and treatment, that is, what symptoms will it control, functions will improve, and time to and duration of efficacy. When implemented by a simple and effective action plan, the factors important during acquisition may fade in importance and be forgotten once a behavior is habitual (Gardner, 2015). The following examples illustrate how different illnesses and clinical settings allow investigators to understand how the CSM operates in diverse contexts.

Regarding acute conditions and care seeking in primary care, Cameron, Leventhal, and Leventhal (1995) found that new symptoms are critical for care seeking and that care seekers' symptom representations are more likely to have an identity, long timeline, and severe consequences and are frequently targets for efforts to control.

Regarding care seeking in an emergency care setting, common sense represents recurrent heart attacks as acute, with one event unrelated to the next. Onset of symptoms (e.g., chest and/or shoulder pain, profuse sweating) as sudden and rapid and symptoms are recognized by laypersons and practitioners alike. However, significant numbers of individuals with MI present with "atypical" symptoms (Grosmaitre et al., 2013). For example, pain can be experienced in the upper abdomen rather than the chest and interpreted as gastric rather than heart. Bunde and Martin (2006) described how the perception and interpretation of atypical symptoms related to delays in seeking hospital care by individuals having an MI; those quick to seek care had "textbook symptoms" (e.g., chest or shoulder pain, profuse sweating); and a prior history of cardiac problems. Those who were slower to seek care reported gastric pain, chronic fatigue, breathlessness, and swollen feet. For the physician, breathlessness, chronic fatigue, and swollen feet are signs of heart failure, while for the layperson, they are misperceived as being unrelated to a serious heart condition and instead taken as commonsense indicators of aging; after all, "one's heart is not in one's feet." Patients articulate these misperceptions: "When you hear about having heart problems … you're supposed to feel maybe a pain in your left arm, maybe a pain in your chest, or pressure… It would have been clearer to me if I had chest pain and then I would have said, okay, I'll call and say I'm having chest pain…" (Horowitz, Rein, & Leventhal, 2004). Symptoms related to the problems of everyday life, for example, stomachache and fatigue, are unlikely to stimulate care seeking, and even dramatic events unrelated to the prototype can be "ignored"; for example, as one heart failure patient said, "I guess that I could have gone to the doctor after I had that collapse on the hallway floor. It might have been a good idea" (Horowitz et al., 2004).

Regarding adherence for chronic conditions without and with acute, episodic features, the influence of deep-level acute and chronic models on the representation of illness and self-management is evident among both hypertensive and asthmatic patients. Hypertension lies at one extreme on the dimension of symptom experience, as hypertension is asymptomatic for the vast majority of patients. Though patients are told, and most agree that, "People can't tell whether their blood pressure is up" (80% of hypertensive sample), the same respondents believe they "can tell when my own blood pressure is up" (92% of same sample) from symptoms, for example, headaches, dizziness, and warm faces. A majority (70%) also believed treatment moderated their symptoms (Meyer, Leventhal, & Guttmann, 1985). The coherence of the representations of hypertension and medication treatment, consistent with an underlying acute model seemingly "resting" on a chronic model, was likely responsible for high levels of adherence and good blood pressure control. Newly diagnosed individuals with hypertension (73% of 65) and non-hypertensive patients (48% of 50) in the same clinic believed they could tell when their blood pressure was elevated.

Asthma, a chronic (often asymptomatic) inflammatory process punctuated by episodic and highly symptomatic episodes that can be life threatening, was represented as both chronic and acute. Although 92% of a sample of 198 asthmatic patients believed asthma was chronic, that is, they would definitely, probably, or possibly always have it, more than half (53%) of the sample also believed they only had asthma when symptomatic; asthma was not there when they were asymptomatic (Halm et al., 2006). These patients controlled flares, but were unlikely to use peak flow meters to monitor their status, and make and keep routine visits for asthma (see also Kaptein et al., 2008). Using medication when symptomatic while claiming asthma a lifelong condition represents a joining of acute and chronic models in an episodic model at the deep level.

Automating Action for Long-Term Self-Management

It is clear that many patients adhere to treatment for lifelong periods, though it is often less than half of patients sampled who manage to do so consistently. Two aspects of long-term adherence have been examined: (a) how did highly adherent patients achieve *and* sustain lifetime self-management and (b) how can practitioners enhance effective management among patients who are nonadherent?

Regarding patient strategies for forming routines, Phillips et al. (2013) found that patients who developed habitual routines for consistent use of antihypertensive medication linked medication use to specific environmental cues, for example, to specific times and places. Factors typically related to the initiation of treatment, for example, treatment-related beliefs, the presence or absence of barriers to adherence, and feedback confirming treatment efficacy, were unrelated to habitual performance. In sum, once perfected, high levels of adherence are maintained independent of the conditions essential for treatment initiation. The importance of routines for long term was again made clear in a recent study of 306 low-income patients with asthma; 68% were African American and/or Hispanic and over 60 years of age (Brooks et al., 2015). Only 38.6% reported high levels of adherence to daily medication. Highly adherent patients integrated daily use of their inhalers with existent habit patterns. An example of such a routine was "…. putting the inhaler in the bathroom and using it when I get up in the morning." This group of "super-adherers" was 3.7 times more adherent than patients who did not integrate medication with daily routines. Although initiating and converting adherence into systematic habit is more common among educated, financially well-off patients, any patient who does so is highly adherent; strategies work for those who use them! Bolman, Arwert, and Völlink (2011) reported similar findings, observing that habit strength for taking prophylactic asthma medication predicted patient adherence, along with medication beliefs; they too contributed to adherence.

Highly adherent patients with diabetes, "experts" in controlling A1c, reported similar strategies (Tannenbaum et al., 2015). They stated that although it is necessary to recognize the long-term health threats associated with diabetes, one needed to put these thoughts aside and focus on action: "You just cannot be a bystander in this disease." Their strategies included monitoring daily behavior to identify times and places for incorporating medication use. They searched for "start points," for example, "You change your food in the super market, not when you sit down to eat," and urged a gradual approach to change, "take one day at a time," that gave their bodies time to adjust to new routines such as exercise. They emphasized the need to experiment and monitor blood glucose levels to detect safe and risky foods: "tested a lot at first—to test out my food" and recommended seeking assistance when confused, for example, "called nurse to discuss reading." They were clear on the importance of establishing routines or habits: "testing became second nature, like tying my shoes"; "in the morning, wash face, brush teeth, test blood." By monitoring, testing, and continually updating behavior, they created a coherent commonsense system that operated automatically.

Regarding communication in the clinical setting to facilitate routines for adherence, Phillips, Leventhal, and Leventhal (2012) asked patients to complete a brief questionnaire the day following a clinic visit. The questions assessed whether the physician discussed commonsense factors and action plans to manage the condition ("The doctor told me how to monitor my problem to see if the treatment is working") and whether the physician understood their feelings about their problem ("My doctor understood my feelings about this problem"). When interviewed 1 month later about treatment adherence, problem resolution, and subsequent visits to the emergency room (ER), patients who endorsed the commonsense items a month earlier were more adherent, had better problem resolution, and were less likely to go to the ER. In contrast, patients who had praised their practitioners' psychosocial skills a month earlier reported both poorer adherence and problem resolution, though they were still highly satisfied with the visit. In short, satisfaction was unrelated to adherence and negatively related to problem resolution. Further, all patients who had visited the ER post clinic visit had higher scores on the psychosocial items. This study illustrates the importance of spelling out the details of when and how to perform self-treatment and what to expect during after doing it; doing so ensures effective communicators. How one defines a problem sets the stage for action and evaluation of treatment efficacy (Omer, Hwang, Esserman, Howe, & Ozanne, 2013). Though telling patients when, where, and how to respond—giving them an action plan—is effective in providing strategies for action, it is not the same as assisting them with acquiring the skills for planning on their own or for building automatic management routines.

Concluding Comments and Future Directions

The CSM embeds patients' experiences, their symptoms, temporal expectations, concrete causes, and outcomes, in a conceptual framework of contemporary cognitive science. The CSM differs from models that focus on beliefs and/or utilities abstractions imposed on patients by the investigator that do not capture the concrete details of everyday life and performance. These details are essential for developing effective interventions. Although studies are few in number, positive results have been reported for interventions to modify postpartum depression (Howell et al., 2012) and increase adherence to antihypertensive medications. Research is needed to determine whether standardized interventions can assist patients with forming habitual routines for daily self-management, critical for control of multiple common chronic conditions, and whether similar interventions can be effective for lifestyle behaviors. The CSM also reshapes our views of constructs central in behavioral research; habit is an example. Habits are generally addressed as overt, that is, visible responses, and they often are. Habits reside, however, throughout the CSM; there are habits for attending and monitoring the body and its functions, habits for responding to somatic cues, and habits for seeking advice. Habitual or automatic processes function in conjunction with more conscious, deliberative processing throughout the operation of commonsense modeling, and habits can be "objects" in attention. Communications that enhance patient attention to and adoption of responses in specific settings and times of day will be critical for habit formation for long-term adherence.

It is also necessary to enhance awareness of the deeper structures underlying illness and treatment prototypes and habitual behavior. Patients need to be aware of the influence on their expectations and behaviors of implicit, deeper-level prototypes such as the acute model. Deciding and/or forgetting to continue treatments after months and years of adherence for a serious chronic condition because "I haven't had any symptoms for 2 years" is consistent with an acute view of the illness, but dangerous for control and longer-term health. Data on heart attacks are illustrative of the problem, showing that medication adherence declines precipitously a year or two post attack; in the absence of symptoms, it may seem that the threat is over and that one can and indeed should stop treatment. The chronic template—that treatment is part of oneself for life—needs to be built into the system, with particular attention to conditions that are chronic but have episodic flares (e.g., asthma, diabetes, congestive heart failure); treating flares alone is insufficient for long-term control. It is also unknown if or how underlying prototypes of the self-change over time. If one expects treatment to result in a return to "normal," and the "normal" prototype in the implicit mind of the 65- or 75-year-old individual is what they were at 50 years of age, it is not surprising they may feel that a treatment is ineffective even though it is doing its job biologically. Additional details on the role of social context and influence of affective processes on the cognitive behavioral pathway for self-management are being spelled out in detail not possible in an encyclopedia entry. The CSM is a work in progress; its "Bayesian" properties and their implications for practitioner patient communications to enhance adherence are the next major steps in the advancement of its theoretical framework and empirical testing.

Author Biographies

Howard Leventhal, PhD, Member, National Academy Medicine-NAS; Distinguished Professor of psychology, Rutgers University; Adjunct Professor, Mt. Sinai and Northwell University. He has graduated 65+ PhD students. His research has spanned topics related to fear and action plans, preparation for medical procedures, smoking cessation, affective and cognitive co-effects on health behavior; postpartum symptom reduction, symptom perception and interpretation, and patient self-management of illness. He is the primary developer of the commonsense model of self-regulation.

L. Alison Phillips, PhD, Assistant Professor of Psychology, Iowa State University. Dr. Phillips' research focuses on the psychosocial and contextual factors, including patient–provider communication, required for health habit development for chronic illness self-management (medication adherence, exercise). Her work utilizes mobile technology (electronic monitoring pill bottles and accelerometers/Fitbits) to objectively measure behavior in healthy adults and in patients with hypertension, type 2 diabetes, and stroke, as well as patients in primary care.

Edith Burns, MD, Professor of Medicine, Professor Population Health-Epidemiology, Medical College of Wisconsin, Clinical Professor of Medicine Marquette University, Fellow Gerontological Society of America. Mentor to >20 T35 and MSTAR medical student research trainees and >20 geriatric medicine fellows. Her research topics are immunology of aging, successful aging, self-management of chronic illness (e.g., diabetes, CHF, joint impairment), patient expectations and timelines for outcomes, risks for hospital readmission after elective surgery, and multimorbidity in geriatric populations.

Jenna Herold Cohen, MS, 5th year, Doctoral Candidate in Clinical Psychology at Rutgers University. Her research interests include factors that aid in adaptive cancer survivorship. Her dissertation will improve knowledge of factors affecting fear of recurrence among patients who have completed treatment for lymphoma. This work is being conducted under the supervision of Howard Leventhal, PhD, with committee members from Memorial Sloan Kettering Cancer Center (Smita Banerjee, PhD) and clinical faculty at Rutgers University.

Implicit Processes and Health Behavior Change

Aya Avishai and Paschal Sheeran

Department of Psychology and Neuroscience, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

Prominent theories in health psychology, including the health belief model, protection motivation theory, social cognitive theory, the transtheoretical model, and the theory of planned behavior, all assume that changing people's conscious beliefs (e.g. behavioral intentions, risk appraisals) will promote health behavior change. However, meta-analyses indicate that a medium-to-large change in intention engenders only a small-to-medium change in behavior and that a large change in risk appraisal has only a small effect on behavior. Dual-process models of health behavior explain this modest impact of conscious beliefs on behavior by pointing out that health behavior is governed not only by conscious beliefs but also by implicit processes that could activate conflicting behavioral schemata. More particularly, the reflective–impulsive model (RIM) proposes that there are two information-processing modes: reflective and impulsive. The reflective mode is slow and based on rules of language and logic. The key processes are reasoning (e.g., from knowledge about the consequences of an action to a decision to act) and intending. The impulsive mode, on the other hand, draws upon the store of associations that the person has acquired over many experiences. The key impulsive process is spreading activation whereby perceptual input activates related elements in the associative store. This mode of information processing is fast and occurs outside of awareness. Accordingly, the defining feature of implicit processes is that people do not realize, nor intend, their impact on health decisions and actions.

The present entry focuses on the implications of implicit processes for interventions to promote health behavior change. In an effort to organize the large and disparate literature on this topic, Figure 1 presents a framework for intervening with implicit processes. The organizing principle concerns the nature and target of the intervention (what factor is modified and how) and suggests that three overarching intervention approaches can be identified:

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

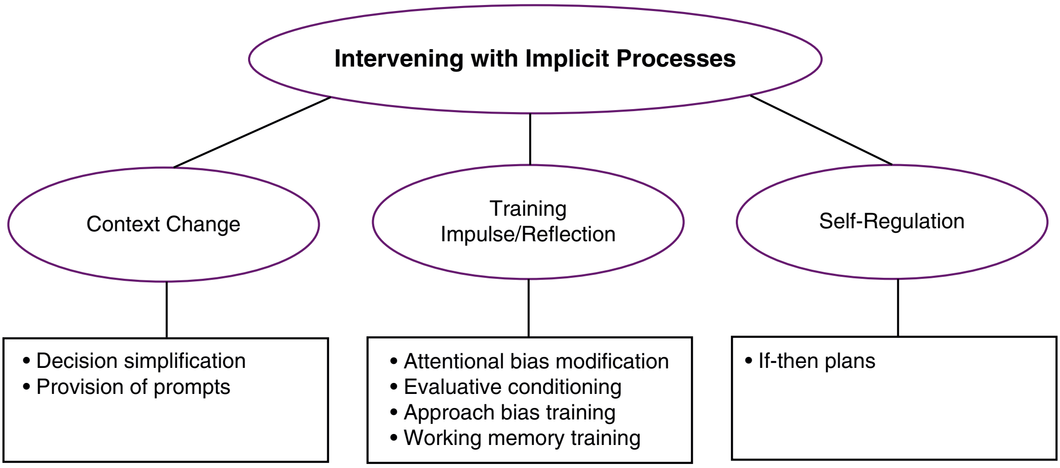

Figure 1 A framework for intervening with implicit processes.

- *Context change* interventions alter features of the physical or social setting in order to change health behaviors. Context change interventions are of two broad types: interventions geared at simplifying decisions and interventions that install prompts. The provision of prompts can guide behavior via the activation of goals or norms or by increasing self-monitoring.
- *Training impulse/reflection* involves practice-based interventions that are geared at modifying either impulsive responses (i.e., attentional bias, implicit affect, or approach bias) or the person's reflective control over impulsive responding.
- *Self-regulation* interventions give people tools to better align their thoughts, feelings, and actions with their health goals. Forming if-then plans or *implementation intentions* (Gollwitzer & Sheeran, 2006) is the most extensively researched and best validated of these tools.

Changing the Context

Decision Simplification

Simplifying decisions reduces the burden on the reflective system and helps to ensure that implicit choices are healthful. Health decisions can be simplified by the options that are made available, the ease with which those options can be selected, and the default options that are already in place. Correlational studies indicate that the availability of fresh fruit, vegetables, and low-fat milk is inversely related to overweight/obesity and that the availability of cigarettes is positively associated with smoking rates. When an intervention increased the availability of healthy food and drinks in vending machines by 50%, the proportion of healthy items that was purchased also increased (French et al., 2010).

Introducing variety can also improve health decisions: When individuals can choose a different fruit to one they had consumed earlier, then fruit is more likely to be selected than a sweet. The ease with which an option can be chosen also is important. An experiment among coffee shop consumers found that when the cognitive demands involved in making healthy eating decisions were lowered, there was a decline in the proportion of high-calorie items purchased (Allan, Johnston, & Campbell, 2015). Defaults also simplify decisions by creating a standard, preselected option that does not require people to make an active choice. For instance, a country's default could be that all residents are registered as organ donors (and residents opt out if they do not want to register) or that residents are not registered as donors by default (and opt in if they wish to register). When countries with the different defaults are compared, countries with an opt-out default have higher rates of donor registration than countries with an opt-in default.

Provision of Prompts

Changing self-reported (explicit) goals and norms and increasing conscious monitoring of behavior are known to promote health behaviors. The provision of prompts can also instigate these processes implicitly. For instance, Papies and colleagues primed the goal of eating healthily among patrons of a butcher's store by putting a sign about a low-fat recipe at the entrance (or not). Restrained eaters ate fewer meat snacks that were available on the store counter when the sign was present than when it was absent. Similarly, a flyer about low-fat recipes also decreased snack purchases (by 75%) among overweight/obese patrons of a grocery store (see Papies, 2016, for a review).

Social norms also exert an implicit influence on health behavior. For instance, people eat more when they are in pairs or in groups of four than when they are alone, and people are largely unaware of how dining companions influence their eating behavior—citing taste and hunger as key influences instead. Portion size, plate size, and the amount of food on the plate can each activate consumption norms. Including photographs of vegetables on the bottom of food trays in a school cafeteria doubled the proportion of students eating green beans and tripled the proportion eating carrots (Reicks, Redden, Mann, Mykerezi, & Vickers, 2012).

Injunctive norms or social pressure can also be primed. People entering a hospital were twice as likely to engage in hand hygiene when a picture of a pair of eyes was placed over the sanitary gel dispenser (King et al., 2015). Subtle prompts can also promote self-monitoring. Geier, Wansink, and Rozin (2012) gave participants containers of potato chips and had them watch a movie. Participants who encountered a red potato chip following a fixed number of regular chips (and thus could monitor their consumption) ate half as many chips as participants who were given only regular chips. Similarly, in a study that examined eating wings at a sports bar, participants whose food debris was left on their plate ate less than those whose finished wings and bones were removed by the waitstaff (Wansink & Payne, 2007).

Training Impulse–Reflection

People who smoke, drink, or overeat tend to show biased attention to relevant stimuli, more positively evaluate those stimuli on implicit measures, and exhibit greater approach motivation in relation to those stimuli. Interventions have targeted both the respective impulses (attentional retraining for attentional bias, evaluative conditioning [EC] for implicit affect, and approach bias training for motivational bias) as well as people's reflective control over such impulses (working memory [WM] training).

Attentional Retraining

Attentional retraining modifies paradigms such as the Stroop and visual dot probe (VDP) so that participants gain practice at not giving attention to unhealthy stimuli. A single session of attentional retraining with heavy drinkers decreased attention to alcohol relative to soft drinks

(Schoenmakers, Wiers, Jones, Bruce, & Jansen, 2007), indicating that attentional bias could be altered. Craving for alcohol and preference behavior were not affected by the intervention, however. Repeated sessions appeared to have stronger effects. In the Alcohol Attention-Control Training Program (AACTP), participant bias is assessed, goals for attentional bias reduction are set, and participants' progress is monitored. Hazardous and harmful drinkers who undertook the program demonstrated a reduction in alcohol attentional bias as well as a reduction in alcohol consumption over 3 months (Fadardi & Cox, 2009).

Schoenmakers et al. (2010) undertook the first small RCT of repeated attentional retraining in alcohol-dependent patients. Results showed an increase in attentional bias in the control group and a significant decrease in attentional bias for alcohol stimuli in the experimental group. The experimental group was also discharged from treatment sooner and relapsed later than the control group. Attentional retraining also proved effective in reducing chocolate consumption. However, a recent double-blind RCT observed no reliable effect on smoking cessation outcomes.

Evaluative Conditioning

EC tasks repeatedly pair a focal stimulus (e.g., beer) with a highly valenced stimuli (e.g., illness) in order to alter the underlying affective associations. Participants who completed an EC task that paired beer with negative affect exhibited less positive attitudes, had fewer cravings, and consumed less beer after training than did those in the control group (Houben, Schoenmakers, & Wiers, 2010). In a second study, participants who underwent EC had more negative implicit attitudes regarding alcohol and also drank less alcohol during the subsequent week compared with controls. EC was also effective in altering eating attitudes and behavior. After training to associate snacks with unhealthy outcomes, participants' implicit attitudes toward those snacks were more negative, and they were less likely to choose a snack as a parting gift after the experiment (Hollands, Prestwich, & Marteau, 2011). Learning to associate fruit with positive images also increased the proportion of fruit selected in a behavioral choice task.

Approach Bias Training

Repeated consumption of unhealthy substances forges associations between those stimuli and approach responses. Approach bias training targets this automatic motivational tendency. Go/no-go, stop signal, and approach/avoidance tasks have each been used in approach bias training. Heavy drinkers who undertook a go/no-go task that paired beer with "no-go" responses exhibited more negative implicit attitudes toward alcohol and also consumed less alcohol (Houben, Nederkoorn, Wiers, & Jansen, 2011). A go/no-go task involving palatable foods engendered a significant reduction in weight over 1 month, and training was especially effective among participants with higher BMI at the outset of the intervention (Veling, van Koningsbruggen, Aarts, & Stroebe, 2014).

Stop signal training consistently presents behavioral stop signals in close temporal proximity to high-calorie foods in order to create strong associations between these foods and response inhibition. Stop signals proved effective in reducing snack consumption in multiple studies, and the observed effects were especially pronounced when participants were hungry or habitually consumed the relevant snack food.

Wiers, Eberl, Rinck, Becker, & Lindenmeyer (2011) examined the impact of approach/avoidance training on relapse rates among patients with alcoholism. Patients were instructed to respond to pictures of alcohol by making an avoidance movement (pushing the joystick) and to pictures of nonalcoholic soft drinks by making an approach movement (pulling the joystick). Approach/avoidance training reduced approach bias and implicit attitudes toward alcohol and also led to better treatment outcomes 1 year later.

Working Memory Training

Automatic impulses have greater influence on behavior among participants with low WM capacity and when WM is compromised by cognitive load. The implication is that WM training could reduce the impact of antagonistic implicit processes on health behaviors. Houben, Wiers, and Jansen (2011) reported that 25 sessions of WM training (one session every 2 days) significantly increased memory span. Training also reduced weekly alcohol consumption both 1week and 5 weeks post-training. WM training proved especially effective in reducing alcohol consumption among participants who had strong implicit preferences for alcohol at the outset. Although there is much debate about the magnitude and mechanisms of WM training transfer effects, research is ongoing to test the impact of WM training on other health behaviors.

Self-Regulation

If-then plans or *implementation intentions* are a key self-regulation tool in health psychology. Implementation intentions provide a structure in which people (a) identify key opportunities for, or obstacles to, performing health behaviors, (b) specify a way to respond to each opportunity and obstacle, and then (c) formalize a link between the opportunity or obstacle and the response:

If (opportunity/obstacle) arises, then I will (respond in this way)!

Meta-analyses indicate that forming implementation intentions promotes effective self-regulation (Gollwitzer & Sheeran, 2006) and leads to greater physical activity and healthy eating. Implementation intentions are an effective intervention for health behavior change because the opportunities or obstacles specified in plans become highly accessible and thus people are in a good position to identify their moment to act when they encounter it. Moreover, strong associations are forged between the opportunity/obstacle and the specified response, meaning that people are in a good position to seize that moment and respond exactly as they had spelled out in advance.

Evidence indicates that forming if-then plans endows responses with key features of automaticity (i.e., swift and effortless responding). Thus, although implementation intentions are formed in a conscious act of will, automatic processes are recruited that serve to promote the initiation of the planned responses. This marriage of explicit and implicit processes that characterizes the operation of if-then plans has been termed "strategic automaticity." Neurophysiological evidence supports this characterization. Whereas action control by conscious intentions operates in a "top-down" manner, if-then plans operate in "bottom-up" fashion. The stimulus control of behavior observed in implementation intentions is akin to the operation of habits.

The previous section reviewed evidence that extensive practice-based training can help to overcome the unwanted impact of implicit goals, attitudes, and social influence on health behaviors. However, if-then plans also offer a simple and effective strategy for regulating unwanted implicit influence. For instance, Gollwitzer, Sheeran, Trötschel, and Webb (2011) observed that forming if–then plans about how to drive safely protected driving behavior from the antagonistic impact of priming the goal of being fast. Another study measured implicit attitudes toward chocolate and had participants form if-then plans to instigate reflection whenever they were tempted to eat some ("If I am tempted to have chocolate, then I ask myself, 'do I really want to do this?'"). Findings showed that if-then plans led to reduced chocolate consumption over the subsequent week. Whereas positive implicit attitudes predicted greater consumption among control participants, this association was actually reversed for participants who formed if-then plans (Sheeran, 2013). If–then plans also proved effective in reducing the implicit influence of binge drinker stereotypes on young people's alcohol consumption in a field experiment over 1 month (Rivis & Sheeran, 2013). In sum, implicit processes are key to the effectiveness of implementation intentions in changing health behaviors by automatizing the initiation of healthful actions and controlling disruptive automatic influences.

Conclusion

Implicit processes have important implications for behavior change interventions. Implicit processes can be harnessed in order to promote healthful decisions (e.g., via context change interventions). Moreover, when implicit processes threaten to engender risk behavior, training impulse–reflection and forming if-then plans can prove effective in attenuating their influence. Although research on intervening with implicit processes is still in its early stages and much remains to be done to test interventions over extended periods among both representative samples and patients, this approach holds considerable promise. A key implication of dual-process theories is that behavior change interventions will be most effective if they target not only conscious beliefs but also implicit processes and exploit potential synergies between beliefs and implicit processes.

Intimate Relationships and Physical Health

Fiona Ge*, Jana Lembke, and Paula R. Pietromonaco

Department of Psychological and Brain Sciences, University of Massachusetts Amherst, Amherst, MA, USA

Romantic relationships are connected to physical health in many ways. Simply being in a romantic relationship generally predicts better health outcomes, but the quality of the relationship, individual differences such as attachment style (expectations that partners will or will not be supportive and responsive to one's needs), and couples' behavioral interaction styles also play a role in health. We review how each of these broad categories of predictors is associated with people's voluntary health-related behaviors, health-related physiological responses, and health and disease outcome and discuss applications of this research for medical practice.

Relationship Status and Quality

People who are in a happy relationship tend to evidence better health than those who are not in a relationship or are in a poor-quality relationship. According to a recent meta-analysis, marital quality is linked to health via multiple pathways, including physiological markers, health behaviors, and direct health outcomes (Robles, Slatcher, Trombello, & McGinn, 2014).

Physiological Health Correlates of Relationship Quality

Research examining relationship quality and endocrine function has focused on the hypothalamic–pituitary–adrenal (HPA) axis, a major stress response system that governs the release of cortisol, a steroid hormone. Cortisol is released into the bloodstream in response to environmental stressors, and it affects metabolic, immune, and nervous system functioning. Over time, the continued release of cortisol may have adverse effects on the body, which can increase

susceptibility to illness and accelerate chronic disease. Conversely, a flattened cortisol slope (low reactivity) in response to a stressor also serves as an index of psychological maladjustment and is typically associated with self-regulatory problems under chronic stress. Consistent with this idea, poorer marital quality has been related to flatter cortisol responses throughout the day for men and women. Women in more satisfying relationships, however, show greater morning cortisol levels and a steeper decline in cortisol levels throughout a typical work day, indicating better physiological recovery from work than women who were less satisfied with their marriages.

Although partners' daily cortisol levels tend to be related, greater relationship satisfaction may shield spouses from the effects of each other's cortisol responses to stress. For instance, women's cortisol levels are less closely associated with their husband's cortisol levels when the women were more satisfied in their relationship. Additionally, spouses who reported greater marital satisfaction showed less convergence in cortisol patterns during a discussion of relationship conflict (Laws, Sayer, Pietromonaco, & Powers, 2015). Thus, high-quality relationships may minimize the extent to which one partner's physiological stress responses spill over to those of their partner, although the mechanisms through which this process occurs remain to be specified.

Functioning of the cardiovascular system is another biological indicator of health, and lower reactivity is generally better. Overall, individuals in high-quality marriages have lower cardiovascular reactivity than single individuals and even more so than individuals in low-quality marriages. Similarly, marital dissatisfaction has been associated with higher blood pressure among individuals with mild hypertension. These findings indicate that relationship quality—not just relationship status—matters for health.

A recent survey based on a US national sample found that greater marital adjustment was associated with less interleukin-6, a pro-inflammatory cytokine and a marker of inflammation, particularly for younger women (Whisman & Sbarra, 2012). For men, in contrast, being married buffered against elevations in C-reactive protein, another marker of inflammation, compared with men who were unmarried. It has also been found that older, happily married individuals may evidence stronger antibody responses than those who are unmarried, bereaved, or in an unhappy marriage. Furthermore, it has been found that people who perceive that their relationship contains both positive and negative aspects have greater inflammation compared with those who perceived their relationship in a primarily positive way, suggesting that relationship ambivalence has negative consequences for health.

Relationship Quality and Health Behavior

Being in a relationship can motivate health-enhancing behaviors, perhaps because those behaviors are viewed as a shared goal for both members of the couple. Furthermore, individuals in a relationship may have greater support in seeking healthcare and following treatment regimens. For instance, people who were married or had a partner were 1.5–2 times more likely to attend cardiac rehabilitation than their unpartnered counterparts (Molloy, Hamer, Randall, & Chida, 2008).

In some cases, however, relationships do not promote better health. Having a partner with unhealthy habits—such as smoking—may hinder the other partner's attempts to break similar habits. Satisfaction with one's relationship, not just relationship status, also relates to health. For instance, while married individuals generally show healthier sleep patterns than unmarried individuals, being in a more satisfying marriage is associated with fewer sleep disturbances in women. Couples in more satisfying marriages also are more likely to use healthcare services than couples in distressed marriages. In contrast, greater relationship dissatisfaction tends to promote health-compromising behaviors, such as greater alcohol consumption.

Relationship Quality, Mortality, and Disease Recovery

Mortality risk is generally lower among those who are married versus unmarried, who marry later in life, or who have been married for a longer period. In addition, being in a relationship has been linked to lower morbidity and higher survival rates after the diagnosis of different diseases or surgery, such as cardiovascular disease, coronary heart disease, hospital-diagnosed infectious diseases, and coronary artery bypass grafting.

Relationship quality has also been linked to physical health outcomes. For example, greater marital quality predicted a better survival rate over 8 years for patients with heart failure, especially among women (see Robles et al., 2014). Similarly, greater relationship negativity predicted a higher risk of coronary heart disease. Additionally, the risk of coronary artery calcification was higher when both partners had positive and negative (ambivalent) perceptions of each other than when one partner had ambivalent perceptions and the other perceived the partner as purely positive (Uchino, Smith, & Berg, 2014).

Attachment and Health

Based on day-to-day experiences in close relationships from childhood through adulthood, people develop attachment orientations (e.g., expectations, beliefs, goals) that guide how they think, feel, and behave with close partners. These attachment orientations also promote different ways of perceiving and regulating stress, which in turn affect health-related physiological patterns. Overreacting to and poorly recovering from relationship stressors—a tendency observed in insecurely attached individuals—can exhaust physiological systems and eventually produce health problems.

Physiological Health Correlates of Attachment

Both attachment avoidance and anxiety are associated with disruptions in the HPA axis, but because anxiously attached people are particularly sensitive to relationship stressors and are continually monitoring the relationship for signs of threat, they are susceptible to heightened HPA responses. For example, anxiously attached individuals exhibit elevated HPA axis activity during travel separations, a situation that threatens anxious people's need for their partner's closeness (see Pietromonaco, DeVito, Ge, & Lembke, 2015). Anxiously attached individuals also show increased cortisol levels in response to generalized stressors in experimental settings, and because they underestimate their partner's availability and care, they take longer than nonanxious individuals to recover from the stressor even when presented with support from their partner.

Recent evidence sheds light on the interplay of both partner's attachment on stress responses. Couples consisting of an anxious wife and an avoidant husband showed increased cortisol reactivity in anticipation of a discussion of relationship conflict followed by a sharp decline before the discussion began (Beck, Pietromonaco, DeBuse, Powers, & Sayer, 2013). This pattern was accompanied by less constructive behaviors during the conflict and was distinct from patterns observed in other attachment pairings. These findings, together with other recent work (see Pietromonaco & Powers, 2015), underscore the importance of the situational context (e.g., both partners' characteristics) in understanding the link between attachment and physiological responses.

Attachment insecurity (anxiety, avoidance, or both) is associated with cardiovascular risk factors. Attachment avoidance predicts elevated cardiovascular reactivity in the face of attachment-related stressors, a likely consequence of avoidant people's defensive, repressive, and distancing coping strategies. Although a partner's presence should mitigate insecure individuals' sympathetic nervous system arousal in the face of stress, this does not seem to be the case. Avoidant and anxious individuals who were anticipating a stressful situation showed greater cardiovascular reactivity to stress in their partner's presence versus absence, suggesting that they were not comforted by their partner once the attachment system was activated, perhaps because they were anticipating not only the stressor but also the possibility of being rejected by their partners.

Attachment insecurity may impact health via immune functioning, which can be measured via speed of wound healing, inflammatory cytokines (IL-6), and T-cell counts. While this area of research is just developing, immune functioning seems to be impaired by attachment insecurity. Other work suggests that the link between attachment and immune functioning is moderated by gender. It is possible that some markers of immune functioning vary with one type of attachment insecurity but not the other or that other moderating variables are involved (e.g., relationship quality, situational aspects). Research building on these initial findings will yield a better understanding of the link between attachment insecurity and immune system dysregulation.

Attachment and Health Behavior

Attachment insecurity is linked to a variety of health-compromising behaviors, such as riskier sexual behavior, greater substance use, lower levels of exercise and higher rates of smoking, less participation in preventative healthcare, and poorer relationships with physicians.

Factors such as self-esteem and communication styles may partly explain the link between attachment and health behavior (see Pietromonaco et al., 2015). For example, securely attached university students held higher self-esteem than those who were insecurely attached, which in turn predicted their greater engagement in health behavior. Communication styles may explain the link between attachment and risky sexual behavior: anxiously attached individuals were less likely to talk with their partners about AIDS-related issues, which predicted riskier sexual behavior.

The Dyadic Influence of Attachment on Health

Research integrating work on attachment and social support has found that people low in attachment anxiety reported better health outcomes when they perceived their partners as more supportive, but individuals high in attachment anxiety did not benefit from their partners' greater support (Stanton & Campbell, 2014). Relatedly, individuals who were anxiously attached and who perceived lower social support showed greater severity of inflammatory bowel disease severity. Because anxious individuals' relationship fears may cause them to underestimate their partner's support, these findings indicate that individuals' *perceptions* of relationship support matter for health, not just the amount of support.

Another line of research has taken into account the interplay between both partners' attachment styles in relation to health. When caregivers and patients with Alzheimer's disease (AD) were both high in anxious attachment, the patients reported greater physical symptoms (e.g., pain, nausea); when caregivers were low in anxious attachment, patients' attachment anxiety was unrelated to their reported physical symptoms (Monin, Schulz, & Kershaw, 2013). Caregivers' low attachment anxiety may buffer AD individuals' perceptions of their symptoms, particularly for those who are anxiously attached.

Negative Relationship Interactions

Although high-quality relationships provide a source of support for individuals' health and well-being, relationship interactions—when they go wrong—can be a major source of stress (Robles et al., 2014).

Physiological Correlates of Conflict

Research on relationship conflict and endocrine responses has focused on the stress hormone cortisol. Greater positive behaviors during a conflict have been associated with increased cortisol levels, while spouses who displayed mainly negative behaviors showed no change in cortisol levels during the conflict, a nonresponsive pattern that is often linked to poorer outcomes. Another potentially problematic response pattern is heightened cortisol reactivity, which has been found among men who coped with stress by seeking support, women who received less spousal support, and men and women whose partners had greater need for social support.

Relationship-oriented factors also contribute to individuals' endocrine reactivity in response to a conflict. Greater demand–withdrawal communication patterns, characterized by wives' criticism and blaming and husbands' avoidance and disengagement, are associated with greater cortisol reactivity in response to a conflict for both spouses. Similarly, husbands' withdrawal in response to wives' negative behaviors was associated with wives' greater cortisol reactivity (Kiecolt-Glaser et al., 1996).

Negative relationship interactions evoke greater cardiovascular reactivity, such as blood pressure, heart rate, and cardiac output. Hostile interactions are linked to couples' increased blood pressure, whereas positive or neutral interactions are not linked to a change in blood pressure, implying that the negative aspects of relationship interactions typically outweigh the positive or neutral aspects of the discussions in influencing physiological reactivity. In fact, dispositionally hostile husbands (vs. low hostile husbands) paired with hostile wives evidenced greater resistance to blood flow through the cardiovascular system throughout a conflict discussion (Broadwell & Light, 2005). Other studies examining support provisions during conflict interactions found that low spousal support adversely impacts blood pressure (Heffner et al., 2004).

Engaging in marital conflict has been associated with dysregulation of the immune system, which has negative implications for health such as impaired wound healing (Robles et al., 2014). Conflicts characterized by hostile and negative behaviors are especially likely to elicit poorer immune responses. Social cognitive factors, such as the extent to which people think about their feelings and the circumstances during a conflict discussion, have been associated with immune responses such that high-level cognitive processing seems to buffer against inflammation in the face of stressful events (Graham et al., 2009).

Positive Relationship Interactions

Endocrine Pathway

Positive relationship interactions—such as showing physical affection or support—are important for health, likely because they reduce stress and protect against cortisol increases. Daily displays of intimacy are one way that relationship interactions confer health benefits. In one study, dual-career couples reported time spent on intimacy and provided multiple daily saliva samples for cortisol analysis over a 1-week period. Greater amounts of intimacy on a given day appeared to increase positive affect, which in turn reduced cortisol, suggesting that positive affect generated by intimacy aids in stress reduction (Ditzen, Hoppmann, & Klumb, 2008). Similarly, husbands' supportive behaviors during heated conflict interactions helped down-regulate stress hormones in wives, perhaps because husbands' constructive engagement during conflict reduces wives' perceived threat and speeds recovery from physiological stress.

Cardiovascular Pathway

Simply being in a loving, low-conflict relationship supports physiological patterns necessary for good cardiovascular health for both men and women. For instance, the extent to which partners viewed their romantic relationships as positive, important, and secure predicts life satisfaction and reductions in nighttime blood pressure, especially for women. In a sample of 250 healthy older adults, frequent spousal interaction reduced progression of carotid artery thickening for men in well-adjusted marriages (Janicki, Kamarck, Shiffman, Sutton-Tyrrell, & Gwaltney, 2005).

Perceiving one's partner as supportive in times of stress also promotes physiological responses correlated with better cardiovascular health. One study of 94 married couples found that perceptions of informational support from one's partner helped reduce the effects of momentary, everyday life stress on systolic and diastolic blood pressure. This finding suggests that providing useful advice or helping with problem solving protects against blood pressure increases that are associated with cardiovascular risk. Other work suggests that it is not the type of support received during a conflict, but whether partners were happy with the support that is associated with blood pressure and cortisol reactivity (Heffner et al., 2004).

Relationships also may impact cardiovascular health via loving touch. A history of frequent physical contact between partners has been associated with higher oxytocin production and lower cardiovascular reactivity. Experimentally induced touch has a similar effect: cohabiting couples who engaged in handholding followed by a 20-s hug showed attenuated blood pressure and heart rate reactivity in response to a public speaking task compared with those in a no-touch control group (Grewen, Anderson, Girdler, & Light, 2003). Also, evidence suggests that positive physical contact (but not verbal support) can buffer against physiological responding to a stressor. Physical contact between partners can even be used as intervention to improve health. Compared with a no-treatment control group, couples participating in a 4-week-long "warm touch" intimacy-building intervention showed enhanced oxytocin, lower stress hormones, and, among husbands, lower systolic blood pressure (Holt-Lunstad, Birmingham, & Light, 2008). Clearly, warm and affectionate relationships contribute to lower sympathetic nervous system reactivity to acute stressors, a correlate of good cardiovascular health.

Immune Pathway

Provisions of support confer benefits for physical health via inflammatory responses over and above individual differences. For example, wives in more well-adjusted marriages showed lower blood levels of IL-6 (a marker of inflammation), even after controlling for significant demographic and health-related variables, and reports of partner *support* (but not negative partner interactions) were uniquely associated with IL-6 (Whisman & Sbarra, 2012).

Another way to measure immune functioning is via the body's ability to heal from injury. Neurochemical activity related to positive relationship functioning aids in wound healing: compared with individuals who showed lower levels of oxytocin, individuals exhibiting the highest levels (i.e., upper quartile) of oxytocin healed faster from experimentally induced wounds (Gouin et al., 2010). Greater oxytocin and vasopressin also were associated with more positive communication behaviors and fewer negative behaviors during a social support marital interaction. Thus, supportive marital interactions may promote greater oxytocin and vasopressin response, which counteract stress and aid in wound healing.

Recommendations for Future Research and Conclusion

More work is needed to determine the conditions under which physiological reactivity to momentary relationship stressors translates to observable, long-term effects on health. For example, attachment is associated with subtle biological stress response patterns that likely translate to concrete health outcomes over time, but limited work has directly tested this link. Also, it is unclear how long it takes for psychophysiological responses (e.g., heightened cortisol reactivity) to produce a diagnosable disease. Because serious health problems such as cancer and arteriosclerosis can take years to develop, it will be important to examine the connection between relationship processes and health over time.

Additional work is needed on clinical samples such as couples in which one partner has a chronic illness. Recent research by Manne, Siegel, Kashy, and Heckman (2014) illustrated the potential for conducting basic psychological research with applications for medical practice: in a study of 254 women with breast cancer and their husbands, how couples viewed the cancer (e.g., going through it as a team) affected their intimacy, and this association was mediated by how they communicated (i.e., having greater perceived self-disclosure and responsiveness). Medical treatments for chronic illness that include a relationship component hold promise: A meta-analysis found that patients receiving a couple-oriented intervention showed greater improvements in their depressive symptoms, marital functioning, and pain than when only usual medical care was prescribed (Martire, Schulz, Helgeson, Small, & Saghafi, 2010). This research points to relationship interventions as potential nonpharmacological medical treatments. Indeed, research at the nexus of health psychology and relationship science has the promise to be translated to medical practice and lay a groundwork for developing new, low-risk methods of improving physical health.

Author Biographies

Fiona Ge is a PhD student in social psychology at the University of Massachusetts Amherst. She is interested in studying how social interactions between romantic partners shape individuals' emotional, physiological, and social well-being. She is also interested in examining how communication patterns among romantic couples vary by culture.

Jana Lembke is a social psychology graduate student at the University of Massachusetts Amherst. Her research focuses on the role of positive partner interactions in relationship well-being. She is currently examining how couples reconnect with each other following instances of relationship conflict and how these types of interactions may contribute to relationship satisfaction.

Paula R. Pietromonaco is a professor in the Department of Psychological and Brain Sciences at the University of Massachusetts Amherst. Her research focuses on attachment, emotion, and health. Her current work examines how couple members influence each other's psychological, behavioral, and physiological responses to stress and the extent to which these processes contribute to their emotional and physical health over time.

Medical Decision Making

Meng Li[1] and Gretchen B. Chapman[2]

[1]Department of Health and Behavioral Sciences, University of Colorado Denver, Denver, CO, USA
[2]Department of Psychology, Rutgers University–New Brunswick, New Brunswick, NJ, USA

Medical decision making encompasses decisions made in all health and medicine contexts by patients, healthcare workers, health policy makers, and the general public. The study of medical decision making follows research on judgment and decision making more generally: It compares actual or descriptive decision making to normative or rational models of decision making, where the latter provide a benchmark for how decisions should be made. It also explores interventions that can improve decision making or guide choice behavior in a particular direction (i.e., toward selection of a particular healthy option).

Medical decisions are often difficult because they entail choosing among options with uncertain outcomes; they require trade-offs between competing goals, often with overwhelming amounts of information; they involve taking on immediate costs for long-term benefits; they may also require strategic interactions among multiple agents. Below we characterize medical decision making by discussing some selective theoretical and empirical issues related to each of these topics.

Risk and Uncertainty

Many medical decisions involve uncertain outcomes. For example, a patient must decide whether to undergo surgery, not knowing if the surgery will be successful. A physician must decide whether to recommend a preventive measure, such as cholesterol-lowering medication, not knowing whether the patient would be fine even without the medication. According to normative expected utility theory, the utility of each outcome (e.g., stroke) should be weighted by the probability that the outcome will occur. Consequently, it is critical that decision makers be able to assess, at least implicitly, the probability of key outcomes and to weight the utility of outcomes in proportion to their probability. In a number of cases, however, outcomes are systematically over- or underweighted, and low likelihood events tend to be overweighted and

thus have more influence on decisions than they should. This phenomenon is illustrated in the American response to the 2014 Ebola outbreak in West Africa. Although contracting Ebola in the United States was an extremely low likelihood event (only four cases of Ebola were diagnosed in the United States, only two of which were contracted in the United States), the response of some US public officials was indicative of a much higher level of risk. For example, in October 2014, the governors of New York and New Jersey announced a mandatory quarantine for any healthcare workers returning from treating Ebola patients in West Africa to the United States via a New York or New Jersey airport. It appears that decision makers draw a large distinction between an outcome with a 0% likelihood and one with a small positive likelihood. For example, people will pay more to reduce the risk of an adverse event from a toxin from 5 in 10,000 to 0 in 10,000 than they will pay for a risk reduction from 15 in 10,000 to 10 in 10,000, even though both are the same net reduction in risk (Viscusi, Magat, & Huber, 1987). Similarly, decision makers draw a large distinction between 100% and a proportion that is slightly smaller than 100%. Consequently, 100% of a small category can seem larger than 50% of a large category, whether the percentages refer to probability, effectiveness, disease coverage, or something else (Li & Chapman, 2009, 2013).

Difficult Trade-Offs

A medical decision can be especially difficult if it encapsulates a trade-off between two important but opposing goals or attributes. Trade-offs in medical decision making are prevalent, such as in the choice between quality and length of life in end-of-life decisions or in the design of screening programs that entail either greater false alarms or potential misses of true pathologies. According to normative multi-attribute utility theory, each attribute should be weighted according to its importance, and an overall utility (goodness) for each option could be computed by summing the weighted utility of all attributes. However, real-life decisions often violate this normative prescription, and the weight that people assign to attributes can shift depending on irrelevant factors, such as how the problem is described.

One often-debated issue in health policy settings involves the trade-off between efficiency and equality, such as in the allocation of scarce medical resources, including transplant organs, scarce vaccines, etc. For example, quality-adjusted life year (QALY) is a widely used metric to assess benefits in medical options. The rationale behind the use of QALYs is that more life years saved represents more net benefit, regardless of whose QALYs are saved (QALYs entail younger people being prioritized, as saving them produces more QALYs).

People also hold another important goal in the allocation of medical resources: equality in receiving such resources. People place great value on equality, to the point that they are willing to save fewer lives to achieve equal allocation of lifesaving resources (Ubel, Baron, & Asch, 2001). However, the preference for equity at the expense of efficiency is also volatile and subject to change depending on how the question is posed. For instance, in the choice between younger and older lives when not all lives can be saved, people usually prefer to save younger lives, demonstrating a preference for efficiency (Li, Vietri, Galvani, & Chapman, 2010), but such preferences fluctuate systematically. When people read descriptions on allocation outcomes (e.g., 500 20-year old people will be saved; 500 60-year old people will be saved), they prefer to save younger individuals; however, when they read general principles on how different lives should be prioritized under scarcity (e.g., “younger people should be valued more,” “older people should be valued more,” or “all lives should be valued equally regardless of age”), people demonstrate greater preference for equal allocation across young and old recipients (Li, 2012).

Another example in which preference for efficiency versus equality can be shifted with a fairly subtle change in description comes from a study by Colby, DeWitt, and Chapman (2015). Participants allocated 6 transplant kidneys to 12 potential recipients, 6 of whom had a high chance of transplant success. When the 12 recipients were presented in one group, participants tended to allocate the kidneys efficiently, giving them to the 6 recipients most likely to benefit from them. However, when the 12 recipients were presented in 2 groups of 6 each, participants tended to spread the kidneys across the 2 groups, even though this meant sacrificing efficiency.

Information Overload

All decisions entail a comparison and selection among multiple options, even if some options are not salient (e.g., choosing nothing, doing nothing). But what happens when there are a large number of options available, accompanied by a large amount of information about them? This is the situation many Americans face after the recent ratification of the Patient Protection and Affordable Care Act (ACA), which allows them to select from among dozens of healthcare plans. Providing too many healthcare plans can decrease decision quality. For example, Johnson, Hassin, Baker, Bajger, and Treuer (2013) presented participants with premium, co-pay, and deductible information for multiple health plans and found that participants frequently showed near-chance levels of performance in selecting the lowest cost plan because they gave too much weight to out-of-pocket expenses and deductibles. Although Johnson et al.'s participants made hypothetical choices, other researchers who analyzed data from actual health plan choices also found that consumers frequently chose dominated health plans—plans that were more expensive but provided no better benefits than alternative plans—because consumers focused too heavily on deductibles (Bhargava, Loewenstein, & Sydnor, 2015). Thus, choosing from a large choice set makes for a difficult psychological task, sometimes resulting in the decision maker violating normative principles such as dominance. Therefore, medical decisions can be improved by simplifying choice sets or providing smart defaults to decision makers.

Discounting Future Outcomes

Frequently, medical decisions involve delayed outcomes. For example, a calorie-dense diet and low levels of physical activity lead to increased risk of obesity and associated comorbidities such as diabetes and heart disease. However, these consequences are delayed, often by years or decades. Decision makers value delayed outcomes less than equivalent immediate outcomes; consequently, it is difficult for decision makers to forgo the immediate temptations of a piece of cheesecake or the TV episode instead of a trip to the gym. According to normative discounted utility theory, delayed outcomes should be discounted in a consistent manner, and thus people should not change their preferences between a larger later reward (e.g., the long-term benefit of weight loss) and a smaller sooner reward (e.g., the enjoyment of a piece of cheesecake) at different time points, that is, if you decided that the long-term benefit of weight loss is more important than the enjoyment of cheesecake that you can have soon, you should be able to stick to this decision at any given time. However, preference between these two types of rewards frequently changes with time: People often choose the larger later reward initially (such as on New Year's Day), when they are temporally distant from both rewards, but later fall for the temptation when it becomes available immediately (as the dessert tray rolls by). This inconsistent choice marks the typical pattern of self-control failure.

As a solution to this problem, decision makers will sometimes take advantage of the opportunity to precommit or bind themselves to the earlier preference for the larger later reward. For example, Schwartz et al. (2014) invited grocery store shoppers to lay their money on the line to precommit to buying more healthy foods such as fresh produce. The shoppers agreed to forfeit the discount they already received for buying healthy foods if they did not meet their healthy foods purchase goal. Indeed, these shoppers increased their healthy food purchases relative to a control group who merely indicated hypothetically whether they would precommit. Similarly, dieters who do not keep desserts in the house are taking advantage of a precommitment device, as are people who prepay for a gym membership in the hopes of motivating themselves to work out frequently to "get their money's worth." Another solution to the problem of discounted future outcomes is bundling temptation with a desired behavior, so one is allowed to indulge in a pleasure only when one engages in a necessary but unpleasant health behavior. For example, Milkman, Minson, and Volpp (2014) found that people visited the gym more often if they could listen to addictive audio books only when they were at the gym.

Strategic Behavior

Some medical decisions are made in a strategic setting where the choices made by an individual affect the outcomes of others while at the same time the decisions of others affect the outcomes experienced by the individual. Take vaccination as an example. Because of herd immunity, an individual's vaccination protects not only herself from infection but also her social contacts, because she is now less likely to spread the virus to others. Consequently, if enough individuals in a population are vaccinated, the unvaccinated members are protected from infection. Thus, vulnerable individuals who cannot receive vaccination themselves (e.g., infants) can be cocooned in this fashion. Because of this positive externality from vaccination, an individual's decision about whether to vaccinate may be affected by how many others in the population are vaccinating (Galvani, Reluga, & Chapman, 2007). This strategic interaction can be modeled using game theory (Chapman et al., 2012): individuals can "defect" by getting a free ride, that is, forgoing vaccination because they receive protection from others who vaccinated, or they can "cooperate," that is, vaccinating in part to protect those around them.

Free riding may contribute to the anti-vaccination movement because those opposed to vaccination can forgo immunization without bearing much risk of contracting infectious disease, as long as the majority of the surrounding population is immunized. When critical numbers of those opposed to vaccination are clustered in one geographical region, however, herd immunity can dip below the threshold that is necessary to prevent the spread of disease, making the larger population vulnerable to an outbreak, such as the measles outbreak in a theme park in California in 2015. Other medical decisions that entail externalities include overuse of antibiotics, which does not affect the user negatively but contributes to the development of resistant strains of bacteria, and the over-ordering of expensive medical tests for which the physician does not pay but which will drive up healthcare costs and insurance premiums.

Numeracy

Normative models of decision making assume that decision makers will make informed decisions, provided that they are in possession of the relevant facts. However, decision makers vary in the capacity to comprehend and use information to approach choices. For example, numeracy, or the capacity to process numerical information, is essential in medical decision making, as such decisions frequently involve numbers (e.g., risk probabilities, efficacy information, cost, time). Numeracy levels among Americans are worrisome, with many people, even those who are highly educated, are particularly lacking in the ability to process percentages and fractions. These basic numerical competencies are critical in the medical context, such as when one needs to calculate medication dosage based on a child's body weight. A recent review (Reyna, Nelson, Han, & Dieckmann, 2009) concluded that patients who have low numeracy are more likely to misinterpret graphs containing medical information, more easily influenced by factors irrelevant to the decision at hand (such as how the information is presented), and more likely to overestimate small risks and have poorer health outcomes when the health condition requires a high degree of self-management.

Perhaps more disturbingly, medical professionals do not necessarily possess the level of numeracy that is required to correctly understand risk information. And the lack of capacity to comprehend risk information can incur serious consequences. For example, despite the commonly held belief that cancer screening saves lives, some cancer screening tests can produce a large number of false positives, encouraging overtreatment for nonprogressive cancer while yielding little or no life-saving benefit, and inflating the 5-year survival rate. Therefore, to evaluate the effectiveness of a screening test in saving lives, a reduced mortality rate should be used as the gold standard, instead of improved survival rates. Unfortunately, a study by Wegwarth, Schwartz, Woloshin, Gaissmaier, and Gigerenzer (2012) showed that about half of physicians do not share this knowledge and instead incorrectly believe that increased early detection constitutes evidence that such screening saves lives. This lack of numerical competency among physicians may have contributed to the ill-deserved enthusiasm toward cancer screening tests and the resulting financial and health toll of their overuse.

Healthy Nudges

Given the myriad ways in which actual medical decisions deviate from normative models of decision making, researchers and clinicians alike consider what can be done to improve medical decisions. Decision psychologists and behavioral economists have recently developed nudges (Thaler & Sunstein, 2008), or changes to the decision environment that facilitate selection of the healthy option, while maintaining freedom of choice. One well-known nudge is the default effect, or the tendency for people to stick with the option they will get automatically if they take no explicit action. For example, people prescheduled for a flu shot appointment (which they can cancel if they do not want it) are more likely to get vaccinated than are those who are not prescheduled (Chapman, Li, Colby, & Yoon, 2010). Although both groups have a choice to have a flu shot appointment or not, for the prescheduled group, the default is having a flu shot appointment, and for the comparison group the default is not having an appointment. Because most people tend to stick with their default status, and because having a flu shot appointment is a strong predictor of actually getting a flu shot, vaccination rates increased by 36% (from 33 to 45%) in the group with a default vaccination appointment relative to the group where an appointment has to be actively scheduled.

There are other types of nudges toward healthy behavior. For example, because people tend to conform their behavior to that of the group, giving people information about what others do will nudge them toward that same behavior. Social norms have been used to reduce caloric intake (by printing recommended calorie intake on menus, combined with menu calorie labeling; Roberto, Larsen, Agnew, Baik, & Brownell, 2010), to increase children's vegetable intake at school lunch (by placing photographs of vegetables on wells of the lunch tray; Reicks, Redden, Mann, Mykerezi, & Vickers, 2012), and to encourage walking (by informing participants who wear pedometers how much others are walking; Chapman, Colby, Convery, & Coups, 2015). Another example of a healthy nudge is the position effect, in which food options displayed at prominent, easy-to-reach positions are chosen more frequently. Researchers have used the position effect to encourage healthy eating in cafeterias and restaurants (e.g., Rozin, Scott, & Dingley, 2011).

In summary, medical decision making includes not only decisions that are made in strictly medical settings but also decisions made in everyday life that impact health. Research on medical decision making can inform health professionals as well as the general public about the pitfalls in medical decisions, how to overcome them, and how to use decision biases to the advantage of people's health.

Author Biographies

Meng Li is an assistant professor in the Department of Health and Behavioral Sciences at the University of Colorado Denver. Her work, which has been featured on JAMA, Lance, Psychological Science, and other top journals, utilizes decision biases to "nudge" people toward healthy behavior, such as vaccination, healthy diet, and hand sanitizer use. Her more recent work explores policy issues, including resource allocation on money and health, price transparency in healthcare, and work–life balance policies.

Gretchen B. Chapman is a professor of psychology and a member of the Institute for Health and the Center for Cognitive Science at Rutgers University. Her research combines judgment and decision making with health psychology to examine preventive health behaviors such as vaccination. She conducts field studies to evaluate decision theoretic interventions designed to encourage health behavior and laboratory research to examine basic processes in decisions under uncertainty, strategic interactions, and allocation of scarce resources.

Message Framing

Scout N. McCully and John A. Updegraff

Department of Psychological Sciences, Kent State University, Kent, OH, USA

Doctors, health psychologists, and medical professionals implore patients to adopt and maintain health behaviors, but effective persuasion often proves difficult. Message framing offers a relatively simple and versatile way to tailor a health message to increase its effectiveness. Message framing is built upon the idea that all decisions regarding health behaviors carry consequences; generally, engaging in a health behavior will yield more positive consequences than negative consequences, while failing to do so will yield more negative outcomes than positive outcomes. As such, messages about health behaviors can be framed to emphasize what can be gained by performing the behavior (gain framed) or what can be lost by not performing the behavior (loss framed). For example, a message about the flu shot could read, “If you get a flu shot, you will reduce your risk of getting the flu this year” (gain framed), or it could read, “If you do not get a flu shot, you will be at risk of getting the flu this year” (loss framed). The gain-framed message emphasizes the positive consequences of getting a flu shot, while the loss-framed message highlights the negative consequences associated with not getting a flu shot.

Message framing developed as an extension of prospect theory (Tversky & Kahneman, 1981), which suggests that people will make different choices when outcomes are framed as gains versus losses. People are more likely to make risky decisions when faced with a loss, as they would rather gamble for the possibility of no losses (risking greater losses along the way) than accept certain loss. Alternatively, people are risk averse when contemplating a gain, as they would rather maintain a certain gain—even a small gain—than risk losing it all. Rothman and Salovey (1997) extended prospect theory to health behavior messages, proposing that gain- and loss-framed messages would differentially affect behavior depending on the behavior the message endorsed.

After years of examining message framing across various behaviors, people, and situations, researchers have found no general advantage of one frame over the other (Gallagher & Updegraff, 2012). However, research suggests that in specific circumstances, gain-framed messages produce greater behavior change than loss-framed messages, while in other circumstances, loss-framed messages prevail. Thus, message framing research has focused on understanding the moderators or conditions that make either gain- or loss-framed messages more effective in producing behavior change.

Moderators of Message Framing Effects

Moderators of message framing effects can be organized into three categories: behavior-related moderators, person-related moderators, and context-related moderators (see Table 1 for a summary). In this entry, we use the term *behavior-related moderator* to refer to a characteristic of the target health behavior that affects the relative persuasiveness of a gain- or loss-framed message. A *person-related moderator* is a state or trait characteristic of the target individual or audience member that influences the relative effectiveness of a particular frame. A *context-related moderator* refers to a characteristic of the situation in which the message is presented that changes the effect of message frames.

Behavior-Related Moderators

The most influential and widely studied moderator of framing effects is the behavior-related moderator of prevention versus detection behaviors. As mentioned above, prospect theory (Tversky & Kahneman, 1981) proposes that when faced with a loss, people are more likely to make risky decisions, but when faced with a gain, people are risk averse. Rothman and Salovey (1997) theorized that illness detection behaviors (e.g., mammograms, cancer screenings) carry an element of risk because such tests may reveal a health threat. Alternatively, behaviors focused on promotion of health or prevention of illness (e.g., physical activity, sunscreen use) carry little risk because they generally support and improve health. Thus, loss-framed messages should be more effective at promoting high-risk detection behaviors, whereas gain-framed messages should be more effective at promoting low-risk prevention behaviors.

After two decades of research on framing effects in prevention and detection behaviors, a meta-analysis concluded that indeed gain-framed messages tended to be more effective than loss-framed messages in promoting prevention behaviors, but loss-framed messages were no more effective than gain-framed messages in promoting detection behaviors (Gallagher & Updegraff, 2012). For prevention behaviors, gain-framed messages produced significantly higher rates of behavior in the domains of smoking, skin cancer prevention, and physical activity. Effects of message framing were weak for safe sex, diet, oral health, and vaccination, but in no case was a loss-framed message significantly more effective than a gain-framed message in prevention behaviors. Although the effect size of the gain-frame advantage (r = .083) was

Table 1 Recommendations for framing health messages.

	Recommended message frame	
Moderator	*Gain frame*	*Loss frame*
Behavior-related moderators		
Prevention vs. detection	Prevention	*n/a*
Person-related moderators		
Motivational orientation	Approach oriented	Avoidance oriented
Culture	Individualistic	Collectivistic
Perceived susceptibility	Low susceptibility	High susceptibility
Self-efficacy	*n/a*	High self-efficacy
Context-related moderators		
Autonomy vs. heteronomy	Prime autonomy	Prime heteronomy
Color	*n/a*	Red

relatively weak, Gallagher and Updegraff (2012) suggest that given the complexity of health behavior determinants, even a relatively weak effect may work additively with other factors to produce meaningful changes in behavior. In contrast to prevention behaviors, detection behaviors were not significantly affected by message framing. However, in examining specific domains of detection behaviors, the meta-analysis found that loss-framed messages were marginally more effective in promoting breast cancer detection behaviors than gain-framed messages.

Behavior-related moderators provide high-level recommendations for framing, particularly useful when little or no information about the target audience is available. A notable example would be a message created for mass production (e.g., public service announcements), which could be made most effective by framing it according to the behavior's inherent risk. Based on Gallagher and Updegraff's (2012) findings, mass-media messages promoting preventive health behaviors (e.g., physical activity, nutrition, sunscreen use, condom use, oral healthcare) should emphasize the positive outcomes that can be gained by adopting and maintaining these behaviors. When encouraging detection behaviors, healthcare professionals can rely on person- and context-related moderators to help determine the most effective message frame.

Person-Related Moderators

Where behavior-related moderators offer broad recommendations for framing, person-related moderators allow healthcare professionals to tailor framed messages to a patient when characteristics of that person are known. A number of person-related variables have been found to moderate the effect of message frame on health behaviors including a person's motivational orientation, culture, perceived susceptibility, and self-efficacy.

Motivational orientation refers to the degree that a person is predominantly motivated by cues of reward (approach oriented) versus cues of punishment or threat (avoidance oriented). Because gain-framed messages emphasize the reward to be gained by performing a behavior, researchers theorized that gain-framed messages would be more congruent and thus more persuasive for approach-oriented individuals. Alternatively, loss-framed messages emphasize the punishment or negative consequences of not adopting a behavior and thus should be a better match for avoidance-oriented individuals. Indeed, research indicates that approach-oriented people are more responsive to gain-framed messages, whereas avoidance-oriented people are more responsive to loss-framed messages. For example, in the domain of oral health behavior, participants who were primarily approach oriented flossed more after reading a gain-framed article, and participants who were primarily avoidance oriented flossed more after reading a loss-framed article (Sherman, Mann, & Updegraff, 2006). Thus, a clinician may assess motivational orientation using a short survey and then maximize a message's effectiveness by framing it to be congruent with the patient's predominant orientation.

In addition to moderators borne from individual differences, cultural difference factors may also play a role in the relative effectiveness of gain- and loss-framed messages. In a study assessing the moderating influence of culture on flossing behavior, researchers found that people with low exposure to US culture, measured by proportion of life spent in United States and whether parents were born in the United States, flossed more after seeing a loss-framed message compared with a gain-framed message (Brick et al., 2015). While culturally congruent messages resulted in greater flossing, culturally incongruent messages led to the same levels of flossing as seeing no message.

Why might this be? Researchers have found systematic differences in motivational orientation across cultures, with collectivistic East Asian and Latino cultures tending to be more avoidance oriented and individualistic White British and American cultures tending to be more approach oriented. It is possible that because of these cultural orientation propensities, loss-framed messages are more effective among people from (or primarily exposed to) collectivistic cultures, whereas gain-framed messages are more effective among people from (or primarily exposed to) individualistic cultures. Indeed, support for this explanation comes from a study that examined differences in how White and East Asian individuals living in Britain responded to framed messages promoting oral health (Uskul, Sherman, & Fitzgibbon, 2009). White British individuals were more persuaded by a gain-framed message, whereas East Asian individuals were more persuaded by a loss-framed message. Clinically, cultural background can be measured with simple demographic questions often obtained during intake, and as such offers a simple and practical way for health professionals to tailor framed messages to patients, and also may suggest ways to address cultural and ethnic disparities in health.

Perceived susceptibility to a health condition has been studied as another person-related moderator of framing effects, particularly in detection behaviors. Although detection behaviors were originally proposed as inherently risky, people's perceptions of the risk of these behaviors likely fall along a spectrum, with some perceiving very little risk and others perceiving great risk. Specifically, people who perceive themselves to be more susceptible to a disease may be more likely to perceive the detection behavior as risky. Indeed, research on mammography testing indicates that among those with high perceived susceptibility, loss-framed messages are more effective than gain-framed messages but that message frame does not affect behavior when perceived susceptibility is low (Gallagher, Updegraff, Rothman, & Sims, 2011). In the context of oral health (Updegraff, Brick, Emanuel, Mintzer, & Sherman, 2015), moderation by perceived susceptibility was also observed: a gain-framed message was more effective for those who perceived low susceptibility to oral health problems, and a loss-framed message was somewhat more effective for those who perceived high susceptibility.

Finally, self-efficacy has also been proposed as a moderator of message frame, such that loss-framed messages appear to be more effective for those with high confidence in their ability to perform a behavior. However, this finding is currently limited to studies of self-examinations and smoking cessation; similar studies have failed to replicate this moderation in the context of other behaviors such as immunization (Covey, 2014). Although person-related moderators may be difficult for clinicians to apply because they require pre-assessment and tailoring, they can offer valuable framing guidance when behavior-related cues are unclear.

Context-Related Moderators

In addition to behavior- and person-related moderators, context-related moderators may influence the relative effectiveness of gain- and loss-framed messages. Theoretically, context-related moderators could be manipulated within a persuasion situation to increase the effectiveness of a framed message, unlike relatively stable factors like behavior- and person-related moderators. One example of a context-related moderator is the role of perceived autonomy versus heteronomy in health decision making. Autonomy refers to the experience of engaging in actions based on one's personal interests and values, whereas heteronomy refers to engaging in actions based on some pressure or coercion from other people. Pavey and Churchill (2014) found that after priming autonomy (i.e., having people generate sentences with words like freedom, choice, decision), gain-framed message produced greater behavior change than loss-framed messages, but after priming heteronomy (i.e., having people generate sentences with words like pressure, control, must), loss-framed messages were more effective.

Additionally, the use of colors may moderate framing effects. In particular, the use of the color red—which often acts as a cue of threat, due to its association with blood and danger—has been shown to increase the persuasiveness of loss-framed messages (Gerend & Sias, 2009). The domain of context-related moderators requires further study, but it offers the unique benefit of allowing researchers and clinicians to amplify the strength of a framed message by modifying the context in which it is presented. For example, if the target behavior is prevention focused, and the target audience is primarily approach oriented, the clinician could choose a gain-framed message and theoretically amplify it by emphasizing the individual's autonomy and freedom of choice. However, researchers have only begun to investigate the role of context-related moderators, and additional empirical work is needed to replicate and extend these findings.

Mediators of Message Framing Effects

Why do gain- or loss-framed messages have a differential impact on persuasion and behavior? While much is known about the moderators of framing effects, much less is known about the psychological mechanisms—that is, mediators—that account for these effects. Indeed, there may be many processes that make a gain- or loss-framed message more effective, including conscious cognitive processes as well as more implicit or emotional processes. Most of the research that has looked at mediators of framing effects has focused on conscious cognitive processes, such as changes in consciously articulated attitudes or intentions toward the advocated health behavior, but many studies have failed to show that these factors consistently explain effects on behavior (see Gallagher & Updegraff, 2012 for review). It is possible, then, that more implicit or emotional reactions may explain the effects of framing on behavior.

However, to date, two mediators seem to have the greatest potential to explain the influences of framed messages on behavior: elaboration and the subjective sense of "feeling right." Specifically, research has found that people tend to elaborate on a message more—that is, they process the message at a greater depth—when the message frame is congruent with their motivational orientation. For example, people receiving congruent messages were better able to discern strong and weak arguments about the importance of flossing than people who received incongruent messages (Updegraff, Sherman, Luyster, & Mann, 2007). In addition, congruently framed messages may be more likely to lead a person to have a subjective sense of "feeling right" about their reactions to a message than incongruently framed messages (Cesario, Higgins, & Scholer, 2008).

Interestingly, both the elaboration and the "feeling right" accounts highlight the importance of basing a framed health messages on strong, convincing information. If recipients are more likely to think deeply about and "feel right" about their reactions to a congruently framed health message, then incorporating unconvincing or flimsy information into the message may have the unintended effect of *decreasing* the effectiveness of the framing. Thus, the mediation of framing effects is complex and requires further study but is an important direction for future research.

Applying Message Framing

Message framing offers a relatively simple and versatile way for clinicians and health professionals to present health messages in a maximally persuasive way. Specifically, the moderators discussed above offer a number of ways to decide how to determine the frame of the message. If a message is to be mass-produced, or if no information about the recipient is known, the message crafter should consider whether the behavior is a detection or prevention behavior and frame the message accordingly; that is, if the behavior is a prevention or promotion behavior, the clinician should gain-frame the message. However, if more information is known about the audience, the clinician may use some of these characteristics to determine an appropriate message frame. A recipient who is avoidance oriented or perceives high susceptibility may be more strongly persuaded by a loss-framed message. Alternatively, a person from an individualistic culture or with low perceived susceptibly may be better persuaded by a gain-framed message.

Under certain circumstances, having information about a number of moderators can pose difficult clinical decisions if those pieces of information propose conflicting message frames. For example, if the behavior is a detection behavior, and the target individual perceives high susceptibility, but the individual is also approach oriented and from an individualistic culture, which frame should be used? The high perceived susceptibility suggests a loss-framed message, but the motivational and cultural orientations suggest a gain-framed message. Clearly, conflicting information poses challenges for the clinician hoping to put this information to good use. Additional research that examines multiple moderators in concert is needed to determine relative strength and weights of these various moderators so that clinicians can make better informed decisions when selecting message frames.

Message framing is a particularly versatile application, as it can be applied through any number of clinically relevant media, from brochures and signs to videos to live doctor–patient conversations. With a simple modification to the way in which an action (or lack of action) is paired with a consequence, healthcare professionals may be able to increase the effectiveness of their communications and help patients make healthier decisions.

Author Biographies

Scout N. McCully is a doctoral student in psychological sciences at Kent State University. Her work seeks to improve people's success in adopting and maintaining health behaviors, with a focus on simple, scalable, theory-driven interventions.

John A. Updegraff is professor of psychological sciences at Kent State University. His research examines the effectiveness of tailoring persuasive health messages to match the ways in which people think about health behaviors and their environments in general. A central goal of his work is to develop theoretical frameworks and strategies for communicating health information in ways that are personally relevant and effective in promoting long-term behavior change.

Message Tailoring

Mia Liza A. Lustria and Juliann Cortese

School of Information, Florida State University, Tallahassee, FL, USA

Tailoring as a Health Communication Strategy

Much of the world's disease burden is associated with a few modifiable health behaviors like diet and physical activity and risky or unhealthy behaviors such as smoking, alcohol abuse, unsafe sex, use of firearms, and drug use. Most people recognize risks associated with these unhealthy behaviors and the potential benefits of adopting healthy behaviors in lowering their risk for chronic illness. Yet many continue to make unhealthy lifestyle choices even when they experience undesired consequences for their actions (or inaction) or even if they have a genetic predisposition toward a particular chronic disease (King, Mainous, Carnemolla, & Everett, 2009).

Health psychologists recognize that a number of factors can shape health behaviors and that these factors vary from one individual to another. These factors are driven by reciprocal influences of one's experiences, beliefs, values and attitudes, motives and expectations, environment and circumstances, personality traits, mental and emotional states, patterns of behavior, and habits, among others. Health messages primarily designed to raise awareness without considering the complexity of behavior change are deemed to have limited impact on individual actions and decision making. It is for this reason that interpersonal communication continues to be the ideal channel for promoting individual behavior change because of the ability to adjust communication on the fly and to deliver personalized recommendations. Unfortunately, the reach and accessibility of health counselors adequately trained in delivering evidence-based personalized recommendations is limited. Message tailoring, a health communication strategy for disseminating theoretically informed individualized recommendations, seeks to address this need to deliver more efficacious health behavior change strategies on a mass scale.

The Tailoring Process

Message tailoring is defined as a "multidimensional communication strategy that involves developing individualized messages based on a pre-assessment of key individual-difference

---

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

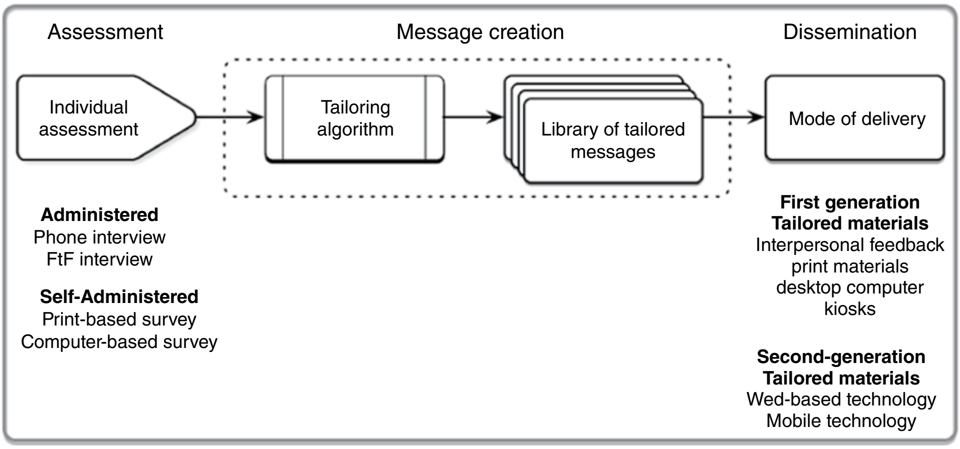

Figure 1 A basic message tailoring system.

variables or characteristics linked to the underlying model of behavior change" (Lustria et al., 2013, p. 1040). It refers to various message design strategies for creating health messages that resonate at an individual level by using knowledge about a person's unique needs and preferences (Kreuter & Wray, 2003). Information about the individual is typically assessed through a survey of relevant factors (e.g., personal, psychosocial) and theoretically informed determinants of the targeted health behavior. This data is then evaluated by an expert system that uses tailoring algorithms to prioritize content and recommendations based on user input. At the most basic level, this process involves selecting messages most relevant for the individual from a database of tailored content. A typical tailoring system includes (a) a way to collect information about the individual (e.g., paper-based, telephone-based, or computer-based assessment), (b) a system to analyze responses (usually via computer algorithms), (c) an extensive message library, and (d) a way to disseminate the tailored messages (e.g., via print media, electronic, or web-based technologies; Figure 1).

As a communication strategy, message tailoring takes into account the heterogeneity of factors that determine an individual's health behaviors and the variety of pathways to success. It is not to be mistaken for simple *personalization* or the inclusion of personal identifiers, the main goal of which is to draw attention to the health message (e.g., names). It is also different from *targeted messaging* or creating messages that might resonate with specific groups of people that share common characteristics (e.g., teenage mothers, dementia patients, breast cancer survivors). Rather, in *tailored messaging*, individual-level assessment enables the creation and delivery of highly personalized recommendations and plans for modifying simple to complex health behaviors based on an analysis of individual drivers for (and barriers to) change.

In contrast to generic messages, tailored messages are designed to directly address factors relevant to the individual and promote recommendations that take the individual's context into consideration. The following is an example of a generic health message aimed at preventing weight gain found on typical websites like the Centers for Disease Control and Prevention (adapted from Centers for Disease Control and Prevention, 2015):

> If you're currently at a healthy weight, you're already one step ahead of the game. To stay at a healthy weight, it's worth doing a little planning now. Or maybe you are overweight but aren't ready to lose weight yet. If this is the case, preventing further weight gain is a worthy goal. As people age, their body composition gradually shifts — the proportion of muscle decreases and the

> proportion of fat increases. This shift slows their metabolism, making it easier to gain weight. In addition, some people become less physically active as they get older, increasing the risk of weight gain. The good news is that choosing a lifestyle that includes good eating habits and daily physical activity can prevent weight gain. To learn more…

In contrast, the following is an example of how a tailored health message differs from the generic message just provided:

> Hi **Pam**! **Based on your current age, weight and height**, **you are slightly at risk** for obesity. This extra weight can but stress on your bones, joints, and organs, which may partly explain **your lethargy and difficulty in sustaining your daily activities**. Too much body fat also raises your **blood pressure** and cholesterol - this can be very dangerous for people like you **who have a family history of heart disease and stroke**. Here's the good news – you can achieve a healthy weight by adopting good eating habits and daily physical activity.
>
> **Being a busy career woman and mom**, we understand that this is easier said than done. So we've created **a few simple steps for you to reach your goal**. **We'll start by recommending easy-to-prepare meals to help lower your daily caloric intake to _____ and a few daily exercises that you can do in 10 minutes or less each day**. Start here…

Message Tailoring Works

A wide evidence base promotes the use of tailored messaging over one-size-fits-all generic messaging. Compared with non-tailored messages, tailored information commands greater attention and is processed more intently, recalled more readily, and perceived as more personally relevant and more positively by health consumers (Kreuter, Strecher, & Glassman, 1999). More importantly, several studies and meta-analyses provide empirical evidence for the benefits of tailored versus non-tailored interventions across a wide variety of health outcomes such as physical fitness, nutrition, mental health, immunization, early detection or screening, sexual health, alcoholism, and chronic disease (e.g., Chodosh et al., 2005; Davies, Morriss, & Glazebrook, 2014; Kessels, Ruiter, Brug, & Jansma, 2011).

Overall, various meta-analyses have pointed to small- and medium-size effects of tailoring on behavior change. Noar, Benac, and Harris (2007) conducted a meta-analytic review of 57 tailored print behavior change interventions and found a mean effect of $r = .074$ of tailoring on health behaviors. The variables that were found to significantly moderate the effect included (a) type of comparison condition, (b) health behavior, (c) type of participant population (both type of recruitment and country of sample), (d) type of print material, (e) number of intervention contacts, (f) length of follow-up, (g) number and type of theoretical concepts tailored on, and (h) whether demographics and/or behavior were tailored on.

Krebs, Prochaska, and Rossi (2010) also conducted a meta-analysis to evaluate the mean effect of 88 computer-tailored interventions focusing on smoking cessation, physical activity, eating a healthy diet, and receiving regular mammograms. They found clinically and statistically significant overall effects across each of the four behaviors. Effect sizes decreased after intervention completion, and dynamically tailored interventions were found to have increased efficacy over time as compared with those based on one assessment only.

Tailored interventions can range from simple, tailored risk assessments or tailored health messaging to more complex and highly individualized health programs, treatment plans, or recommended actions. The most basic tailored interventions involve risk assessment followed by short motivational interventions focused on promoting the targeted health behavior. These brief tailored interventions typically involve single assessments at baseline, after which participants either immediately receive tailored advice via a webpage or print out or are scheduled to receive tailored messages via email or postal mail. For health interventions targeting more complex lifestyle changes or behavior modification, tailoring may be done iteratively or delivered in modules and may be enhanced through interactive features such as goal setting, skills building, tracking and monitoring, and expert and social support tools to help participants achieve their goals (Lustria, Cortese, Noar, & Glueckauf, 2009).

In one example, Woolford, Clark, Strecher, and Resnicow (2010) used mobile phone texting to tailor healthy behavior messages to obese adolescents. Baseline measurement was used to assess behaviors, and then text messages were sent automatically through a computer application that chose from a series of appropriate messages in a library of tailored content. Participants were enrolled in a weight management program, and the tailored reminders helped keep them on track with their weight-loss goals.

Lustria et al. (2013) conducted a meta-analysis of 40 randomized controlled trials and quasi-experimental studies comparing tailored versus non-tailored web-based interventions. The findings indicated that web-based tailored interventions lead to significantly greater improvement in health outcomes as compared with control conditions both at posttest and at follow-up. The researchers concluded that web-based interventions benefited from the inclusion of several different modalities that added an interactive element to interventions, such as audio, video, discussion, and chat, which is ideal for improving user engagement and supporting patients' self-management and skills building.

How Does Message Tailoring Work?

Hawkins, Kreuter, Resnicow, Fishbein and Dijkstra (2008) propose that tailoring improves the efficacy of health communication by enhancing (a) the cognitive preconditions for message processing or acceptance and (b) message impact by selectively modifying the behavioral determinants of desired health outcomes.

Petty and Cacioppo's elaboration likelihood model (ELM) lays the theoretical groundwork for how tailoring can enhance persuasion. ELM is a useful way of looking at how attitudes can be influenced, shaped, or changed as a result of exposure to mass-mediated persuasive messages. According to this theory, attitudes may be influenced as a result of high elaboration, one's thoughtful consideration of the merits of a persuasive message (*central route processing*), or a simple cue in the persuasion context (*peripheral route processing*; Petty & Cacioppo, 1986). When people are motivated (e.g., when the topic is interesting or perceived to be personally relevant) and have the ability to process messages actively and more thoughtfully (e.g., have prior knowledge, no distractions, message is comprehensible), they are more likely to scrutinize the information and make decisions based on its merits.

However, not all situations are conducive for thoughtful reflection, as in the case of a brief message communicated via a televised public service announcement. In situations of low elaboration like this, persuasion may still occur through the influence of heuristic cues like the appearance of the source or the source's perceived trustworthiness. Attitudes formed via the central route are thought to be more enduring, more resistant to counter-persuasion, and more predictive of behavior (Petty, Briñol, & Priester, 2009), and thus messages designed to induce higher elaboration are ideal for persuasion. While the valence of a persuasion attempt can be influenced by a number of factors, it is clear that an individual's motivation and ability to process the message are critical to the outcome. Much of the research on this topic has shown a significant relationship between tailoring and increased attention and perceived personal relevance. Petty et al. (2009, p. 145) note that tailoring "can influence attitudes by serving as a peripheral cue when elaboration is low, by biasing thoughts when elaboration is high and by enhancing the amount of information processing when elaboration is moderate."

The efficacy of tailored interventions is also bolstered when message tailoring is guided by research and by health behavior theories and models (Webb, Joseph, Yardley, & Michie, 2010). Theory and research can inform tailoring in a number of ways by helping prioritize relevant constructs for tailoring (e.g., perceived risk, attitudes, beliefs) and by informing the selection of specific messaging strategies and behavior change techniques (e.g., stage matching, timing, delivery mode) most effective for particular population groups. The most common theories used to guide message tailoring are described below.

Prochaska's transtheoretical model (TTM) has been used extensively and successfully in smoking cessation programs tailored based on patients' readiness to quit smoking. The TTM suggests that a patient's responsiveness to a behavioral intervention is influenced by where they are in the "stages of change": precontemplation, contemplation, preparation, action, maintenance, and termination (J. O. Prochaska & DiClemente, 1983). The model is suited particularly well for guiding tailoring in health interventions related to areas to which people may exhibit various degrees of commitment (i.e., physical activity, nutrition, and smoking cessation; J. M. Prochaska & Prochaska, 2014). Certainly, stage-matched tailoring has proven to be effective in a number of interventions related to smoking, condom use, cancer screening, and hypertension control, among others (Stanczyk et al., 2014). Knowledge about an individual's readiness for change can be very useful in crafting and scheduling the delivery of motivational messages and reminders with the desired goal of moving someone onto latter stages or effecting more lasting change.

Another health communication theory often used to guide message tailoring is the health belief model. The health belief model is a predictive model that examines the likelihood that an individual will engage in a health-promoting behavior (Rosenstock, 1974). The theory suggests that likelihood of engagement in a health-conscious behavior can be predicted by examining an individual's perceived susceptibility, seriousness of the health concern, benefits versus barriers of the healthy choice, perceived threat, self-efficacy, and cues to action. Because all of these factors have the opportunity to affect change, presenting the individual with tailored message focused in any of these areas can result in a choice to engage in a health-promoting behavior.

Often one of the easiest ways to influence behavior is to present a behavior that can be imitated or modeled. This approach is the focus of social cognitive theory, which states that individuals can gain knowledge by observation. Though not developed in the health communication field, the theory has much to offer in this area (Bandura, 1998). Tailored messages may be created in such a way as to present scenarios that can be modeled by the viewer through stories, anecdotes, and testimonials.

Cortese and Lustria (2012) created a web-based tailored intervention to educate teens about sexual health and decision making. Message tailoring drew heavily from constructs in the health belief model and social cognitive theory. Overall, messages were created to raise perceptions of risk (*perceived severity*), address individual concerns about what it will take to adopt the recommended behavior (e.g., money, effort, time; *perceived barriers*), and build confidence that taking the recommended action can reduce risk (*perceived benefits*). Tailored testimonials were presented to model safe sex behaviors and healthy decision making and to increase perceived self-efficacy to carry out the prescribed behaviors. Results of the randomized controlled trial comparing the tailored site with a generic site showed that those in the tailored condition had higher satisfaction with the site and elaborated on the health messages more deeply as compared with those exposed to the non-tailored site.

The theory of reasoned action and planned behavior (TRA/TPB), another predictive model, links together beliefs, attitudes, and behavioral intentions to predict behavior (Fishbein & Ajzen, 1975). A number of tailoring studies have used TRA/TPB successfully. Webb et al. (2010) conducted a meta-analysis to examine the use of theory-based message tailoring and found that studies identifying TPB as their theoretical frame (9 out of 85 studies) reported larger effect sizes compared with all other tailored interventions included in the review. To exemplify how TPB can inform tailoring, Hurling et al. (2007) conducted a randomized controlled trial to evaluate the efficacy of a tailored physical activity program using web and mobile phone technology. Participants in the real-time tailored condition received tailored feedback, tailored solutions to address their perceived barriers, a weekly exercise plan with SMS and email reminders, and access to a message board for social support. Participants in both groups were issued wrist-worn accelerometers to monitor their level of physical activity for 9 weeks. Results showed that the tailored group reported a significantly greater increase over baseline than the control group for perceived control and intention/expectation to exercise. Participants in the tailored condition also lost a greater percent of their body fat than the control group.

The Future of Message Tailoring

Thoughts about applying the process of mass customization (Davis, 1989) to health messaging was first introduced in the late 1980s and early 1990s. Kreuter, Farrell, Olevitch, and Brennan (2000) attributed the turn toward mass customization to three innovations: (a) increasing popularity of audience segmentation in developing health education materials, (b) the introduction of new models of individual health behavior change (e.g., TTM), and (c) advances in computer technology. Of these three, the application of computers for processing individual data and for generating individual reports provided the tipping point for mass production of customized content. First-generation tailored interventions were largely print based or delivered via desktop computers or kiosks and typically involved a single, simple tailoring assessment.

Over time, the sophistication of tailored interventions has greatly increased concomitant with advances in information and communication technologies. These advances have benefited message tailoring by increasing reach, improving delivery, and improving assessment. In particular, web technologies have made it possible to scale the production and delivery of tailored messages to multiple individuals at relatively low cost. Internet delivery improves the reach of effective behavior change interventions to potentially hard-to-reach population groups and provides wider access to expert care and feedback. Synchronous and asynchronous technologies (e.g., email, SMS, chat) present multiple options for the delivery of tailored content, reminders, and feedback. Users can access tailored content at any time and receive "just-in-time" information when and where they need it the most. Users also have more options for scheduling and receiving tailored reminders with the ability to personalize notification settings.

In addition to the availability of multiple delivery modes (e.g., web and mobile technologies), tailored messages may be communicated via different formats (e.g., audio, video, simulations, games, virtual reality). Multimodal options are beneficial for addressing the needs of participants with different literacy levels, learning styles, and technological competencies. Interactive technologies (e.g., e-journaling, quizzes, video, simulations, discussion forums) provide excellent platforms for implementing effective behavior change strategies, such as tracking and monitoring, goal setting, skills building, and providing tailored feedback and social support. As an example, Stanczyk et al. (2014) conducted a randomized controlled trial comparing the efficacy of a stage-matched tailored smoking cessation intervention with tailored video or tailored text and a generic control. Video tailoring was found to be more effective in increasing 7-day point prevalence abstinence than the control condition and resulted in significantly higher prolonged abstinence rates among smokers with a low readiness to quit.

Social media also have the potential for amplifying access to tailored interventions through cross-platform communication strategies and content repurposing (e.g., re-tweeting, blogging). Web 2.0 technologies like social networks, microblogging tools, and video-sharing sites can expand messaging opportunities while also providing highly interactive, dynamic, and flexible content that may improve user engagement.

Perhaps one of the most exciting areas of development in tailored messaging is the use of mobile devices and sensing technologies. Mobile technologies are particularly suited for persuasion as people are deeply attached to their mobile devices and have them wherever they go, making it easy to deliver persuasive messages when and where they need it the most. The delivery of reminders, tailored motivational messages, and coping tips could be triggered during opportune moments—for example, when the mobile system senses a user's location as a place where temptation typically lies.

The new generation of smart phone and wearable technologies (e.g., Apple Watch, Fitbit, Nike FuelBand) have also enhanced users' ability to track and monitor progress on their health goals without requiring manual data entry. These advances are paving the way for more synchronous and interactive tailoring based on real-time tracking through ubiquitous and unobtrusive sensing (Wangberg & Psychol, 2013). Coupled with advances in artificial intelligence and data processing methods, researchers may one day be able to fully automate the tailoring process, conduct iterative, real-time tailoring, and lower the burden for user assessment.

Author Biographies

Mia Liza A. Lustria, PhD, is an associate professor and chair of the undergraduate program at the School of Information, Florida State University. She has a successful record of publications and funded research in consumer health informatics aimed at improving access to healthcare and education through the use of digital and interactive media. Her current work focuses on theory-based message tailoring and the design and evaluation of persuasive technologies for use in behavior change interventions.

Juliann Cortese, PhD, is an associate professor in the School of Communication, Florida State University. Her area of research focuses on the uses and effects of online health content, having examined online tailoring, mediated social support, and mental processes engaged in while examining online content. She has published in top ranking journals including *Patient Education and Counseling*, *Journal of Health Communication*, *Journal of the American Society for Information Science* and *Technology*, *and Human Communication Research.*

Naturalistic Observation of Social Interactions

Angela L. Carey, Kelly E. Rentscher,
and Matthias R. Mehl

Psychology Department, University of Arizona, Tucson, AZ, USA

People's social relationships and daily social interactions can impact health in profound ways. For example, in a meta-analytic review, Holt-Lunstad, Smith, and Layton (2010) found that across 148 studies totaling 308,849 participants, individuals with strong social relationships had a 50% greater likelihood of survival relative to those with poorer social relationships. The magnitude of this effect in fact exceeded many well-known mortality risk factors (e.g., obesity, smoking), providing further evidence that social interactions not only influence quality of life but can also have important implications for human survival. It is therefore just as necessary and important to include social interactions in research on health as it is other mortality risk factors.

Interestingly, when considering existing social health research, there appears to be a discrepancy in the precision researchers tend to afford independent versus dependent variables in what might be called the "social health equation," or the prediction of health outcomes by psychosocial variables (Mehl, Robbins, & Deters, 2012). On the criterion side, researchers measure important health outcomes using an assortment of high-fidelity methods to assess health functioning as objectively and precisely as possible (e.g., endocrinological and immunological biomarkers, markers of gene, or cellular functioning). However, on the predictor side, health-relevant psychosocial constructs tend to be measured with considerably less fidelity, objectivity, and precision. This is evidenced by a general inclination to rely heavily on self-report methods or, more specifically, what participants (can) tell about their psychological and social functioning. Self-reports are undoubtedly valuable given that they provide important information and can be obtained efficiently and at low cost; at the same time, it is clear that they do not afford a level of fidelity and precision that can rival that of objective health outcome measures. For example, the theoretical and empirical distinctness of subjective (i.e., experiential) and objective (i.e., observable) aspects of moral behaviors illustrate the need for greater precision when measuring health-relevant social constructs. With respect to

health-relevant processes, it seems clear that the subjective experience of gratitude differs in important ways from the behavioral expression of gratitude. Whereas the former is first and foremost a result of the interplay of inner cognitive processes, the latter is critically shaped by outer, situational, and cultural factors. For example, subjective experience of gratitude can promote self-esteem and reduce negative emotions such as envy, regret, and resentment, thereby affecting "downstream" constructs such as happiness and depression. Behavioral expressions of gratitude, on the other hand, including enhanced empathy toward others, reduced aggression, and further, the act itself (e.g., inviting an acquaintance to lunch to express thanks for assisting when the babysitter unexpectedly canceled) can lead to more opportunities for social interaction and development of new relationships.

Gratitude has been tied to health outcomes such as enhanced sleep quality and duration, as well as improved physiological health. It has also been found to attenuate stress responses, which in turn can improve cardiovascular function and reduce risk of heart disease. Gratitude is often assessed, however, via self-report only, which makes it challenging to truly disentangle experienced and observed gratitude and to determine how the two independently relate to health outcomes. Given this, it is important to be able to separate these two components measurement-wise, which can only be accomplished through the combination of first-person self-report and third-person observational assessments. Analyzing behavioral observations in conjunction with subjective reports of gratitude enables social scientists to achieve a deeper understanding of the interaction between what is behaviorally occurring and what is subjectively experienced in people's daily lives, thus increasing measurement fidelity and precision in operationalizing health-relevant constructs. In short, the field of health psychology could benefit substantially from a multi-method approach to studying daily social interactions that complements self-reports with observational assessments.

Ambulatory Assessment Methods

Although the majority of research investigating social interactions and their influence on health continues to be based on self-report surveys, the last 20 years have seen a steady increase in the use of ambulatory assessment methods that can capture aspects of participants' daily lives "in vivo." Ambulatory assessments are defined as the use of field methods to assess the ongoing behavior, physiology, experience, and environmental aspects of people in naturalistic or unconstrained settings. Ambulatory assessment uses ecologically valid tools to understand biopsychosocial processes as they unfold naturally in time and in context (www.ambulatory-assessment.org).

Ambulatory assessments have several key advantages (Mehl & Conner, 2012). First, ambulatory assessments take place directly within participants' everyday lives; they maximize generalizability across a wide range of real-world contexts. Second, they capture individuals' in-the-moment or close-in-time behaviors, thoughts, and feelings and thereby bypass memory-related biases that can undermine the validity of global and retrospective self-reports (e.g., recall-related errors resulting from serial position effects, mood effects, and heuristics and estimation strategies). A third advantage of ambulatory assessments is that their typical high density of longitudinal measurements renders them uniquely suited to studying how individuals' behaviors, thoughts, and feelings change over time in ways that cannot be adequately modeled within a laboratory setting. When experiences are assessed in real time (or as close to their occurrence as possible), participants' responses tend to more accurately represent what is occurring in the moment and are less influenced by applicable heuristics or schemata. In this way, intensive longitudinal ambulatory assessments are ideally suited for identifying individualized patterns of behavior and behavior change over time. Ambulatory assessment methods are also often referred to (with similar but not always identical meaning) as ecological momentary assessment, intensive longitudinal, experience sampling, and diary methods (see Mehl and Conner (2012) for further information).

Ambulatory Assessment of Physiology and Experience

Ambulatory monitoring allows for the sampling of physiological activity in daily life. Modern-day mobile technology allows for the reliable measurement of biological signals via portable signal recording devices that capture activity such as blood pressure, electrodermal activity, body temperature, and hormones, as a person goes about their everyday life.

If researchers' primary interest involves the momentary sampling of experiences in everyday life, daily diary assessments are some of the most commonly used methods. These typically involve once-a-day assessments via Internet surveys for a prolonged period of time (e.g., a few weeks) in order to assess events or experiences that can easily be recalled at the end of the day, such as emotions in response to daily stressors. With experience sampling methods (ESM), participants complete self-report assessments repeatedly throughout the day, mainly through use of mobile technology, at random (i.e., signal-continent sampling) or predetermined (i.e., interval-continent sampling) times, or when a target event such as an argument with a romantic partner has occurred (i.e., event-contingent sampling).

Assessment of Behavior

There is tremendous value in obtaining subjective reports of individuals' daily thoughts and experiences using each of the aforementioned ambulatory methods. Yet, one important lesson from psychometrics is that people are not always in the position to accurately report what they do. Sometimes they may actively censor information that they do not want to report; other times (and probably more often), they bias their self-perceptions in socially desirable ways for psychological self-protection. However, there are also other times when people want to honestly and accurately report information, but they simply cannot, due to limitations inherent to human information processing; for example, it is nearly impossible to recall the number of times one sighs or laughs in a day (and it would be highly impractical to be able to do so). In circumstances such as this, some of the same concerns pertaining to global and retrospective self-reports may also apply to momentary self-reports. Although ambulatory self-reports can provide more accurate representations of individuals' perceived daily lives than retrospective or global assessments in the laboratory can, they still require individuals to report on their thoughts and behaviors and therefore are inherently limited to capturing what surpasses the perceptual threshold and enters into working memory. This can be problematic given that participants' responses to self-report scales can be affected by recent events or experiences, thereby rendering them potentially susceptible to momentary influences including mood effects, socially desirable responding (i.e., impression management and self-deception), and, perhaps most importantly, lack of awareness. Another potential concern is measurement reactivity, whereby participants' behaviors and/or responses might systematically change as a result of prolonged and repeated momentary self-report assessments. For example, repeatedly reporting on one's behavioral expression(s) of gratitude might render participants mindful of their grateful behavior (or lack thereof) and consequently alter future expressions of gratitude. It is also possible that participants may lose motivation and become more careless with their responses over time leading to increased measurement error.

Naturalistic Observation of Social Interactions

Naturalistic observation methods extend the area of ambulatory assessment to real-world observational methods. Naturalistic observation methods are well suited to addressing some of the limitations inherent in momentary self-reports. Furthermore, these observational methods aim to capture individuals' behavior from the perspective of an observer and can thereby offer a complementary approach to the study of everyday social interactions through the eyes (or the mind) of the "actor." Researchers have directly observed behavior in the real world through use of small cameras placed in participants' homes, as well as live videographers. In one study at the Sloan Center on Everyday Lives of Families (CELF) at the University of California, Los Angeles, videographers with ambulatory cameras accompanied participants to work, in transit, in public, and as they reunited with their families at the end of the day. This study collected more than 1,400 hr of video recordings from 32 different dual-earner families over the course of 2 weekdays and 2 weekend days, as they normally lived their lives (e.g., Ochs, Graesch, Mittman, Bradbury, & Repetti, 2006). This study has yielded several important findings, one of which is that job stressors (collected via daily diary assessments of experiences at work) appear to be linked with increases in expressed marital anger and withdrawal (derived from the video recordings). Additionally, self-reported negative mood mediated the association between experienced job stress and observed at-home marital behavior (e.g., Story & Repetti, 2006). In adopting a multi-method approach that combined self-report and observational methods, this research provided real-world evidence of "spillover effects," in which stressors experienced outside of the home impact behavior, cognitions, and emotions inside the home.

Although video-based methods produce large amounts of data that allow for detailed and nuanced investigations of participants' naturalistically observed daily social interactions, they are very labor and resource intensive and afford a certain amount of intrusiveness (i.e., having cameras and often even members of the research team present in the setting). An issue that accompanies direct observational techniques such as these is the potential that participants' awareness of being video recorded might produce evaluation apprehension and, as a consequence, behavioral reactivity, in which the participants alter their behavior in response to being observed.

The Electronically Activated Recorder (EAR)

One methodology that can alleviate some of these potential issues while preserving the ability to observationally capture social interactions during daily life is the Electronically Activated Recorder (EAR) (Mehl, Pennebaker, Crow, Dabbs, & Price, 2001). The EAR is a portable digital audio recorder designed to intermittently capture snippets of ambient sounds from individuals' momentary environments, providing acoustic logs of their daily lives as they naturally unfold. The EAR allows researchers to unobtrusively capture behavior in real time, bypassing many of the previously mentioned limitations that often accompany self-report methods. In its most recent version, the EAR is a software application (the "iEAR") that runs on iPod touch devices and can be downloaded freely from Apple's App Store. To protect the iPod device from impact, it is handed to participants in a protective case with a clip so that participants can wear the EAR by attaching it to a belt, the outside of their clothing, or a bag as they go about their normal daily lives. The EAR's sampling rate can be freely programmed, and sampling patterns that have proven useful in prior EAR research are 30 s every 12 min (or 5 times per hour; the default sampling pattern) and 50 s every 9 min. This translates roughly into recording 5 and 10%, respectively, of the participants' day, leaving 95 and 90%, respectively, of their day private (i.e., unrecorded). In studies where there are special privacy considerations, such as using the EAR in the workplace, weekend monitoring (i.e., recording Friday evening through Sunday evening) may be preferable and the only way to obtain good compliance and valid information. In cases where there are no out-of-the-ordinary privacy concerns (e.g., among students or older, retired adults), monitoring on both weekdays and weekend days is preferable and can provide more generalizable information about participants' typical patterns of social interaction.

The current version of the EAR, that is, the iEAR app, also offers a randomization feature that allows researchers to randomize the length of the interval between each recording. At 100% randomization, recording times are fully random; at 50% randomization yields random recordings within half and one and a half times the programmed interval; for example, with a sampling rate of 30 s every 12 min, 30-s recordings will occur randomly between 6 and 18 min after the previous recording. Because of the electronic nature of the recording, participants cannot tell when the EAR is recording. The ability to set a "blackout period," which is a prespecified period of guaranteed non-recording, is another feature of the current iEAR app. It is recommended to adjust the blackout period to participants' reported bedtime and wake-up time to maximize the obtained information and the protection of participants' privacy.

When it comes to determining a desired sampling pattern (with respect to frequency and length of recording), researchers should first consider the natural base rate of their targeted behavior (i.e., how often does it happen in a day?); low base rate behaviors (e.g., crying, conflict) can require more frequent and longer-term sampling than higher base rate behaviors (e.g., watching TV, talking to the partner) to ensure that sufficient variability in the target behavior is represented in the recordings. With respect to deciding on the length of an individual recording sample (e.g., 30, 50 s, 2 min), researchers need to consider how much information coders need to clearly identify the (presence or degree of) construct. For example, if the researcher is interested in demand–withdraw interactions, a complex or "molar" psychological construct, longer recording segments (e.g., 2–3 min) might be necessary to reliably infer the pattern from a couple's way of discussing a problem. Alternatively, if the researcher is mostly interested in relatively narrow or "molecular" behaviors, such as whether or not a person is talking, laughing, sighing, or watching TV in any given recording segment, relatively short recordings (e.g., 30 s) will likely provide sufficient information. In our research, we have successfully employed both 50- and 30-s recording segments but have found 30-s segments to be usually preferable for both pragmatic and psychometric reasons (Mehl et al., 2012). Our default sampling rate of 30-s recordings every 12 min yields quite a high sampling density (approximately 5 samples per hour) that should provide good resolution for between and many within-person analyses; and, consistent with findings from decades of thin-slice research, we have found 30-s sound bites to yield surprisingly rich information about a person's behavior and social context at a given moment.

How Can the EAR Sound Files be Analyzed?

To extract relevant information from the EAR sound files, researchers can use a psychological rating or behavior counting approach. With the psychological rating approach, trained expert raters listen to the recordings and judge the degree to which they indicate the presence of a construct of interest (e.g., social support). To date, the majority of EAR studies have utilized a behavior counting approach. Here, trained coders make binary "behavior present" versus "behavior absent" codings for each recorded sound file using a standardized coding system referred to as the Social Environment Coding of Sound Inventory (SECSI) (Alisic, Barrett, Bowles, Conroy, & Mehl, 2015; Mehl et al., 2012). The SECSI captures a person's daily social environment, behaviors, interactions, and affect using the following four core categories: the participant's current (a) location (e.g., home, in transit, in public), (b) activity (e.g., watching TV, doing housework, eating), (c) social interaction (e.g., alone versus with others, talking to someone in person, talking on phone), and (d) emotional expression (e.g., crying, sighing, laughing). Conceptually, the EAR captures information about the types of social environments individuals are in (i.e., person–environment effects at the level of situation selection) and how they interact within those environments (i.e., person–environment effects at the level of person–situation interaction). In addition, all of the participants' utterances are transcribed verbatim, providing the ability to extract information about individuals' everyday language use from the sound files (e.g., via computerized text analysis). The language data can in turn be utilized to examine how natural language use reflects psychological states and traits; for example, individuals' personal pronoun use has been investigated as an automatic, nonconscious linguistic marker of interpersonal focus. To assess the psychometric properties of the EAR data, inter-coder reliability estimates are obtained either from double codings (i.e., independent sets of codings by two trained coders) or from codings accompanying a standard set of training EAR recordings. It is important that reliability estimates are calculated for the targeted unit of analysis. That is, if a researcher analyzes the EAR data at the aggregate level (e.g., percentage of sound files in a day in which the participant laughed), then the reliability should be reported for the aggregate measure; if a researcher analyzes each EAR sound file individually (within person), then an estimate of the coding of an individual sound file should be provided. In our lab, we first test inter-coder reliability at the level of the sound file by having all coders of a study code a standard set of training EAR recordings; this initial reliability check is part of the coder training and enables us to calibrate coders. Following this, we submit every sound file to an independent double coding and then estimate the reliability of the average measure composed of the two sets of codings. In our experience, it is reasonable to rely on single codings for narrow and highly concrete behaviors (e.g., whether or not the participant is talking or whether or not the TV is switched on); broader and more abstract psychological behaviors (e.g., disclosure, support, conflict) are more difficult to code reliably and thus tend to warrant a double-coding approach.

Ethical Considerations Pertaining to the EAR Method

Importantly, recording ambient sounds around participants raises ethical and legal concerns. EAR studies conducted within our laboratory routinely implement a series of safeguards to protect participants' privacy and ensure confidentiality of the data. First, data collection is limited to a fraction of a person's day; using the default sampling pattern (i.e., 30 s every 12 min), only 5% of a participant's total day is recorded, leaving 95% of the day private. Limiting the recordings to a brief 30 s yields sound files that are long enough to reliably extract behavioral information, yet also short enough to capture as little contextualized personal information as possible. Additionally, the latest version of the iEAR features a privacy button that, upon pressing it, guarantees participants a prespecified (by the researcher) time of non-recordings (e.g., 5 min; a countdown timer provides visual feedback for how much longer privacy is guaranteed). Another safeguard, and one of the most important, is that all participants are given the opportunity to listen to their EAR recordings and to delete any sound files that they do not want on record before investigators access any of the data.

What makes the EAR unique from other ambulatory assessment methods designed to assess behavior is that it differs in its assessment perspective. With traditional self-report-based ambulatory assessment methods, the participant is the agent and responds with subjective experiential accounts of an event, whereas the EAR adopts the perspective of a bystander or observer, yielding corresponding objective behavioral accounts (i.e., "participant as object"). In this sense, the EAR alleviates the burden placed on participants to interrupt their day and respond to a series of questions. It does, however, place the burden of potential psychological discomfort on participants: the knowledge that they are being intermittently recorded could cause participants to feel that their privacy is being violated or feel something akin to evaluation apprehension. Most participants experience some awareness when first equipped with the EAR, but this heightened self-consciousness tends to decrease within the first couple of hours and stays relatively low after that (Mehl & Holleran, 2007).

One of the more serious challenges, however, concerns the issue of potentially recording bystanders. In the United States there are relatively few restrictions regarding the recording of behavior in public places, but some states only permit recordings of private conversations if all interactants have knowledge of the recording device. In our studies, we usually equip the EAR with a neon triangle-shaped alert sign that displays a picture of a microphone, alerting people around the participants that the device may be recording. Participants are further encouraged to openly mention the EAR in conversations with others. This safeguard is aimed at minimizing expectations of privacy for bystanders, thereby indirectly eliciting their passive consent (i.e., through bystanders "behaving" in the awareness of being recorded). For further protection, all sound files are coded by staff who are trained and certified to conduct research with human subjects, and any identifying information that is captured in the sound files is omitted from the transcripts. Participants also always have the option to delete any sound files that may contain information about bystanders. Finally, in most studies, it is recommendable to protect the sound files through a Certificate of Confidentiality that the National Institutes of Health issues (upon a simple application and at no cost) to protect study data from forced third-party disclosure.

Health and Social Interaction Research Utilizing the EAR Methodology

As an unobtrusive observational method, the EAR has the unique advantage of being able to capture health-relevant behaviors that are rarely studied, as they may reside largely outside of conscious awareness and therefore tend to evade self-report assessment. Coupled with other more traditional momentary assessment methods, the EAR provides a comprehensive representation of health-relevant social processes as they naturally occur in everyday life. For example, 13 rheumatoid arthritis patients wore the EAR for 2 separate weekends spaced approximately 1 month apart to test the degree to which naturalistically observed sighing in daily life served as a behavioral indicator of self-reported depression and physical pain symptoms (Robbins, Mehl, Holleran, & Kasle, 2011). Sighing emerged as significantly and substantially related to patients' levels of depression but was not associated with their reported pain and number of symptom "flare" days. A second study tracked spontaneous swearing in the daily interactions of breast cancer and rheumatoid arthritis patients to investigate its potential role in coping with chronic illness (Robbins, Focella, et al., 2011). Interestingly, naturalistically observed swearing in the presence of other people, but not swearing when alone, was associated with decreases in self-reported emotional support and increases in depressive symptoms—suggesting that swearing can undermine emotional support with potential consequences for psychological adjustment. Importantly, both sighing and swearing are health-related behaviors that are difficult if not impossible to study with ambulatory self-report methods and are, by nature, optimally assessed from an (unobtrusive) observational perspective. Together, these findings highlight the utility of the EAR method in capturing largely unconscious behaviors that have potentially important implications for health.

The EAR has also been used to assess the impact of parents' psychological health on familial environments. For example, Slatcher and Trentacosta (2011) examined the association between parental depressive symptoms and child problem behaviors. Thirty-five two-parent families with children between the ages of 3 and 5 years were recruited into the study. Both parents completed a depression questionnaire, and the EAR was administered at two separate time points to capture the children's behavior and language. The children wore the EAR for two 1-day periods that took place 1 year apart from each other. Fathers' depressive symptoms correlated positively with children's crying, acting out, and watching TV at EAR Time 1, as well as children's watching TV at EAR Time 2. Mothers' depressive symptoms correlated positively with children's crying at EAR Time 2, and both mothers' and fathers' depressive symptoms were positively associated with their children's negative behavioral symptoms at Time 2. In addition, mothers' and fathers' depressive symptoms uniquely predicted increases in children's anger word use from Time 1 to Time 2.

In more recent research, the EAR has been used to investigate family interactions as they relate to physical health, or more specifically, to examine the associations between naturalistically observed family conflict and youth asthma symptoms (Tobin et al., 2015). Fifty-four adolescents with asthma wore the EAR for a 4-day period to capture conflict with parental figures and audible symptoms of asthma (i.e., wheezing), and both adolescents and parental figures completed daily diary reports of conflict and asthma symptoms. EAR-observed family conflict was strongly associated with both self-reported asthma symptoms and coder-observed wheezing, providing evidence that everyday conflict can have important implications for health symptoms such as asthma, particularly in the context of family interactions outside of the laboratory.

Finally, the examples of research findings presented here are not intended to represent an exhaustive review of existing EAR research within the field of social health psychology. Rather, these examples serve to illustrate the utility of combining both subjective experiential reports with behavioral observations in order to gain a deeper understanding of how daily social interactions impact health and, in some cases, how health impacts social interaction.

Mobile Sensing Methods

A relatively new and rapidly developing approach to objectively documenting social interactions in daily life is mobile sensing methods. With the fast-paced development of mobile devices, that is, smartphones and wearables, coupled with the growing number of people who now own and depend on them, there is no question that objective assessment of aspects of social interactions will soon be at least partially absorbed by mobile sensing. Generally speaking, mobile sensing applications are used to make inferences about users' behavior, emotions, environments, and daily life patterns through computer integration of the data that comes from both interactions with the actual user interface of mobile devices (e.g., duration of phone calls, number of text messages) and the multiple sensors that are embedded in smartphones (e.g., GPS, Bluetooth, accelerometers). Wearable devices such as portable smart watches will also be increasingly incorporated into research on account of the behavioral (e.g., physical activity) and physiological (e.g., heart rate) information they gather. Mobile sensing applications have much to offer in the amount of data they can collect and in the ways in which they open the field up to the objective characterization of a person's moment-to-moment social environment (e.g., location via GPS, solitary vs. social via Bluetooth, sedentary vs. active via accelerometers), and research within social and health psychology is swiftly moving in this direction. It will undoubtedly continue on its trajectory of becoming the new gold standard method for "big data collection," given that these devices can automatically store and transmit vast amounts of real-world user interaction data essentially instantaneously. Mobile sensing methods can potentially provide mass amounts of real-world data across thousands of participants, thereby critically reducing the resource burden for the researcher (i.e., studies can be run remotely at scale rather than locally in person). An example of one such mobile sensing method is EmotionSense (Rachuri et al., 2010). EmotionSense is a platform for creating mobile applications that can easily be installed onto off-the-shelf smartphones, with a focus on gathering not only data pertaining to participants' emotions, as the name would suggest, but also proximity and patterns of conversations with others. The EmotionSense apps are able to collect experience sampling self-reports as well as passive measurement of physical activity, mobility, and socializing via internal sensors and settings that can be configured for researchers' specific experience sampling studies.

Many mobile sensing applications sound ideal for conducting real-world research, but there are also limitations to utilizing mobile sensing as a methodology for naturalistic observation of social interactions. One of the most immediate concerns to address is the question of how to appropriately synthesize and interpret data derived from mobile sensing methods. Even the most advanced social sensing tools still struggle with extracting information at a level that is useful and readily interpretable for researchers. Physical activity is typically downloaded as a raw stream, meaning that artifacts have to be filtered out and activity states (e.g., sitting, standing, walking, running) have to be algorithmically computed. In a similar way, raw GPS data provides relatively little psychological information and requires post-processing to label the coordinates and make psychological sense of frequented locations (e.g., identification of home or the work place). Additionally, self-reported activity often differs from accelerometer-derived activity, and because people do not always carry their phones with them, further errors can be introduced into the existing algorithms. Intensity of physical activity also presents a crucial issue; mobile devices often struggle with basic extraction of information regarding intensity level of activity, and this is particularly important given that intensity provides significant health-relevant information, above and beyond the knowledge that someone has simply been active.

Another issue that accompanies mobile sensing methods involves some ethical concerns. Guaranteeing protection of participants' privacy is difficult; there is still the challenge of finding ways to ensure that participants' data, which largely resides online, will remain both de-identified and stored safely and securely. Moving beyond these pragmatic concerns, mobile sensing methods also differ widely from other forms of naturalistic observation in terms of what they can and cannot collect (or algorithmically produce) regarding daily social interactions. These apps can likely provide more, and potentially better quality, information regarding electronic forms of communication (e.g., text messaging, online social network use), and this increased accuracy greatly benefits the study of computer-mediated social interactions and their relation to health. However, due to privacy reasons, mobile sensing may face more challenges tracking in-person social interaction.

There is no question regarding whether smartphone sensing applications have been effectively established as proof of concept. However, for this area of research to move forward in a way that can significantly benefit social and health psychologists, more research is needed to ensure that algorithms are producing data with a level of precision that is acceptable to health researchers. In other words, what researchers urgently need are thorough psychometric validations of sensor data as they accumulate in the context of people's natural use of their smartphones and in the context of existing mobile sensing applications.

Much work is being done to move the field of mobile sensing forward, and it will inevitably introduce impactful changes regarding the collection of naturalistic observation data and the assessment of social interactions and health. Implemented (and validated the right way), these methods can further help reduce the discrepancy that exists between the fidelity of the measures on the "social" side and the fidelity of the measures on the "health" side of the "social-health equation" (i.e., the prediction of health outcomes from psychosocial variables). Recent EAR research has demonstrated that assessing social interactions and health through use of both momentary self-report (e.g., rheumatoid arthritis "flare" days; parental depressive symptoms) and behavioral observation (e.g., swearing in the presence of others; child problem behavior in the home) can undoubtedly produce a more nuanced picture of how social and health constructs manifest and interact within the real world. Further, adopting a combined naturalistic approach affords researchers the ability to disentangle whether and when a person's experiential report of an interaction may differ from what is captured observationally and what such discrepancies might indicate. The ability to capture and make sense of any such theoretical and empirical distinctness is an example of how this combination of ambulatory assessment methods can serve to increase precision and fidelity of health-relevant psychosocial variables, ensuring a methodologically sound approach. When both sides of the "social-health equation" are held to comparable levels of precision, researchers can more comprehensively assess how real-world social interactions impact health on a variety of levels and ultimately, with the assistance of rapidly evolving mobile technologies, determine how researchers can utilize this knowledge to improve and maintain health and well-being.

Author Biographies

Angela L. Carey, MA, is a social psychology doctoral student at the University of Arizona. Her research centers around social interactions and social support influences on coping in the context of major life upheavals (e.g., divorce). Her work utilizes the Electronically Activated Recorder (EAR) in combination with other methods (e.g., daily dairies, linguistic analysis) to study how different types of real-world social interactions change over time and in relation to self-reported adjustment and well-being.

Kelly E. Rentscher, MA, is a clinical psychology doctoral candidate at the University of Arizona. Her research involves a multi-method approach to studying how couples cope with stress and chronic illness, how relationship processes affect health over time (and vice versa), and how couple-focused interventions can target these processes to improve health outcomes. Her research employs linguistic analysis, observational, and naturalistic methodologies in laboratory and real-world settings.

Matthias R. Mehl, PhD, is associate professor of psychology at the University of Arizona. He has developed the Electronically Activated Recorder (EAR) as a methodology for the unobtrusive naturalistic observation of daily life and explores other novel methods for studying daily life. In 2012, he coedited the *Handbook of Research Methods for Studying Daily Life* (Guilford Press). He is a founding member of the Society for Ambulatory Assessment.

Optimism and Physical Health

Maria G. Mens[1], Michael F. Scheier[1],
and Charles S. Carver[2]

Optimists are people who expect good things to happen to them. Pessimists are people who expect bad things to happen to them. Folk wisdom has long held that this difference among people is important in many aspects of living. In this case, folk wisdom appears to be right. A substantial body of research suggests that optimists experience better physical health than pessimists.

Defining Optimism

Defining optimism in terms of expectancies links the optimism construct to a long tradition of expectancy-value theories of motivation. These theories hold that people pursue only goals they both value and expect to obtain. Expectancies reflect a person's confidence that sought after goals will be attained and are particularly important when impediments arise in goal pursuit. If a person is confident about eventual success, he or she will persist despite difficulties. However, if confidence wanes, the person is likely to disengage effort, sometimes disengaging from the goal itself.

Expectancies exist at many levels of generality. A student can have expectancies about her ability to get to class on time, expectancies about her ability to learn a topic, and expectancies about her likelihood of finding a fulfilling career. The principles of expectancy-value theories pertain equally well to expectancies that are specific and expectancies that are more general. They should even apply to the most broad or general kinds of expectancies, which characterize optimists and pessimists. The "confidence" that is at issue in optimism is simply broader in scope, pertaining to most situations in life rather than just one or two.

Measuring Optimism

Research on the effects of optimism has flourished over the past 30 years. This research has taken several different routes to assessing optimism, leading to somewhat distinct literatures. The most common approach asks people whether they think that good or bad things will generally happen to them in the future. In this method, individuals are asked to respond to statements such as "I am optimistic about my future" (e.g., Scheier, Carver, & Bridges, 1994). Most of the research linking optimism to physical health has used this approach to measuring expectancies.

Researchers who study optimism often refer to optimists and pessimists as though they were distinct groups. However, this usage is often a verbal convenience. All approaches to the measurement of optimism provide scores that vary continuously across large numbers of people. Thus, as often conceived, people actually range from very optimistic to very pessimistic, with most falling somewhere between.

Interestingly, research exists (reviewed later in the chapter) that suggests that optimism and pessimism might not represent opposite poles of the same dimension, but actually might reflect two separate but related constructs. Use of separate terms in this context reflects more than a verbal convenience, but even here people vary in how optimistic or pessimistic they are. For now, we will treat optimism and pessimism as bipolar end points on a single dimension. This is how most of the researchers treated optimism and pessimism in the work that we review.

Effects of Optimism on Physical Health

Early Research on Optimism

Initial research on the benefits of optimism focused on relationships between optimism and subjective well-being. This research clearly demonstrated that optimists experience less distress when faced with various stressors, such as undergoing coronary artery bypass surgery (e.g., Scheier et al., 1989) or being diagnosed with cancer (e.g., Carver et al., 1993). Over time, researchers became increasingly interested in whether optimism might also predict better physical health outcomes. Early research on optimism and physical health focused on the effects of optimism on short-term health outcomes, as the main motivation was simply to test as efficiently as possible whether such relationships exist. These studies consistently found that optimists have better physical health than pessimists.

An example of this type of short-term health outcome is rehospitalization after coronary artery bypass surgery. Rehospitalization after bypass surgery is fairly common for a variety of reasons (e.g., wound infection, myocardial infarction, need for subsequent surgery), but it is quite costly in terms of healthcare expenditures and patients' well-being. Scheier et al. (1999) investigated whether optimists might respond better to surgery and be less likely than pessimists to need rehospitalization. To test this idea, they administered a measure of optimism to over 300 men and women who were scheduled to undergo bypass surgery. Six months later, they found that optimists were less likely to have been rehospitalized.

Larger Epidemiological Studies

More recently, a number of epidemiological studies have substantially extended the research linking optimism and physical health. Typically, these studies enroll samples of initially healthy participants and measure the incidence (number of new cases) of disease over many years. Long periods of follow-up time are necessary, as many diseases, such as cardiovascular disease and cancer, take years and even decades to develop. Furthermore, because most people do not develop the disease, studies have to recruit large numbers of participants in order to have adequate statistical power to detect associations. Participant numbers in these studies have ranged from the 1,000s to upward of 100,000.

One of the largest epidemiological studies to investigate the effects of optimism was conducted by Tindle et al. (2009). They administered a measure of optimism to over 95,000 initially healthy Caucasian and African American women. Eight years later, they found that optimists were less likely to have developed coronary heart disease and were less likely to have died from any cause, as compared with pessimists.

Pathways to Cardiovascular Disease

Research on disease incidence and mortality strongly suggests that optimism plays a role in susceptibility to cardiovascular diseases, such as coronary heart disease and stroke. Research on various biological markers further supports this idea, demonstrating that optimism is related to markers that may represent physiological pathways to the development of future cardiovascular diseases.

One physiological pathway implicated in a number of cardiovascular diseases is atherosclerosis, or the development of plaque, which narrows and hardens the arteries. Atherosclerosis is a progressive condition, normally increasing with age. Matthews et al. (2004) investigated whether optimism might slow this progression. They followed a sample of middle-aged women for 10–13 years, measuring the intima–media thickness of the carotid artery as a metric of atherosclerosis. They found that optimists had a slower progression of atherosclerosis. In fact, the individuals highest in optimism showed almost no progression of atherosclerosis at all.

Another important risk factor for cardiovascular disease is high blood pressure, which can damage the heart and the arteries over time. Several studies have shown that pessimists have higher systolic and diastolic blood pressure throughout the day (e.g., Räikkönen & Matthews, 2008) and tend to have larger blood pressure responses to stressors (e.g., Terrill, Ruiz, & Garofalo, 2010).

In addition to atherosclerosis and blood pressure, optimism has also been linked to a number of other risk factors for cardiovascular disease such as obesity, cholesterol, and triglyceride levels (Boehm, Williams, Rimm, Ryff, & Kubzansky, 2013b), as well as metabolic syndrome, which is a cluster of conditions (i.e., high blood pressure, high blood sugar levels, excess abdominal fat, and high cholesterol levels) that put an individual at risk for cardiovascular diseases and diabetes (Cohen, Panguluri, Na, & Whooley, 2010).

Non-cardiovascular Disease Outcomes and Immune Function

Although optimism has shown strong associations with cardiovascular outcomes, evidence linking optimism to other diseases, particularly cancer and HIV, has been more equivocal. Some studies have found that optimism is related to lower mortality in patients with cancer (Allison, Guichard, & Gilain, 2000) and slower disease progression in patients with HIV (e.g., Ironson et al., 2005). However, other studies have not found that optimism predicts cancer and HIV-related outcomes (e.g., Tindle et al., 2009), and a recent meta-analysis failed to find a significant association between optimism and cancer (Rasmussen, Scheier, & Greenhouse, 2009).

The inconsistent relationship between optimism and cancer/HIV outcomes may be partially attributable to the nuanced relationship between optimism and various aspects of immunity. The immune system consists of multiple interacting components, and psychological factors can have positive and negative effects on different aspects of the immune system. These effects can further be moderated by specific contexts and situations.

In terms of the positive effects of optimism on immune outcomes, multiple studies have demonstrated that optimism is associated with lower levels of circulating pro-inflammatory cytokines and indicators of the inflammatory process, such as interleukin-6, homocysteine, fibrinogen, and intercellular adhesion molecule 1 (e.g., Roy et al., 2010). High levels of circulating inflammatory markers are considered an index of systemic or chronic low-grade inflammation. Such systemic inflammation is thought to be involved in a number of diseases, including cardiovascular disease, arthritis, and diabetes (e.g., Libby & Theroux, 2005). Thus, chronic inflammation may be another biological pathway by which optimism influences the development and progression of cardiovascular diseases, as well as other diseases.

In contrast to the effects on inflammation, optimism has shown more qualified relationships with indicators of cell-mediated immunity (e.g., circulating levels of T cells, natural killer cell cytotoxicity, delayed-type hypersensitivity skin test). Cell-mediated immunity is particularly important for combating viruses that enter human cells, such as the HIV virus, and for the removal of cells that have become cancerous. Research suggests that optimism may be related to better cell-mediated immunity under some conditions, namely, when individuals face brief, controllable stressors. Optimism may be related to diminished levels of cell-mediated immunity, though, when people face more prolonged and uncontrollable stressors (for a review, see Segerstrom, 2005).

One of the first studies to identify this qualified relationship was conducted by Cohen et al. (1999). They followed a sample of young women for 3 months, assessing the experience of stressors weekly. Among women who experienced only a brief stressor, lasting 1 week or less, optimism was associated with higher levels of circulating T cells. The opposite pattern was found among women who experienced a stressor for multiple weeks. For these women, optimism was associated with lower levels of circulating T cells and lower natural killer cell cytotoxicity.

Explanations for this pattern have varied. Some authors have argued that optimists are particularly vulnerable to disappointment when their positive expectations are disconfirmed (Tennen & Affleck, 1987). This disappointment could then explain the negative relationship between optimism and immunity when stressors prove difficult to resolve or control (e.g., Cohen et al., 1999). Although possible, this explanation is inconsistent with a large body of research suggesting that optimists experience less distress when they encounter negative outcomes, for example, when they are diagnosed with breast cancer (Carver et al., 1993).

Segerstrom and colleagues proposed an alternative explanation for the negative relationship between optimism and immune response in some circumstances (Segerstrom, Castañeda, & Spencer, 2003). Specifically, they argued that optimists are more likely to engage actively in trying to resolve stressors and to persist in these efforts despite difficulties. During a prolonged stressor, this persistence strategy may have costs reflected in a sustained physiological stress response and reduced cell-mediated immunity. However, this strategy likely has long-term benefits in terms of eventual stressor resolution. Pessimists, who are more likely to give up dealing with a stressor, may not incur these physiological costs during a prolonged stressor, but they may also be less likely to deal with the stressor adaptively.

Subsequent research has generally supported this second explanation (Segerstrom et al., 2003). For example, Solberg Nes, Segerstrom, and Sephton (2005) gave optimists a difficult task while monitoring physiological indicators of stress. Optimists were more likely to persist at the task, but this persistence was associated with higher levels of cortisol and greater skin conductance.

If the negative effects of optimism on immunity are attributable to greater persistence, more research will still be needed to determine whether this association explains the inconsistent relationship between optimism and cancer/HIV outcomes. Similarly, more research will be needed to demonstrate which of the multiple plausible physiological pathways actually underlie the effect of optimism on cardiovascular outcomes. In the future, research will likely need to move beyond simply demonstrating associations between optimism and physical heath. Instead, research should focus on documenting how optimism influences specific physiological pathways, which ultimately result in the development and progression of specific diseases.

Another fruitful area for future research will be to investigate the effect of optimism on a wider array of physical health outcomes. The effects of optimism on various physiological pathways (e.g., metabolic syndrome, inflammatory markers) strongly indicate that optimism contributes to other diseases. New research is beginning to support this idea. Initial research has found that optimism may play a role in diabetes management, being associated with better glycemic control among individuals with diabetes (Brody, Kogan, Murry, Chen, & Brown, 2008). Additionally, studies have shown that optimism is related to several pregnancy-related outcomes, such as birthweight and gestational age (Lobel, DeVincent, Kaminer, & Meyer, 2000), as well as in vitro fertilization success (Bleil et al., 2012).

Remaining Questions

Psychological and Behavioral Mechanisms

We have discussed several physiological pathways that might underlie the relationship between optimism and specific disease outcomes. What these physiological pathways do not explain is how optimism exerts physiological effects in the first place. In this regard, optimism has a number of effects on behavioral and psychological factors, which may account for the relationship between optimism and health. However, little research has actually tested whether these effects mediate the association between optimism and health.

One of the most likely reasons optimists experience better health is they engage in more positive health behaviors, while pessimists tend to engage in health-damaging behaviors. A number of studies have shown that optimists have a better diet (e.g., more fruits and vegetables), are more physically active, and are more likely to consume alcohol in moderation (e.g., Steptoe, Wright, Kunz-Ebrecht, & Iliffe, 2006). In contrast, pessimists are more likely to be smokers (e.g., Steptoe et al., 2006) and to suffer from substance abuse problems (e.g., Carvajal, Garner, & Evans, 1998). Few studies have formally tested whether these health behaviors mediate the relationship between optimism and physical health, but some evidence suggests that these health behaviors have physiological effects. Boehm, Williams, Rimm, Ryff, and Kubzansky (2013a) found that the tendency of optimists to eat a better diet and smoke less had a beneficial impact on their serum levels of antioxidants (see also Steptoe et al., 2006; Tindle et al., 2009).

The tendency of optimists to engage in proactive efforts to maintain their health is thought to be a manifestation of a broader tendency to engage in active, approach-oriented coping strategies. A number of studies have found that optimists utilize coping strategies that directly address the stressor (e.g., seeking information about the problem) or directly alter cognitions about the stressor (e.g., positively reframing a stressful situation). Pessimists, in contrast, utilize avoidance coping strategies such as denying that a problem exists (for a meta-analytic review of the different coping strategies used by optimists and pessimists, see Solberg Nes & Segerstrom, 2006).

These coping strategies have a pervasive influence on how optimists and pessimists experience stressors. As mentioned previously, optimists experience less distress and higher levels of subjective well-being when confronted with a variety of stressors, perhaps especially so for those that are acute in nature. Decades of research have shown that stress impairs physical health, while subjective well-being is associated with better health and longevity (e.g., Diener & Chan, 2011). The tendency of optimists to engage in adaptive methods of coping that minimize distress may ultimately contribute to their physical health as well.

Another potential mechanism concerns the effects of optimism on social relationships. Optimism is associated with greater social network size and to ties with others that cross age, educational, and racial boundaries (Andersson, 2012). Optimists are also more satisfied with their relationships and report greater social support than pessimists (e.g., Assad, Donnellan, & Conger, 2007). As both social network size and perceived social support predict physical health (for review see Cohen, 2004), these factors may also contribute to the relationship between optimism and health.

Dimensionality of Optimism

Throughout this chapter, we have been referring to optimism as a single bipolar dimension ranging from optimism to pessimism. Many people working in the field construe optimism and pessimism in this fashion and analyze their studies accordingly, but as noted earlier on, researchers have also explored the possibility that optimism and pessimism may be somewhat distinct constructs. This view is consistent with the fact that factor analysis of generalized optimism scales often yields two separate components—one measuring expectancies for positive outcomes and one measuring expectancies for negative outcomes. Psychometrically, it remains unclear whether the distinction between optimism and pessimism is meaningful or merely an artifact of how optimism is measured.

Recent research on physical health has contributed to the discussion of dimensionality, suggesting that when analyzed separately, optimism and pessimism may have differential effects on physical health outcomes. In fact, most of the research linking optimism to inflammatory outcomes suggests that it is mainly pessimism driving this effect, not optimism (e.g., Roy et al., 2010). Pessimism was also found to be a stronger predictor than optimism of in vitro fertilization success (Bleil et al., 2012). These findings raise the possibility that the detrimental impact of pessimism on health is stronger than any salutary effects of optimism, but much more research is needed to answer this question definitively.

Conclusion

A substantial body of research suggests that optimism has a pervasive influence on physical health. The effects of optimism have been observed on short-term health outcomes, such as rehospitalization after surgery, and long-term health outcomes, such as mortality. This research clearly demonstrates that optimism is related to the development and progression of cardiovascular diseases, as well as a number of plausible physiological pathways to the development of these diseases. Optimism has shown a less consistent relationship with HIV/cancer outcomes, which may be due to the qualified relationship between optimism and immunity.

More recent research has begun to investigate a wider array of physical health outcomes as well. Several questions remain concerning the relationship between optimism and physical health, including what psychological and behavioral factors allow optimism to create health-related physiological responses, as well as how best to conceptualize optimism. As time passes, the answers to these and other questions are likely to be resolved. Research on optimism and physical health has flourished for decades. There is no reason to expect that the tide of research will recede anytime soon.

Acknowledgment

Preparation of this chapter was facilitated by support from the National Center for Complementary and Alternative Medicine (AT007262) and the Templeton Foundation. We would like to thank Nabila Fahin Jahan for reading an earlier draft of the paper.

Author Biographies

Maria G. Mens is a graduate student at Carnegie Mellon University. She is interested in the health effects of optimism and pessimism and the processes that underlie a sense of purpose in life and the links between purpose in life and well-being.

Michael F. Scheier is a professor of psychology at Carnegie Mellon University. His work falls at the intersection of personality, social, and health psychology. He does research on the associations between personality and health, including optimism and pessimism, as well as work on coping with stress, adjustment to chronic disease, and goal adjustment processes and well-being.

Charles S. Carver is a professor of psychology at the University of Miami. His work at various times has addressed topics in personality, social psychology, health psychology, and experimental psychopathology. His current research mostly examines individual differences in impulsiveness versus constraint, how those differences are produced, and what their consequences are for effective self-regulation.

Patient Adherence

Kelly B. Haskard-Zolnierek and Briana Cobos

Department of Psychology, Texas State University, San Marcos, TX, USA

Introduction and Definition

The primary factor in achieving optimal health and the effectiveness of a medical treatment plan is determined by the patient's adherence toward their treatment regimen. Adherence is defined as the extent to which a patient's behavior corresponds with the agreed-upon treatment guidelines set forth by a healthcare provider. The terms "compliance" and "persistence" are essentially synonymous with the term "adherence"; however, adherence is preferred because compliance suggests that the patient is passively obeying the guidelines of the medical provider. Persistence describes the degree to which the patient follows the guidelines or behavior modifications recommended by a provider for a predetermined duration of time. Adherence includes various health-related behaviors such as taking medication, filling prescriptions, attending follow-up appointments, self-management of a chronic and/or acute disease, receiving immunizations, and/or modifying one's lifestyle behaviors. These behaviors are intended to provide optimal health when followed.

The terms "adherence" and "concordance" similarly describe a situation in which a treatment plan is negotiated and collectively determined between the patient and physician. The primary objective of concordance is to establish a therapeutic relationship between the patient and physician. However, "adherence" is the preferred term because it suggests an agreement between a patient and a healthcare provider, that is, negotiated, planned, and discussed with a collaborative and therapeutic effort to determine a treatment plan and/or behavior modifications aimed at providing optimal health for the patient.

In contrast, nonadherence constitutes the patient failing to follow the recommended treatment regimen. An individual can be nonadherent by not taking their medication, discontinuing their medications before the recommended time set forth by their healthcare provider, not taking their medication dosage correctly, and/or disregarding certain behavior modifications that are part of the treatment plan. Furthermore, an individual can be nonadherent by not filling a prescription, which is referred to as "nonfulfillment."

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

Intentional nonadherence is another form of nonadherence in which an individual actively decides not to follow a healthcare provider's treatment recommendations or guidelines. Within this type of nonadherence, the individual usually takes an active approach in deciding whether to adhere or not adhere to their treatment plan. Individuals' beliefs and knowledge of their health condition and treatment regimen play an important role in their decision. For example, the individual may actively decide to discontinue medication due to aversive symptoms subsiding.

Alternatively, an individual can be unintentionally nonadherent toward treatment. This type of nonadherence can occur when the individual forgets to take a medication or lacks knowledge or understanding about how to take medication or adhere to a treatment plan. This has less to do with the individual's belief or knowledge. Instead, this type of nonadherence is due to unforeseen circumstances, such as the complexity of a treatment plan causing the individual to forget certain behavior modifications or medication dosages. Therefore, nonadherence could ultimately lead the individual to not experience the benefits of their treatment plan and can further worsen an individual's well-being.

Rates of Nonadherence

Rates of nonadherence vary depending on regimen, disease, disease category (i.e., acute versus chronic), and other factors. On average, rates of nonadherence range from 25 to 50%, with greater rates of nonadherence in lifestyle change regimens (e.g., making major dietary changes or maintaining a consistent exercise regimen). Rates of nonadherence tend to be higher for more complex regimens such as those that require multiple doses per day or have more complicated dosing instructions, such as associated dietary restrictions. In addition, rates of nonadherence to chronic diseases can be greater due to the long-term nature of these regimens as compared with adherence to short-term regimens for acute diseases. A meta-analysis of 569 studies published from 1948 through 1998 reported the highest rates of adherence in HIV and cancer and the lowest rates in pulmonary diseases, diabetes, and sleep disorders (DiMatteo, 2004a). Other meta-analytic work has shown that across 116 studies, patients with serious illnesses such as end-stage renal disease or heart disease who are in poorer health (either objectively or according to self-ratings) are less adherent (DiMatteo, Haskard, & Williams, 2007). These variations in rates of adherence across diseases could be due to the complex nature of some disease regimens, other factors such as adverse side effects, and other restrictions on one's activities and lifestyle. This nonadherence could also be due to personal factors such as depression, cognitive deficits, and pessimism that can accompany serious illnesses.

Consequences of Nonadherence

There are various causes of nonadherence to treatment regimens. For example, contributing factors toward nonadherence can include the following: adverse medication side effects, a long duration of treatment, frequency of expected intake of medication, or the complexity of the treatment. Nonadherence is an important healthcare issue because of the associated financial, health, and other consequences. Patients who are nonadherent are more likely to utilize healthcare resources, thus increasing healthcare costs.

The economic burden of nonadherence in the United States is estimated to be between \$290 and \$300 billion dollars each year. This burden is caused by individuals who are unable to modify health or lifestyle behaviors, patients unable to attend medical visits, secondary illnesses that arise due to uncontrolled chronic health conditions, and unnecessary hospitalizations or emergency room visits because of uncontrolled health conditions (DiMatteo, Haskard Zolnierek, & Martin, 2012). Nonadherence could also cause either additional economic burden in the US workforce by loss of productivity at work or an increased rate of employee absenteeism. Nonadherence has been associated with higher costs in various diseases, wherein patients face greater annual healthcare costs because of their nonadherence (Iuga & McGuire, 2014).

Conversely, increased rates of adherence provide economic benefits. An increase in adherence rates would reduce the use and cost of healthcare resources needed during relapses, emergencies, and/or hospitalizations that could have been prevented by the patient following their treatment regimen. Therefore, nonadherence represents a serious issue for healthcare professionals, patients, and the healthcare industry, in which optimal health outcomes are exclusively determined by the individual's adherence toward a treatment regimen.

Nonadherence toward a treatment regimen can have further adverse effects on an individual's health outcomes by causing additional health complications or secondary illnesses. The consequences of nonadherence on an individual's health vary based on the type of illness and the treatment regimen. For example, types of health conditions that require strict adherence toward their treatment regimen and medication include kidney transplantation, end-stage renal disease, and HIV. The primary cause of kidney transplant rejection for patients is nonadherence toward their immunosuppressant medication (Cukor, Rosenthal, Jindal, Brown, & Kimmel, 2009). Individuals who are nonadherent toward their medication are at an increased risk of rejecting their organ or experiencing kidney failure. Furthermore, for individuals with end-stage renal disease, adherence to hemodialysis regimens is crucial in order to decrease the individual's risk of earlier mortality or further complications. Individuals diagnosed with HIV face an increased rate of drug resistance to their antiretroviral medication if they are not strictly adherent toward their medication regimen as well. As a result, nonadherence causes an increased risk of mortality and future adverse effects such as faster progression of the virus.

Health conditions that are not solely dependent on medication have been shown to have suboptimal adherence rates. For example, treatment regimens for individuals with diabetes or primary hypertension usually include a complex treatment regimen that includes medication, as well as diet and lifestyle modifications in order to obtain optimal health. Nonadherence to treatment regimens for these health conditions can have an adverse effect on an individual's health over time. Individuals diagnosed with diabetes and are nonadherent can experience adverse complications such as ketoacidosis (diabetic coma), stroke, kidney disease, blindness, damage to the nerves, the development of heart disease, and an increased risk of early mortality. Furthermore, individuals diagnosed with primary hypertension have a treatment plan that usually consists of antihypertensive medication as well as lifestyle change. Nonadherence to antihypertensive medication and behavior change can lead to the development of heart disease, kidney damage, congestive heart failure, and stroke. Therefore, adherence to the agreed-upon treatment plan is critical to decrease an individual's risk of developing secondary illnesses or adverse complications and to increase the likelihood of optimal health outcomes.

Another consequence of nonadherence is erosion of the physician–patient relationship. Ideally, a patient and physician work together in a collaborative manner using open communication to reach the common goal of good health outcomes for the patient. If a patient does not admit to struggles with adherence, it may be difficult for the physician to trust the patient, and the quality of their relationship can be negatively affected.

Measurements of Adherence

There are multiple methods of measuring adherence to treatment, but unfortunately no "gold standard" measurement method exists. Numerous measurement approaches can be used based on the setting and context of the measurement (e.g., clinical settings versus research contexts). Measurement approaches are typically grouped into two categories: direct and indirect methods. Direct methods include direct observation of patients taking their medication and measurement of levels of the medication or metabolite in blood or urine. Direct approaches can be very accurate but may also be more invasive, expensive, and time consuming. Indirect measures include patient self-reports either via interview or questionnaire, family member reports, pill counts, pharmacy refill records, or electronic monitors (e.g., measurement via special pill bottle caps such as MEMScap™ that record the time and date each time a pill bottle is opened). Each of these measures has both benefits and drawbacks. Pharmacy refill records, for example, can be inaccurate because they do not directly show ingestion of medication or behavior such as incorrect timing of doses. Electronic monitors not only can be very accurate but also are a more expensive way to measure adherence and also do not indicate ingestion of medication. Although self-report measures can be subject to biases in memory or the desire to present oneself in the best possible light, they do tend to be the simplest, most common, and least expensive approach to adherence measurement. In general, a multimethod approach to measuring adherence is recommended.

Predictors of Nonadherence

Researchers have attempted to understand the factors that influence patient nonadherence and the factors that may promote adherence to treatment. Predictors of nonadherence have been grouped into several categories: patient-related factors, regimen-related factors, provider–patient interaction level factors, and healthcare system-related factors (Osterberg & Blaschke, 2005).

Patient-related factors that predict nonadherence include such elements as mental health, beliefs and attitudes, understanding, motivation, and social support. Patients with poor mental health (particularly depression) tend to be less adherent. Meta-analytic work reveals a strong relationship between nonadherence and depression across 31 studies of patients with chronic diseases (Grenard et al., 2011). This association may be due to a pessimistic attitude, forgetfulness, or lack of motivation that often accompanies depression. Furthermore, patients who do not believe in the benefit of their regimen or have negative attitudes toward it may be less adherent. Such patients make a conscious choice not to follow their treatment regimen, as they are not convinced that it will help them or alleviate their symptoms. In addition, patients who do not understand their regimen or how to follow it correctly may be unintentionally nonadherent. When patients first receive instructions on how to take medications, they may not understand the instructions due to poor health literacy (i.e., an inability or struggle to understand and process health-related information). Also, patients who are lacking in social support, particularly that who comes from a loving family, may also be less adherent (DiMatteo, 2004b). A patient's support network may play many roles in promoting adherence, including giving reminders to the patient, encouraging the patient in their health-related goals, and providing tangible support such as driving the patient to medical appointments.

There are several regimen-related factors that may be associated with nonadherence. These include side effects, frequency of dosing, and complexity of the regimen. A review of 61 studies reported that in diseases such as diabetes and HIV, greater dose frequency and more complex regimens (e.g., more medications, special requirements associated with medication taking) are associated with poorer adherence (Ingersoll & Cohen, 2008).

Physician–patient communication is also associated with patient adherence. A meta-analysis of 106 studies (Zolnierek & DiMatteo, 2009) reported that patients of physicians who communicated effectively had 19% higher adherence. Mutual trust, open communication, sharing in the process of making medical decisions, and partnership are all interpersonal factors in the medical provider–patient relationship that are central to achievement of patient adherence.

Healthcare system factors may also play a role in nonadherence. Numerous studies have indicated that the cost of medications may predict nonadherence, as patients delay refills or take their medication less frequently due to cost issues (Briesacher, Gurwitz, & Soumerai, 2007).

The information–motivation–strategy model has been proposed to explain three basic factors that are central to achievement of adherence (DiMatteo et al., 2012). First, patients do not understand their regimen and how to follow it. They lack the information and understanding needed to adhere. Communication with their physician may have been ineffective, or they may have difficulty understanding the regimen due to poor health literacy or forgetting the instructions they were given. Second, patients may not be motivated and committed to adherence to their treatment regimen. This lack of motivation or commitment could be due to their beliefs about the treatment regimen or their negative attitudes about it or to a lack of support that encourages the patient’s adherence. Third, patients may lack the resources and strategies to support adherence. These strategies could include tools to help them remember to take their medication or a plan for getting to the pharmacy for refills. Understanding the predictors of adherence is helpful in designing interventions to improve adherence.

Interventions to Improve Adherence

As discussed, adherence is influenced by multiple factors, and researchers have proposed a variety of interventions in an effort to reduce rates of nonadherence. Interventions have been proposed on multiple levels, including patient, provider, and system-related levels. For example, a policy-level intervention might involve reducing out-of-pocket costs of medications. Unfortunately, fewer than half of published interventions have been found to improve adherence (Haynes, Ackloo, Sahota, McDonald, & Yao, 2008; van Dulmen et al., 2007). Evidence suggests that multifaceted interventions that address multiple barriers to adherence may be most effective. Strategies that have been found to be effective in multicomponent interventions include more intensive communication with and counseling of patients, providing reminders, and providing closer follow-up (Haynes et al., 2008). A recent review of 182 randomized clinical trials of interventions to improve medication adherence reported that the most successful interventions were complex and personalized and involved several approaches to improving adherence (Nieuwlaat et al., 2014). Examples of these approaches included increased support from family members or personalized care, education, and communication from healthcare providers such as pharmacists.

Educational interventions with monitoring, support, and follow-up were most strongly associated with improvements in adherence in a systematic review (Viswanathan et al., 2012). These authors compared interventions in various categories of chronic disease and stratified by patient, provider, and system-level interventions. Specific examples of successful interventions included asthma self-management and case management interventions for depression

(Viswanathan et al., 2012). Other techniques that have been successful include reducing daily dosing frequency and providing reminders in the form of alarms or alerts, which can be helpful with the unintentional aspect of nonadherence.

In promoting patient adherence, it will continue to be important to be aware of and address barriers at the patient, provider, and system levels. In addition, future research should continue to study the most successful components of interventions and improve these interventions to enhance adherence and health outcomes.

Author Biographies

Kelly B. Haskard-Zolnierek is an associate professor of psychology at Texas State University. Her research involves two main areas: patients' adherence to medical recommendations and medical visit communication in the provider–patient relationship. Her current research involves evaluating mobile health interventions to improve patient adherence. Dr. Haskard-Zolnierek has coauthored a book on patient adherence, published in 2010 by Oxford University Press, and a 2009 meta-analysis of the relationship between physician communication skills and patient adherence.

Briana Cobos completed her master of arts degree at Texas State University in psychological research. Her general research area is in health psychology. Ms. Cobos' research interests include predictors of nonadherence in individuals diagnosed with both a mental health condition and a chronic illness. She has coauthored various papers with a focus in health psychology and mental health conditions.

Patient Satisfaction

Summer L. Williams[1] and Tricia A. Miller[2]

[1]Department of Psychology, Westfield State University, Westfield, MA, USA
[2]Department of Psychology, University of California, Riverside, CA, USA

Introduction

The field of patient satisfaction is extensive as an area of empirical research and covers many constructs and facets of the patient experience in medical care. Literature reviews and meta-analytic studies have explored patient satisfaction in relation to a multitude of external variables such as patient health outcomes and domains within the clinical care context. Many aspects of healthcare delivery have focused on the patient as a consumer of health services and likewise an essential evaluator of the quality of that healthcare experience, wherein the satisfaction of the patient becomes a critical element in the quest for improved healthcare delivery and health outcomes. Patients' perceptions of care have become increasingly more important and valued as key indicators of outcome measures. Health researchers are keen to the importance of patient satisfaction, and thus they are engaged in ongoing efforts toward quality patient satisfaction measurement and translating patient satisfaction findings to inform health policy and make system-level changes.

Assessment and Measurement of Patient Satisfaction

Patient satisfaction as a healthcare outcome is typically measured via self-report, in which patients report their preferences, expectations, and level of satisfaction with the medical care they received within a variety of domains, including access to and cost of care, empathy, competence, attention and information given by the provider, continuity of care, attention to psychosocial issues by the provider, and overall quality of care (Hall & Dornan, 1988).

Typically patients report their perceptions of care immediately after their visit or some time later by phone, mail, online survey, or an in-person interview. One of the most widely used measures of patient satisfaction is the Patient Satisfaction Questionnaire, developed by the

General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

RAND corporation, to assess general or global satisfaction with care as well as patient satisfaction with a number of individual domains such as technical quality, interpersonal manner, communication, financial aspects, time spent with doctor, and accessibility and convenience (Ware, Snyder, & Wright, 1976). This 50-item measure has been shortened in subsequent versions to include 18 items, known as the Patient Satisfaction Questionnaire-18 (PSQ-18), for ease of use in healthcare settings (Marshall & Hays, 1994).

Later measures of patient satisfaction extended to include more detailed aspects of the medical interview and include the Medical Interview Satisfaction Scale (MISS-29) and refinements of it, developed for use in British general practice consultations (Meakin & Weinman, 2002; Wolf, Putnam, James, & Stiles, 1978). One of the most recent and widely used measures of patient satisfaction is the Consumer Assessment of Healthcare Providers and Systems—Clinician and Group Surveys (CG-CAHPS) developed by Dyer, Sorra, Smith, Cleary, and Hays (2012). This measure extends questions of patient satisfaction beyond the clinician level and into the healthcare system level by looking at aspects of care such as access.

One of the major early concerns with assessing patient satisfaction was the lack of standardization across studies in its measurement, with some measures yielding low reliability and the validity of the measuring instruments generally unknown. Additional challenges to measuring patient satisfaction include recent concerns over whether patients have the expertise, medical knowledge, and health literacy to provide an accurate assessment of their medical care (Manary, Boulding, Staelin, & Glickman, 2013) and questions as to the accuracy of patients' recall of their medical experiences (Aharony & Strasser, 1993).

Perhaps though one of the toughest challenges to measuring patient satisfaction has been concern over the high reported levels of satisfaction across studies (Williams, Coyle, & Healy, 1998). The concern lies in whether patients are accurately reporting their levels of satisfaction and, if so, what factors might be driving such high satisfaction scores across studies. Social psychological concepts have been applied to understanding high satisfaction scores. Cognitive consistency theory asserts that patients are likely to report satisfaction with their care as a way of justifying the time and effort they have spent seeking that care (LeVois, Nguyen, & Attkisson, 1981). Patients especially prone to this bias are those who continue their care despite adverse situations in the healthcare setting. It may be that dissatisfaction with care is only reported when the patient experiences an extreme negative event (Williams, 1994).

Key Research Findings in Patient Satisfaction

Due to the sheer number of empirical studies on patient satisfaction, the literature and findings can often be unclear. Meta-analytic studies within the area of patient satisfaction have become paramount in cutting through the diffuse nature of the literature in order to document the important role that patient satisfaction plays in the medical care forum and in the quality of care provided.

Early research on patient satisfaction suggested that it may be hard to discern patients' true attitudes toward their care because patients often fear unfavorable treatment in the future if their provider learns that they expressed dissatisfaction (e.g., through self-report) (Ley, 1972). In one of the first meta-analytic studies conducted addressing patient satisfaction, Hall and Dornan (1988) uncovered a bit of reluctance on the part of patients to evaluate their healthcare providers and to report on satisfaction with their medical care. The authors determined that patients' reluctance to report on satisfaction was related to patients' viewing their care as subpar in some regard yet not wanting to criticize their providers. Of the 221 studies included in the meta-analysis, patients were overall more satisfied with their care when their physicians were still in training. This finding begs the question, what is it about physicians in training that makes their patients more satisfied? It is within the physician–patient relationship that the research has focused on correlates of patient satisfaction to gain a better understanding of the mediators involved; one key mediator of patient satisfaction is provider–patient communication.

The importance of physician–patient communication skills is now, more than ever, a central component in medical school curricula and residency training programs thanks to a multitude of research demonstrating that beneficial patient outcomes, including patient satisfaction, are linked to good communication skills in providers (Williams, Weinman, & Dale, 1998). Aspects of physician communication such as instrumental communication (i.e., task-directed skill) and discussion of psychosocial issues (i.e., socio-emotional communication) with the patient have been found to be most related to and predictive of patient satisfaction (Inui, Carter, Kukull, & Haigh, 1982; Roter, Hall, & Katz, 1987). Other communication barriers such as lack of warmth and friendliness from the provider, failure to take the patient's concerns into account, unclear expectations and explanations, and ambiguous diagnosis and causation of illness have been found to decrease satisfaction (Jackson, Chamberlin, & Kroenke, 2001).

Additionally, providers who use medical jargon or fail to consider a patient's level of health literacy may also be inadvertently contributing to their patient's decreased satisfaction (Roter et al., 1997). Providers who take the time to educate their patients in a comprehensible manner will likely result in many positive clinical outcomes, including not only patient satisfaction but also reduced patient anxiety, patients' enhanced ability to cope with symptoms, enhanced recovery after surgery, and increased patient adherence (Sitzia & Wood, 1997). It stands to reason that providers in training, who are practicing, developing, and honing their communication skills that involve the aforementioned aspects of communication, would produce more satisfied patients.

However, provider communication alone does not speak to the entire relationship between aspects of the care visit and patient satisfaction. Other studies have linked increased patient satisfaction to the sheer amount of time spent in the clinical encounter, specifically during the physical exam as opposed to the history-taking portion of the visit (Robbins et al., 1993). These physician practice behaviors have an impact on patient satisfaction that goes beyond just how "good" of a communicator the provider is. Patients have entered into more collaborative partnerships with their providers and expect discussion of health education and treatment effects, among other information on which they might base their future health behaviors and decisions (Robbins et al., 1993).

Other Correlates of Patient Satisfaction

Patient adherence to treatment guidelines is one health outcome that has been positively correlated with satisfaction (Jha, Orav, Zheng, & Epstein, 2008). This makes sense: a patient is more likely to adhere when a common understanding of treatment and self-care expectations has been reached, and this association likely goes back to effective provider communication and establishment of collaboration with the patient (Manary et al., 2013).

Other researchers have explored various patient demographics and health status (i.e., age, gender, socioeconomic, mental health, etc.) and their possible influence on a patient's satisfaction. The most consistent determinant characteristic is age, such that older patients are generally more satisfied than younger patients (Hall & Dornan, 1990; Zahr, William, & El-Hadad, 1991). Part of the reasoning behind this finding may hinge upon the expectations of older and younger patients. Cartwright and Anderson (1981) found that older patients expect less information from their physicians. With the advent of the Internet and accessibility of medical information, younger patients today might expect more information from their providers especially when dealing with cancer; younger patients may even be going into the interactions with more knowledge than older patients (Norum, Grev, Moen, Balteskard, & Holthe, 2003). A mediator of this finding might be the education level of the patient. Greater satisfaction is associated with lower levels of education (Hall & Dornan, 1990). On the other hand, demographics such as sex and race seem to reveal mixed results in relation to patient satisfaction. Pascoe and Attkisson (1983) demonstrated that US Whites, as a whole, tend to be more satisfied with their care than non-Whites, yet the authors indicate that the interaction of ethnicity and socioeconomic status can confuse the results. Hall, Irish, Roter, Ehrlich, and Miller (1994) reported that within routine medical care visits, lower satisfaction was associated with younger female physicians and the least amount of satisfaction was found among male patients who were examined by younger female physicians. Other findings show no significant relation with sex and race (Marple, Lucey, Kroenke, Wilder, & Lucas, 1997).

It is clear that the relationship between demographic variables and patient satisfaction is complex. Social and cultural issues in healthcare have pointed to the need for further examination of the various social inequalities involved in patient care and the recognition that patient distrust of providers, discrimination, mental health disparities, diversity in the clinical encounter, limited English proficiency, stereotypes, and bias operate within the bounds of the clinical encounter and very likely affect patient satisfaction in a multitude of ways (Smedley, Stith, & Nelson, 2003).

Emerging as another patient factor related to satisfaction is the health status, both mental and physical, of the patient. Jackson et al. (2001) report various studies that have shown psychological distress, depression, and personality disorders to be associated with lower levels of satisfaction. Often these psychological factors are comorbid with chronic physical illness (Linn & Greenfield, 1982). Providers may be quite unaware of the expectations patients bring with them to their visits and may likewise not be comfortable addressing patients' psychosocial concerns in general (Jackson et al., 2001; Roter et al., 1987).

Future Directions in the Patient Satisfaction Literature

Although quantitative studies have provided much in the way of concrete correlates and outcomes in the field of patient satisfaction research, there is an ever-pressing need for more qualitative research as well. In their review of the literature, Aharony and Strasser (1993) point to the void in studies looking at patients' qualitative comments about their care. The authors suggest that there is still much to be done in content analyzing the written remarks of patients and those verbalized during interviews and focus groups. Such qualitative research might bring about a better understanding of the cognitive and affective processes that a patient moves through in evaluating his/her care, as well as allowing for more ethnographically accurate and representative data on the patient experience (Aharony & Strasser, 1993).

There are also ways in which the methodology of patient satisfaction research could be improved. Moving from correlational designs to those that would allow for more methodological and statistical control is essential. The research paradigm should progress into theory-driven hypotheses, larger sample sizes, and factor analysis and regression models that would examine the direct and indirect impact of dependent variables (e.g., overall satisfaction; Aharony & Strasser, 1993).

To address the concern over patients being inaccurate reporters of their satisfaction, survey instruments should focus on the patient–provider interactions, as well as on the overall care team of the patient, and evaluate all interactions within that framework. This is where patient-reported measures seem to be the most credible (Manary et al., 2013).

Still the largest barrier remaining for this area of research is agreement on a common definition of "patient satisfaction." The underpinnings of this research need cohesive grounding in theory in order to drive accurate and reliable data comparisons across studies (Manary et al., 2013).

Author Biographies

Summer Williams is an assistant professor of psychology at Westfield State University in Western Massachusetts. Her areas of research interest include health communication, patient satisfaction and adherence, health outcomes and health inequities, and social and psychological determinants of health. She has recently published chapters in *Assessment in Health Psychology* and the *Handbook of Health Behavior Change*.

Tricia A. Miller received her PhD in psychology from the University of California at Riverside. Her research focuses on the social psychological process of health and medical care delivery including patients' health literacy. She also studies the effect of provider–patient communication on the promotion and maintenance of treatment adherence and patients' overall health outcomes.

How do people deal with threats and challenges pertaining to acute and chronic diseases? Answers to this question generally invoke the concept of coping: attempts to remove or diminish a stressor or limit its impact. Coping responses vary widely, based in part on the duration of the disease (acute vs. chronic), its severity and prognosis, and the person's overall interpretation, or appraisal, of the illness and its implications. Coping can also be affected by personality, such that a given stressor elicits different coping responses from different people. In this way, personality and situational coping both play roles in subsequent mental and physical health outcomes (Sharpe, Martin, & Roth, 2011; also see Kern & Friedman, 2011; Carver & Connor-Smith, 2010). This chapter outlines several aspects of personality and coping, describes how they relate to each other, and suggests how they may relate to outcomes in the context of physical health and illness.

Personality

The psychology of personality includes a very broad range of ideas (see Carver & Scheier, 2012), but two themes stand out. One is that personality incorporates some internal processes or dynamics that influence the person's thoughts, feelings, and actions. The other is that, despite having the same basic functions, people differ from one another. There are many viewpoints on the nature of the underlying systems and also on what individual differences are most important. Here we outline two viewpoints that have been influential in health psychology.

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

The Five-Factor Model

What is generally termed the five-factor model is a structural framework for describing individual differences. It places personality on five broad trait dimensions, commonly labeled extraversion, neuroticism, agreeableness, conscientiousness, and openness to experience (e.g., McCrae & John, 1992). Each person is assumed to occupy a position on each of the five traits, though that "position" is less a fixed point, perhaps, than a central tendency with variability around it (e.g., Fleeson, 2001). This model was not only developed mainly through studies of how people are described in natural language, but links have also developed between this view of personality and analyses of childhood temperament (e.g., Hambrick & McCord, 2010; McCrae et al., 2000).

Extraversion is a dimension of approach and engagement with incentives, as reflected in descriptors such as active, assertive, energetic, and enthusiastic (McCrae & John, 1992). Some views of extraversion also emphasize qualities of sociability (Ashton, Lee, & Paunonen, 2002), and virtually all views incorporate an element of positive affect (Ozer & Benet-Martinez, 2006).

Neuroticism is the tendency to respond to threat, frustration, and loss with negative emotions (McCrae & John, 1992). Individuals high in neuroticism are vulnerable to anxiety, moodiness, and general emotional distress (see Carver & Connor-Smith, 2010). Another term for neuroticism is emotional instability (McCrae & John, 1992).

Agreeableness refers to investment in establishing and maintaining social relationships (Jensen-Campbell & Graziano, 2001). Agreeableness facilitates compassion (Ozer & Benet-Martinez, 2006), and people high on this trait are more forgiving and trusting than those low on it (McCrae & John, 1992).

Conscientiousness concerns thoroughness and trustworthiness. It includes qualities such as planfulness, persistence, and organization (McCrae & John, 1992), competence, self-efficacy, and self-discipline (Bartley & Roesch, 2011). Conscientiousness implies being perseverant in goals and tasks (Ozer & Benet-Martinez, 2006). People with this trait act in ways that facilitate achievement striving (McCrae & John, 1992).

The final factor generally termed openness to experience incorporates qualities such as curiosity and imagination (McCrae & John, 1992). Persons who are high on openness are flexible and willing to involve themselves in new and atypical experiences (McCrae, 1996). Openness to experience often overlaps with qualities such as creativity and inspiration (Ozer & Benet-Martinez, 2006).

Optimism and Expectancy-Value Process Models

Another individual difference variable that figures prominently in the coping literature is optimism (see Carver, Scheier, & Segerstrom, 2010 for a review). Optimism, which does not fit neatly into the five-factor model, derives from a different research tradition, following from expectancy-value models of motivation. Optimism consists of a generalized favorable versus unfavorable expectancy for one's future. As is true of all expectancy-value models, this construct assumes that a favorable expectancy promotes greater motivation, resulting in greater persistence and generally better outcomes.

Optimism forms a lens, or cognitive filter, that influences life at multiple levels. It affects people's appraisals of challenging or stressful situations and their subsequent reactions (both behavioral and physiological) to those situations. Optimism is not the view that adversity will not occur; rather, it incorporates the belief that adversity and threat can be overcome

(Fowler & Geers, 2015). Whether people are optimistic or pessimistic influences the extent to which they experience distress in the context of adversity, and it influences the manner in which people cope.

Optimism and the Five-Factor Model

Although standing somewhat apart from the five-factor model, optimism shares qualities with four of the five traits of that model. Optimism is positively associated with extraversion, agreeableness, and conscientiousness and negatively associated with neuroticism. The one factor with which optimism is not associated is openness to experience. In general, neuroticism and extraversion are the most correlated of the big five traits with optimism. However, optimism is not simply low neuroticism and high extraversion; rather, it reflects a more complex profile (Sharpe, Martin, & Roth, 2011).

Coping

Coping is generally defined as the cognitive and behavioral efforts made by an individual to manage or reduce external or internal demands associated with a stressor that seem to tax or exceed the individuals' resources (Lazarus & Folkman, 1987). Coping takes many forms, and a variety of distinctions have been made within the realm of coping. Coping may be cognitive or behavioral. It may effective or ineffective. Some would say that coping consists of intentional use of strategies, but others would say that some coping consists of involuntary reactions. Several distinctions are elaborated upon in the following sections (for more detail, see Carver & Connor-Smith, 2010).

Problem-Focused Versus Emotion-Focused Coping

A distinction was made early in the literature on coping between problem-focused and emotion-focused coping (Lazarus & Folkman, 1987). Problem-focused coping comprises active efforts to remove the stressor or reduce its impact by engaging in such activities as problem solving, conflict resolution, information seeking, and decision making. Emotion-focused coping comprises a set of efforts to manage and reduce the emotional distress provoked by the stressor (see Gross, 2014). Problem-focused behaviors are most commonly used, and are thought to be more useful, in situations where the stressor is controllable. Emotion-focused coping is more common in situations of low controllability.

Emotion-focused coping is more diverse than problem-focused coping. Included in this category are activities as diverse as relaxation, meditation, music therapy, physical exercise, massage, cognitive restructuring, and humor. Also included in this category are avoidant strategies such as self-distraction, shopping, wishful thinking, and retreating into substance use. These responses are all intended to regulate stress-induced emotions.

Many emotion-focused responses are quite useful. Even distraction away from a threat can be useful in the short term, especially if a person has already taken suitable action. Some emotion-focused coping responses, however—particularly those with avoidant properties—are not effective in the long term and can have adverse consequences for longer-term health and well-being.

Problem-focused and emotion-focused coping categories are distinguishable in principle, but they often are used jointly (Lazarus, 2006). They can also facilitate one another. Although problem-focused coping is aimed at removing the stressor or blunting its impact, a secondary consequence of effective problem-focused coping is a reduction in distress. Although emotion-focused coping is aimed at emotion regulation, the reduction in distress can also make it easier to turn to problem-focused coping.

Engagement Versus Disengagement Coping

A particularly important distinction is the one made between engagement and disengagement coping. Engagement coping, also known as approach coping, is geared toward dealing with the stressor and its emotional consequences (Skinner, Edge, Altman, & Sherwood, 2003). Disengagement coping involves trying to avoid or escape from dealing with the threat. Engagement coping encompasses both problem-focused and some of the emotion-focused techniques. Emotion-focused techniques that would be viewed as engagement coping would include support seeking, emotion regulation, acceptance of the reality of the challenge, and cognitive restructuring.

Disengagement techniques are avoidant in nature, including reactions such as denial, wishful thinking, and substance use. Often people use disengagement coping to distance themselves from the stressor. While this can be effective for avoiding distress in the short term, it does not address the situation that is producing the distress. More important, it could worsen long-term outcomes. For instance, a person with a cancer diagnosis who avoids scheduling an appointment for a scan may evade distress temporarily. But that evasion ultimately allows an opportunity for the cancer to progress. This may result in more aggressive treatment and greater overall stress and threat to life. Certain disengagement coping mechanisms can cause other problems, such as drugs, alcohol, and overeating. Disengagement coping may ultimately lead to an abandonment of the goals with which the stressor is interfering in order to avoid experiencing or exacerbating any associated negative emotions (Carver, Scheier, & Weintraub, 1989).

Proactive Coping

A final variation in the concept of coping we will note here is what is termed proactive coping. Proactive coping is anticipating and preparing for obstacles or stressful situations before they arise (Schwarzer & Taubert, 2002). Proactive coping is goal oriented and adaptive, and those who cope proactively are motivated to succeed. This tendency to expect and prepare for challenges plays a large role in the reduction of associated emotional distress and may be dictated by personality traits (Hambrick & McCord, 2010).

Personality and Coping

How do aspects of personality relate to aspects of coping? Personality is not the same as coping, but personality can influence what sorts of coping a person engages in, at several stages in the stress process. Most fundamentally, personality can influence how people appraise and interpret potential stressors. A person who perceives a great threat will turn to coping responses more quickly than a person who perceives a lesser threat. Since appraisals also influence choice of coping response, differences in appraisal affect what actions follow. People also vary in which coping responses come naturally to them. Thus, even given the same appraisal, people may cope in different ways.

The following sections address this issue from the perspective of the two views on personality that were described earlier in the chapter. First we consider the five-factor model.

Five-Factor Model and Coping

A recent meta-analysis of personality traits and coping (see Connor-Smith & Flachsbart, 2007) showed a number of associations between coping tendencies and traits from the five-factor model. For example, the trait of extraversion was fairly consistently related to use of problem-focused coping strategies and cognitive restructuring. These findings are consistent with the view that extraversion is a dimension of engagement with incentives and pursuit of goals.

In contrast to this, the meta-analysis found that neuroticism related inversely to problem solving and cognitive restructuring. Neuroticism also was positively associated with several maladaptive emotion-focused coping strategies, such as wishful thinking and withdrawal. On the positive side, neuroticism was also found to predict greater support seeking, which can be helpful in coping with health difficulties and chronic illness.

Interestingly, persons higher in neuroticism report greater emotional reactivity to negative life events and are more likely to develop anxiety and depression in response to such events (Lahey, 2009). Coping style probably plays a role in this relationship, given evidence that persons high in neuroticism use more disengagement-related strategies than problem-focused coping behaviors (Watson & Hubbard, 1996). Consistent with this pattern, people high in neuroticism also tend not to engage in proactive coping.

The trait of conscientiousness is associated with properties such as self-discipline, competence, self-efficacy, and striving toward achievement. Not surprisingly, then, it is strongly associated with the use of problem-focused, approach coping (Bartley & Roesch, 2011), including proactive coping. People high in conscientiousness also report greater positive affect. This relationship is likely mediated by the use of problem-focused coping in situations of daily stress (Bartley & Roesch, 2011).

Although the term proactive coping is generally reserved for cases of preparation for a particular stressor, there is a sense in which general efforts to live healthy lives represent proactive coping. Such health-promoting behaviors are an important part of managing well-being. Persons who are emotionally stable, introverted, and conscientious are more likely to engage in health-promoting behaviors such as physical activity, a healthy diet, immunizations, safe driving, sleep, weight control, and not smoking (Korotkov, 2008).

Optimism and Coping

Another personality dimension that has been linked to coping is optimism. Solberg Nes and Segerstrom (2006) conducted a meta-analysis of optimism effects. Optimism is systematically associated with greater use of approach coping tendencies, strategies that are active and problem focused. Optimism is also related to the use of social support, both for emotional reasons and for instrumental assistance. In contrast to these tendencies, pessimism is associated with avoidance strategies, essentially efforts to escape the stressor and sometimes to escape even acknowledging the stressor (e.g., Solberg Nes & Segerstrom, 2006).

As one example, in a sample of HIV-positive men and women coping with the loss of their partners to AIDS, optimism was positively associated with reports of using active coping strategies and negatively associated with reports of using avoidant coping strategies and falling into hopelessness (Rogers, Hanson, Levy, Tate, & Sikkema, 2005).

In a study of newly diagnosed breast cancer patients (Carver et al., 1993), optimism was associated with greater use of a range of engagement coping at time-appropriate points in treatment. That is, correlations of optimism with report of planning and active coping emerged prior to surgery but not afterward. Correlations with acceptance and use of humor were present across the first 6 months after treatment, and with positive reframing across the first 3 months. Optimism was also inversely associated with disengagement coping—denial and behavioral disengagement—across the full year after treatment.

Although similar effects have emerged in diverse contexts (Carver et al., 2010), there do appear to be boundaries on such effects of optimism on coping. Very recent research has investigated the role of what has been termed comparative optimism, which statistically is nearly independent of trait optimism as discussed here. Comparative optimism is assessed by items asking about the likelihood that respondents will experience problems in a given life domain compared with other people who are otherwise like them. Comparative optimists say those events are less likely than do other people. Trait optimists who were also comparative optimists minimized the degree of threat posed by particular health challenges; those who were trait optimists but not comparative optimists did not (Fowler & Geers, 2015).

Adjustment and Health

Coping, Adjustment, and the Role of Personality

Coping is associated with the health perceptions and quality of life of patients dealing with chronic illness. Across many diseases and health conditions, coping tendencies are associated with both mental and physical outcomes. There are two ways in which coping can have beneficial effects on well-being. First, it does so to the extent that it removes or eliminates the threat (thereby reducing distress). Second, it does so to the extent that it directly reduces distress.

Which of these classes of coping is more appropriate depends on the context. In the context of a controllable stressor, problem-focused behaviors such as active problem solving and changing one's circumstances are helpful (see Carver & Connor-Smith, 2010 in further readings). In the context of an uncontrollable stressor, these responses are less useful; emotion regulation, use of social support resources, and controlled emotional expression are most beneficial (Penley, Tomaka, & Wiebe, 2002). Reliance on an emotion-focused strategy in the context of a controllable stressor may be less productive, and vice versa. Behaviors that are either pointlessly ruminative or avoidant in nature—e.g., venting, denial, and self-blame—tend to predict poorer adjustment regardless of context (e.g., Moskowitz, Hult, Bussolari, & Acree, 2009; also see Austenfeld & Stanton, 2004 in further readings). This selection and matching of the most beneficial coping strategy (or strategies) to a given stressor is one way to think about how coping influences adjustment. Within this viewpoint, the role of personality is principally to influence choice of coping responses.

A second way in which personality may play a role here is to moderate the effect of coping, such that once a coping response is selected, personality may influence how well the individual implements that response and how well it works for that individual. For example, problem-solving behaviors may be more successfully implemented by people who are conscientious (see Carver & Connor-Smith, 2010 in further readings).

Coping, Personality, and Health

Regardless of whether the role of personality is to influence selection of coping response or to influence the execution of the response, there are at least two pathways by which coping per se may have an effect on health. One path involves the level of wear and tear created on physical systems as a result of ineffective coping with threats and challenges. There is little dispute over the fact that chronic, elevated stress can affect physical health and disease processes via a range of physiological pathways such as the hypothalamic–pituitary–adrenocortical axis and the sympathetic nervous system (e.g., Schneiderman, Ironson, & Siegel, 2005). Effective coping can dampen physiological stress responses, proactive coping can prevent stress responses altogether, and dysfunctional coping can worsen stress responses (Carver & Vargas, 2011). With repeated or prolonged physiological activation, people become physically exhausted and more susceptible to illness.

The key issue here may be the extent to which the stress is invoked repeatedly or chronically. Meta-analyses suggest that persons coping with conditions such as HIV, prostate cancer, and diabetes who implement engagement coping have better physical and mental health than those who do so to a lesser degree (e.g., Moskowitz et al., 2009). On the other hand, poorer physical health outcomes are observed among persons who opt for disengagement coping (Moskowitz et al., 2009; also see Austenfeld & Stanton, 2004).

A second pathway by which coping affects health is a behavioral mechanism. This pathway follows from the fact that some kinds of effective coping involve engaging in health-promoting behaviors and avoiding health-damaging behaviors. In this case, the effect on health is intrinsic to the behavior itself. This pathway, of course, is also influenced by personality. The likelihood of engaging in healthy lifestyle behaviors is greater among persons who are optimistic than pessimistic (e.g., Carver et al., 2010). Of the five-factor model, conscientiousness, agreeableness, and extraversion are also linked to health-promoting behaviors (e.g., Roberts, Kuncel, Shiner, Caspi, & Goldberg, 2007).

Concluding Comments

This review is by no means complete or comprehensive. Coping in a health context is a multidimensional process, influenced by the healthcare environment, family factors, and life changes, along with physical demands such as pain and treatment side effects. Variation in these demands illustrates how different coping responses may be required for various components of a stressor. In part for this reason, it is challenging to predict coping responses from personality dispositions alone.

There is much more to be said about coping and personality in the context of different health stressors, as well as the inevitable variation based on demographic differences such as age, gender, ethnicity, socioeconomic status, and stage of disease. More research is needed on the extent to which coping is stable across situations. The concept of proactive coping is another area in need of further investigation, for example, to understand whether proactive coping follows from particular personality profiles, or whether it develops over time in response to experiences of adversity. Finally, it would seem desirable to continue to hone programs to teach effective coping, thereby helping patients enhance their use of engagement coping techniques. Enhanced coping would, in turn, increase positive health behaviors and improve health outcomes from morbidity to mortality in the context of clinical settings.

Author Biographies

Dr. Jamie M. Jacobs is a clinical psychologist at the Massachusetts General Hospital Cancer Center and Behavioral Medicine Service and an Assistant Professor of Psychology in the Department of Psychiatry at Harvard Medical School. Her expertise includes effects of stress on health outcomes and the role of coping and stress management in buffering physiological stress and disease processes in the context of cancer. She is also interested in psychological factors that predict nonadherence to cancer treatment regimens, in order to guide intervention development to improve adherence and symptom management.

Charles S. Carver is distinguished professor of psychology at the University of Miami. His background is in personality and social psychology, but he has also been active in health psychology and experimental psychopathology. One aspect of his research has focused on coping processes and optimism as a personality disposition, in the context of major health threats.

Personality and Health Behaviors

Christopher S. Nave[1,2] and Michelle R. Dixon[2]

Introduction

Health behaviors are positive or negative in valence and are associated with an individual's overall health. There are two types of health behaviors: health-promoting behaviors and health-compromising behaviors. Health-promoting behaviors include all behaviors that enhance or promote one's health (Sarafino & Smith, 2011). Health-promoting behaviors are considered beneficial for individuals to engage in and are frequently recommended by physicians, dietitians, and nutritionists in addition to being used in health behavior interventions. Examples of health-promoting behaviors include maintaining a healthy diet, exercising on a regular basis, and engaging in preventative health habits. Preventative health habits include wearing sunscreen daily, regularly visiting the doctors, drinking adequate amounts of water, and reducing salt intake (Sarafino & Smith, 2011). Individuals who engage in health-promoting behaviors can enhance one's quality of life, increase confidence, decrease illness, and even increase lifespan.

Health-compromising behaviors are harmful or detrimental to one's health, are considered destructive for people to engage in, and should be eliminated from daily life or minimized as much as possible (Sarafino & Smith, 2011). Examples of health-compromising behaviors include smoking tobacco, eating foods high in sugar, using illegal drugs, engaging in excessive alcohol use or binge drinking, and participating in risky sexual behavior. There are many factors that can influence health behaviors. One influence on health behaviors is personality.

Personality is described as a pattern of thought, emotions, and behavior that each individual possesses, while personality traits are any individual difference variable that can be used to predict behavior. Personality traits are a key predictor of important life outcomes like divorce, occupational attainment, mortality at comparable or even greater levels than IQ, and socioeconomic status (Roberts, Kuncel, Shiner, Caspi, & Goldberg, 2007). Personality traits show a remarkable amount of stability throughout the lifespan (Ferguson, 2010) though there are opportunities for personality change and growth (Srivastava, John, Gosling, & Potter, 2003).

A thorough, systematic lexical and empirical approach to studying personality traits has yielded five broad factors, known as the Big Five (McCrae & Costa, 1987). The Big Five includes extraversion, agreeableness, conscientiousness, neuroticism and openness, or intellect/culture (McCrae & Costa, 1987). Extraversion refers to individuals who are outgoing, talkative, and social. Agreeableness refers to individuals who are tolerant and kind. Conscientiousness refers to individuals who are highly organized and achievement orientated. Neuroticism refers to individuals who are anxious and moody, though many researchers study the positive end of this trait and call it emotional stability. Lastly, openness refers to individuals who are open to new experiences and curious. Other researchers (e.g., Goldberg, 1990) believe the fifth factor is best described as intellect/culture, with more emphasis on cognitive ability and IQ.

The Big Five and Health Behaviors

An abundance of research has demonstrated reliable associations between personality traits and health behaviors, many of which that can be organized around the Big Five. Support exists for a health behavior model of personality, where specific health behaviors have increasingly been demonstrated to mediate the relationship between personality and health outcomes (Hampson, Edmonds, Goldberg, Dubanoski, & Hillier, 2015). The following subsections break down a sampling of what we know about personality and its relationship with health behaviors.

Conscientiousness

Conscientious individuals are those who show self-discipline, plan their behaviors, aim for achievement, and practice impulse control. A variety of meta-analyses, large longitudinal studies, surveys, and experimental studies convincingly show that conscientiousness is related to a large number of health-promoting and health-compromising behaviors (Bogg & Roberts, 2013). Previous research has shown that conscientiousness is related to individuals maintaining a healthy diet by consistently eating foods like fruits, vegetables, lean meats, and whole grains and avoiding foods that are high in sugar and unhealthy fats (Bogg & Roberts, 2004). Engaging in frequent exercise is related to conscientiousness although the relationship is not very strong. In a meta-analysis that looked at conscientiousness and activity levels, the results showed that activity level was least related to conscientiousness in comparison with the other health behaviors, though conscientious individuals tend to possess better fitness levels and lower body mass indices than those who are low in conscientiousness (Bogg & Roberts, 2004). Another health-promoting behavior conscientious people engage in is more periodic health screening and greater attendance at scheduled doctor appointments (Armon & Toker, 2013). In addition to going to doctors more often, conscientious people are also more likely to engage in medication adherence, an effect that nearly doubles in magnitude when examining younger conscientious individuals (Molloy, O'Carroll, & Ferguson, 2014). Medication adherence is a particularly important health-promoting behavior because medication is not effective if the patient is not taking it.

Conscientiousness is also related to individuals avoiding health-compromising behaviors. People who are high in conscientiousness are less likely to smoke cigarettes or use drugs (Bogg & Roberts, 2004). Even conscientious ratings of children assessed by elementary school teachers predict low or no usage of tobacco later in life (Hampson, Goldberg, Vogt, & Dubanoski, 2006). Conscientious individuals are also less likely to consume alcohol to excess (Bogg &

Roberts, 2013) and are unlikely to engage in risky driving as measured by number of accidents, driving violations, speeding tickets, DUIs, and not using seatbelts (Bogg & Roberts, 2004; Raynor & Levine, 2009). Individuals who are high in conscientiousness tend not to engage in risky sexual behaviors (e.g., not using contraceptives or having a large number of sexual partners) and tend to not participate in behaviors that lead to incarceration, conviction, or detention (Bogg & Roberts, 2004). A seminal meta-analysis on conscientiousness and health behaviors found that out of all the healthy behaviors tested, frequency in alcohol consumption and driving while under the influence of alcohol were the most negatively correlated with conscientiousness (Bogg & Roberts, 2004). In summary, conscientiousness is related to the engagement in almost all health-promoting behaviors and the nonengagement in nearly all health-compromising behaviors. People who are high in conscientiousness are more likely to practice healthy behaviors and avoid unhealthy behaviors.

Extraversion

Extraverted individuals tend to be energetic and assertive and take pleasure in talking with others. Findings for how extraversion and sociability influence health behaviors are unclear, particularly with respect to health-promoting behaviors. One area where there is a consistent pattern of results for health-promoting behaviors is in coping with stressful life events. Extraverted individuals tend to manage stress better than introverted individuals and use a variety of coping mechanisms to manage stress (DeLongis & Holtzman, 2005; McCrae & Costa, 1986).

Extraversion is related to a number of health-compromising behaviors. In two large longitudinal studies, individuals high in extraversion tend to drink more at midlife and participate in excessive alcohol use such as binge drinking and frequent drinking (Hampson et al., 2006). Other research shows that those high in extraversion are less likely to limit consumption of alcoholic drinks or use designated drivers (Raynor & Levine, 2009). Tobacco use has also been shown to be moderately positively associated with extraversion (Raynor & Levine, 2009). One possible explanation for the relationships between extraversion and alcohol and tobacco use may be because highly extraverted people are social and enjoy going to social gatherings that involve alcohol or tobacco use. In a large survey study examining college students, extraversion was the strongest predictor of risky sexual practices including number of sexual partners and not using condoms in the last 30 days. Extraverted college students also slept less compared with those lower in extraversion (Raynor & Levine, 2009). Those high in extraversion tend to get less sleep than those who are low in extraversion, perhaps due to their social life and various campus activities (Raynor & Levine, 2009). Highly extraverted people are also less likely to participate in periodic health screenings (Armon & Toker, 2013). Lack of health screenings is a health-compromising behavior because regular heath checkups allow individuals to prevent illness rather than treat illness after it has already been contracted. Overall, the evidence for extraversion shows the trait to be related to engaging in various health-compromising behaviors.

Agreeableness

Individuals who are high in agreeableness are those who tend to trust others, show kindness, and express affection. Agreeableness is related to a number of different heath behaviors. Agreeableness is related to possessing a high body mass index (Sutin, Ferrucci, Zonderman, & Terracciano, 2011). Body mass index is a measurement that primary care physicians use to determine if an individual's weight is healthy or not. Individuals who have a higher body mass index than normal are considered overweight (Sarafino & Smith, 2011). An individual becomes overweight by engaging in health-compromising behaviors such as not maintaining a healthy diet or regularly exercising. One study found that people high in agreeableness are slightly more likely to use drugs and alcohol (Turiano, Whiteman, Hampson, Roberts, & Mroczek, 2012). In a large survey study of college students, agreeableness was not related to alcohol or tobacco use but was slightly negatively correlated to binge drinking and number of sexual partners (Raynor & Levine, 2009). Another study found that agreeableness is related to the avoidance of risky driving (Booth-Kewley & Vickers, 1994), which makes conceptual sense given that agreeableness is the opposite of hostility and aggression. Overall, agreeableness is related to engagement in health-promoting behaviors and avoiding health-compromising behaviors. Research is unclear on the relationship between agreeableness and substance use. More research on agreeableness needs to be done in order to find conclusive evidence with respect to health-promoting and health-compromising behaviors.

Openness and Culture/Intellect

Openness refers to an individual's ability to be highly imaginative and insightful. Out of all the Big Five personality traits, openness seems to be the least related to health behaviors. There are, however, a few health behaviors that previous research has found to be related to openness. Those who are highly open tend to practice healthy eating habits. Conversely, individuals high in openness are less likely to participate in periodic health screenings (Armon & Toker, 2013). One study found that substance use is related to openness (Booth-Kewley & Vickers, 1994). Another study involving college students found that openness was not related to any heath behaviors (Raynor & Levine, 2009). The relationships between openness and the above stated health behaviors are very weak relationships. One explanation for the slight correlations may be due to openness being related to creativity. Creative people may be more open to unique healthy foods, holistic medicine, and recreational drug use such as marijuana. Nevertheless the relationship between openness and health behaviors is not very strong.

Other researchers consider intellect, not openness, to be a major factor of the Big Five (e.g., Goldberg, 1990). Research examining childhood IQ has shown associations between lower IQ and smoking later in adulthood (Hart et al., 2004) and higher IQ and smoking cessation in midlife (Taylor et al., 2003). Other research from a prospective longitudinal study shows that highly intelligent individuals often engage in many of the same unhealthy behaviors compared with individuals of average intelligence (Friedman & Markey, 2003).

Neuroticism and Emotional Stability

Neuroticism refers to an individual's anxiety levels, emotional instability, and sadness. Neuroticism is only related to health-compromising behaviors. Individuals high in neuroticism have been shown to be more likely to engage in substance use (Turiano et al., 2012). One reason for this relationship could be that the anxiety neurotic people experience influences their substance use. Highly neurotic individuals are not only more likely to smoke tobacco, but they are also more inclined to smoke large quantities of cigarettes (Booth-Kewley & Vickers, 1994). When neuroticism is paired with being conscientious, however, research suggests that this combination, described as healthy neuroticism, predicts lower levels of smoking behavior (Weston & Jackson, 2015). One study found that low emotional stability (i.e., neuroticism) is related to alcohol use when combined with high levels of extraversion. This study found that children who rated high in emotional instability and extraversion predicted greater alcohol use 40 years later (Hampson et al., 2006). The relationship between alcohol use and neuroticism only occurs when combined with extraversion. Another study of college students found no relationship between neuroticism and alcohol use (Raynor & Levine, 2009). Highly neurotic individuals are also more likely to experience fluctuations with their weight (Sutin et al., 2011). This relationship may be related to the conception that people who are emotionally unstable may be more likely to eat unhealthy foods as a coping mechanism. Weight fluctuations are considered unhealthy because it usually means that the individuals are not consistently engaging in health-promoting behaviors related to eating and exercising. Neurotics demonstrate higher levels of daily stress and negative affect (Mroczek & Almeida, 2004). Hostility, a subcomponent to neuroticism, has been related to smoking, insufficient physical activity, and overeating (Niaura et al., 2000). Finally, those who are very high or very low in neuroticism are less likely to participate in periodic health screening. Individuals that fall right in the middle on the neuroticism scale are more likely to participate in periodic health screening (Armon & Toker, 2013). Overall, neuroticism has a wide-ranging set of associations with health-promoting behaviors (negative associations) and with compromising behaviors.

Other Personality Traits

Although the Big Five encompasses a variety of personality traits, there are personality and individual variables not captured by the Big Five that are related to health behaviors. In the Dunedin birth cohort study, high negative emotionality and low constraint at age 18 predicted various health risk behaviors (i.e., unsafe sexual behavior, alcohol dependence, dangerous driving habits, violence conviction) at age 21 (Caspi et al., 1997). Honesty-humility is one of six factors of the HEXACO model of personality and refers to an individual who is honest, loyal, and sincere (Ashton & Lee, 2009). One study found that honesty-humility was a significant negative predictor of exercise habits such that those who rated lower in honesty-humility reported more frequent physical exercise (MacCann, Todd, Mullan, & Roberts, 2015). Other traits related to health habits include perfectionism, which is the tendency to strive for flawlessness. One study found that perfectionism is related to engaging in preventative health behaviors (Williams & Cropley, 2014). Dispositional optimism is related to less smoking and alcohol use and more physical activity among older participants (Steptoe, Wright, Kunz-Ebrecht, & Iliffe, 2006). Finally, aggression has been associated with smoking habits such that individuals who tend to express hostility also tend to smoke more (Welch & Poulton, 2009).

Conclusion

Research has shown that personality traits, particularly the Big Five, are in fact predictors of health behaviors. The association between personality and health behaviors does not mean that it is guaranteed that an individual with a certain personality trait will definitely engage in a specific health behavior. It simply means that the individual is more inclined to behave a certain way if they possess a specific personality trait. Recent health behavior models look to use personality and health behaviors to help understand important health outcomes like general health, cardiovascular risk, and mortality (Hampson et al., 2015). Some correlations between health behaviors and personality traits are strong although many are weak. Health behaviors are influenced by a number of diverse factors, with personality as just one of these factors. With that being said, it is likely important to consider personality when implementing health interventions. People with varying levels of a personality trait may mean that a "one size fits all" for altering health behaviors is inadequate. Individuals may find it difficult to change their personality, but they can certainly take their personality into consideration when trying to change their health behaviors. As such, knowing associations between personality and health behaviors could improve intervention-based research by allowing researchers to tailor programs better designed for those with certain personality characteristics. For example, group-based therapies to change behavior (e.g., diet, weight, addiction) may be better suited to patients high in extraversion and sociability compared with highly introverted or highly neurotic individuals. Therapies that involve complicated adherence strategies would likely benefit from including participants with high conscientiousness compared with those with low conscientiousness. Future research is needed to understand and unpack the processes and mechanisms behind associations of personality and health behaviors (Hampson, 2012). Understanding the relationship between personality and health behaviors is important because health behaviors (e.g., smoking, drinking, wearing a seatbelt) can be analyzed as the mechanism by which personality is related to many important health outcomes (e.g., lung cancer, alcoholism, longevity; Hampson, 2012). Personality traits seem to be important individual difference variables to help understand *who* engages in particular health behaviors, which in turn leads to particular health outcomes (e.g., conscientious individuals wear seatbelts more, which in turn may help predict why conscientious people live longer, on average, than individuals low in conscientiousness). As such, it is important for researchers to continue to examine how personality relates to a variety of health-promoting and health-compromising behaviors.

Author Biographies

Christopher S. Nave, PhD, Associate Director, Master of Behavioral and Decision Sciences, University of Pennsylvania. Major research interests include examining associations between personality, health, and behavior across the lifespan, using multi-method approaches to studying individual differences, person perception and impression management, and situational assessment.

Michelle R. Dixon, MA Student, Rutgers University, Camden. Interests include health psychology and the relationships between health, personality, and behavior.

Introduction

The fundamental question in the study of personality and health is who gets sick and who stays well. This question of connections between individual differences and physical health dates back to Hippocrates and Galen, who proposed that four bodily humors—phlegm, black bile, yellow bile, and blood—were the underlying components in health and individuality and excess or deficiency of any humor would have negative consequences for both personality and health. Though replaced by modern physiology, the ancient Greeks' observations of the connections between psychosocial and physical health influence science to this day.

At the beginning of the twentieth century, Walter Cannon's work on the "fight-or-flight" response linked perceptions, emotions, and physiological reactions. Subsequent research at Johns Hopkins University found that "irregular and uneven" people were more prone to morbidity and mortality than wary and self-reliant types, or cool and clever types (Betz & Thomas, 1979). Such efforts combined with the developing field of psychosomatic medicine to set the stage for modern research.

Attention was piqued in the broader scientific community in the 1970s, with research on Type A behavior pattern. A Type A person is hasty, competitive, impulsive, and impatient and is hypothesized to be prone to coronary disease. However, imprecise conceptualization and inadequate assessment hindered rigorous scientific advances; the field of personality and health needed a more comprehensive approach. Such an approach involves multifactor predictors, multifactor outcomes, and models of the specific, multiple pathways to health across time (Friedman & Kern, 2014). We now know that there is at best a weak and non-unique connection between Type A and disease proneness (Booth-Kewley & Friedman, 1987) although elements of Type A behavior (especially hostility) are indeed part of a disease-prone pattern.

Some people tend to select into (put themselves into) stressful, hostile environments and evoke negative reactions from others. This cyclical process of selecting into and evoking

negative interactions and associated unhealthy behaviors shifts people onto a trajectory toward illness and is known as "disease proneness." Alternatively, someone may have a good match with his or her environment, creating psychological and physiological homeostasis, and a virtuous circle of behaviors. Such a person is said to have a *self-healing personality*, and tends to be conscientious, secure, and sociable, and self-selects into healthy environments and elicits positive reactions from others (see Friedman, 1991). This type of person is not necessarily stress-free, but views difficulties as challenges rather than threats, and tends to have good coping patterns and psychosocial resources. The self-sustaining appraisals, decisions, and actions of a person with the self-healing personality set him or her on a healthy pathway to long life (see Friedman, 1991; Friedman & Martin, 2011).

Key Considerations in Defining Outcomes and Contexts

The constructs of "disease-prone" and "self-healing" personalities—with their emphases on multiple predictors and multiple outcomes—highlight important considerations when studying personality and health. Many flawed studies rely solely on self-reported health as the measure of health, sometimes boldly (and invalidly) drawing conclusions about objective health. Self-reported health is highly correlated with subjective well-being, and so people who tend to be cheerful are more likely to report good health than individuals who have a more serious or cautious view of life. Although self-reported personality predicts self-reported health, which in turn predicts mortality risk (Idler & Benyamini, 1997), studying self-reported personality and health is not at all the same thing as studying validly assessed personality and objective health; this confusion has led to many problems in this field (Friedman & Kern, 2014). The most revealing studies avoid such problems by measuring multiple aspects of personality, assessing stress and coping, monitoring health behaviors, and tracking disease and mortality across time. For example, using the Type A classification, a hardworking corporate businesswoman who has climbed her way up the ranks with determination and drive would likely be told (incorrectly) that she is at risk of coronary disease. However, knowing that she has a supportive social network, relishes the challenges she faces at work, and has the resources to prevail over challenges, we can place her in the broader context of her surroundings and life path; research suggests she is on a pathway to good health (see Friedman & Martin, 2011).

Six Pathways to Health or Illness

The self-healing and disease-prone personalities encapsulate broadly defined trajectories of health. For instance, one unhealthy trajectory may involve an imprudent adventurer camping in a lightning storm while another may involve an impulsive neurotic coping with stress by binging on TV and junk food, but both pathways predict premature mortality as a function of personality. Differentiating multiple pathways yields a clearer understanding of causes across time. In general, there are six ways of conceptualizing the pathways from personality to health or disease.

First, personality may disrupt the body's physiological regulation through emotional instability and chronic negative affect. Stress and the long-term breakdown of homeostasis are linked with disease, though the pathways are not yet fully specified. Personality is a predictor and a moderator of stress perceptions, appraisals, and coping mechanisms: some personalities are not only more likely to encounter stressful challenges but are also more likely to both appraise situations as especially stressful and to lack adequate coping responses. Importantly, challenge in and of itself is not necessarily bad. Indeed, challenge, curiosity, and novelty are established elements of thriving. Rather, it is the appraisal of and reaction to challenge and the degree and length of disruption that puts some people at higher risk of disease.

The second, and perhaps the most direct pathway, involves health behaviors. Certain personalities are more likely to engage in healthy behaviors—everything from eating well, not smoking, and being active to wearing a seatbelt and keeping a regular sleep cycle. Other individuals are more likely to engage in unhealthy behaviors. A key question is whether changing a behavior will change long-term disease risk. Altering some behaviors, such as smoking, will have a big impact on health (as long as other unhealthy behaviors are not adopted instead), while others are erroneously thought to be causal but are simply correlational. Often, predictors are not key elements of causal processes (e.g., see Friedman & Kern, 2014).

Third, personality predicts (and often plays a causal role in) social support, social networks, quality of relationships, and amount of interpersonal conflict, all of which are relevant to health. Good social relations are healthy, but poor relationships can cause stress and influence unhealthy behaviors—for example, divorce and marital conflict predict mortality risk (Sbarra, Law, & Portley, 2011). Separating from a spouse may bring about financial burdens, emotional challenges, the loss of social support, and a need to restructure one's identity and social network. These challenges may pass quickly if coped with appropriately but may also have deleterious long-term consequences. Though the precise mechanisms through which social interactions affect health are not yet fully specified, close, high-quality relationships are usually important to a healthy life trajectory.

A fourth pathway linking personality and health involves biological third variables, including genetics, neurological differences, and central nervous system changes due to early environments. These biological variables predispose individuals toward certain personalities and physiological reactions. For example, people born with Down syndrome not only are at increased risk of early mortality and congenital heart disease but also differ predictably in personality from individuals without Down syndrome. In such cases, personality is correlated with health and longevity, but personality is not a causal element in this association (and so changing the personality will not affect health).

Fifth is the key pathway of situation selection and evocation. Certain individuals gravitate toward certain situations and evoke responses from others that fit with their personalities. This pathway reinforces trajectories toward health or disease, where personality facilitates entering healthy or unhealthy situations. The processes of situation selection and evocation suggest that many events that seem to be bad fortune—such as being bullied—are actually predictable to some degree. For example, a hostile or socially unskilled individual may create trouble and thus elicit an unhealthy environment.

Lastly, we can reverse the causal arrow and look at how health predicts—and sometimes alters—personality. Illness can cause changes relevant to depression, anger, worrying, and more. For example, the immune response to infection can cause lethargy. Similarly, some medications or treatment regimens change personality. Although this pathway is not currently well studied, being treated for or coping with chronic illnesses or handicaps may shift personality. A vicious circle of negative outcomes may result.

These multiple pathways between personality and health are not mutually exclusive; they function together, making it important to understand the full picture. Without a broad understanding of how these pathways work across time, interventions may be misguided and may eventually fail. For instance, early research on Type A led the American Heart Association to recommend screening and treatment for depression in patients with cardiovascular disease, but treating these patients for depression does not by itself decrease mortality risk (Friedman & Kern, 2014). Caution is needed to study the full causal pathways to ensure that interventions target the true causal elements of illness. Making people happier will not necessarily make them healthier, and worrying is health protective for some individuals in some circumstances (e.g., Weston & Jackson, 2015). It depends on the situation and the life trajectory of an individual.

Personality Trajectories

What are the pathways to health? How do individuals who thrive and stay healthy live their lives? In particular, what is the relevance of the five broad domains used by researchers to describe personality: conscientiousness, extraversion, agreeableness, openness, and neuroticism?

Conscientiousness

Conscientiousness is the best-established trait predicting health. People who are orderly, achievement motivated, prudent, responsible, and planful are more likely to stay on healthy pathways to long life (Friedman & Martin, 2011; Goodwin & Friedman, 2006). The original finding that conscientiousness in childhood predicts risk of dying at any age (Friedman et al., 1993) has been supported by many other subsequent studies (e.g., Chapman, Fiscella, Kawachi, & Duberstein, 2010).

Conscientiousness predicts, and often affects, health through several pathways that work together to produce a cycle of healthy habits, appraisals, and coping responses. People high in conscientiousness are more likely to engage in protective health behaviors and are less likely to engage in riskier behaviors such as smoking (see Bogg & Roberts, 2004). However, behavioral pathways do not fully explain the healthy outcomes of conscientious people (Martin, Friedman, & Schwartz, 2007).

Highly conscientious people often find their way to less stressful lives. For example, the most conscientious children in the Terman lifespan study (a nine-decade study of personality and health) were the least likely later to be sent to the most difficult US frontline during World War II as adults (Duggan & Friedman, 2014), avoiding the subsequent disruption in family life and career that combat often brings. When they do encounter stress, they may have better coping abilities. The difference in trajectories means that conscientious people are more likely to be productively engaged in society, with better careers, educations, and incomes than their less conscientious counterparts (Hampson, Goldberg, Vogt, & Dubanoski, 2007).

When conscientious people do experience stress, such as a career setback, their personality is more likely to attenuate the negative effects, perhaps because they are more likely to engage in problem-focused coping rather than through substance abuse, problem-denying, or expressing negative emotions (Connor-Smith & Flachsbart, 2007). Taken together, these studies suggest that the pathway from conscientiousness to health occurs across the lifespan through selection into stable situations (marriages, careers), evocation of positive responses from others, and healthy habits that maintain homeostasis.

Extraversion

Extraverts tend to be dominant, sociable, and cheerful and are inclined to elicit positive social interactions. Extraversion provides a good example of why considering the facets (or subtraits) of the Big Five is informative in understanding personality and health; the facets (dominance, sociability, and positivity) relate to health differentially—part of the reason why extraversion is inconsistently linked to physical health (Roberts, Kuncel, Shiner, Caspi, & Goldberg, 2007).

The facet of dominance predicts positive job outcomes, but its relation to health depends on the situation. When combined with positive affect and agreeableness, dominance plays an important role in good leadership, but when combined with hostility, dominance may increase risk of heart disease, unstable relationships, and poor mental health. Further, in stable environments, where dominance can be established, it may be adaptive to take the lead; however, being dominant when the hierarchy is easily threatened can be risky (for a study of monkeys: Manuck, Kaplan, Adams, & Clarkson, 1988). These findings illustrate how the link between personality and health is tied to environmental contexts and other personality variables.

When considering the importance of social relationships to health, one might assume that the sociability facet of extraversion will be predictive of good health. However, although sociability is generally linked with good subjective health and social outcomes, there are mixed results for objective health outcomes. For example, in the Terman sample, extraversion predicted more social ties and higher social competence, but not physical health or mortality (Friedman, Kern, & Reynolds, 2010). Sociability may be linked to health through better coping strategies, social relationships, approach-oriented temperament, and positive engagement with others (Connor-Smith & Flachsbart, 2007). However, these extraverts may also be drawn toward unhealthy situations. Extraverted college students, for instance, are more likely to smoke, drink, get poor sleep, and have multiple sex partners, thus increasing risk of morbidity and mortality (Munafo, Zetteler, & Clark, 2007).

A highly debated topic is that of positive affect (good feelings) and health. There is a small positive correlation of trait positive affect with self-reported health, symptom control, and survival of people with chronic diseases (Howell, Kern, & Lyubomirsky, 2007), but the causal link is unclear, and it would therefore be unwise to intervene with positivity interventions in an attempt to save lives at this stage of understanding. Although individuals with high positive affect are more likely to exercise, to have healthy behaviors and healthy relationships, and to perceive stressors as challenging rather than threatening, these are correlations. Being optimistic in the face of challenge may increase someone's willingness to persist with treatment or attain a goal, but there is no scientific evidence that positive thinking will heal broken bones, unclog arteries, fight cancer, or undo a diagnosis. Positivity interventions may promote health so far as they encourage healthy behaviors or decrease chronic stress but may raise the risks of blaming the victim and encouraging unproductive or irrelevant responses.

Being too positive may put one at increased risk by underestimating one's susceptibility to morbidity or mortality. In the Terman study, children rated as cheerful (sense of humor, cheery, optimistic) were at greater risk of dying at any age, partially due to risky behaviors in adulthood (Friedman et al., 1993). Dispositional optimism may steer individuals toward unrealistic thoughts, or the "above average effect" (illusory superiority), as is reflected in a study of individuals trying to lose weight, where dispositional optimism predicted confidence in ability to lose weight but did not predict actual weight loss (Benyamini & Raz, 2007). Taken together, it appears that optimism combined with conscientiousness is protective as it drives individuals toward achievement, but optimism combined with impulsivity and unrealistic expectations may become detrimental.

Agreeableness

Agreeableness is the tendency to be cooperative, trusting, kind, and generous. People who are agreeable are more likely to use adaptive coping mechanisms (Connor-Smith & Flachsbart, 2007). However, research on the relationship between agreeableness and health is mixed. Some studies suggest that agreeable people have better self-reported health and live longer lives, but other studies have found no relationship (Iwasa et al., 2008).

Though agreeableness does not reliably predict morbidity or mortality (Martin et al., 2007), the combination of agreeableness with other traits may have explanatory power. For instance, hostility involves both high neuroticism and low agreeableness, which predicts poor health and increased mortality risk (Booth-Kewley & Friedman, 1987), likely through chronic stress, and poor health behaviors and social skills. In a meta-analysis of 27 studies, high hostility was associated with higher BMI, more alcohol use, smoking, and markers of heart disease (Bunde & Suls, 2006).

Conscientiousness may also work in tandem with agreeableness in predicting health. High agreeableness and low conscientiousness may be risky, as the individual may be considered a "pushover" and fails to achieve personal goals in exchange for doing what others want them to do (Chapman et al., 2010). As previously discussed, though, low agreeableness is also risky. Therefore, agreeableness may be most predictive of good health when it is paired with protective traits and social contexts.

Openness

Openness involves intellectual curiosity, willingness to experiment, and creativity. People who are open are more likely to cope resourcefully and effectively (Connor-Smith & Flachsbart, 2007). In the MIDUS study (a longitudinal study of health and well-being in the United States), it is found that low levels of openness in patients relate to stroke, hernia, tuberculosis, and bone problems (Goodwin & Friedman, 2006). A subsequent study found that high levels of openness relate to decreased odds of a stroke, heart condition, blood pressure, and arthritis diagnosis (Weston, Hill, & Jackson, 2014).

The intellect facet may play a particularly strong role in predicting health. For instance, higher intellect predicts health status and educational attainment (Hampson et al., 2007). However, some studies of personality and longevity have found no relation between openness and mortality (Maier & Smith, 1999). Openness is the least understood trait in its relation to health, as the pathways are not yet clearly specified, and the objective outcomes from study to study are at odds with one another.

Neuroticism

Neuroticism, the tendency to experience the world as distressful, is frequently studied and further reveals the complex relationship of personality and health. Neurotics are prone to anxiety and depression and are emotionally unstable. It has long been known that people with higher levels of hostility, anxiety, and depression are more likely to be ill, but this is not necessarily a causal pathway, and prospective studies do not always show the same relationship; the commonsense view that neuroticism ("worrying") leads to disease and premature mortality requires significant qualification (Friedman & Kern, 2014).

Consider the strong relationship between neuroticism and subjective well-being. This association makes it difficult to disentangle the effects of neuroticism on objective health outcomes because subjective well-being is related to self-rated health, symptom report, and medical visits. In other words, individuals high on neuroticism are more likely to feel and report symptoms, which can lead to further distress even when there are no objective health differences (Costa & McCrae, 1987). Though neuroticism may sometimes predict increased risk of mortality, various studies find no relation between neuroticism and mortality (e.g., Iwasa et al., 2008). Given these conflicting findings, it is likely that the effect of neuroticism on objective health is moderated by other personality or environmental factors (e.g., Taga, Friedman, & Martin, 2009). There is also little evidence that intervening on neuroticism increases longevity. In fact, it may even be risky to intervene in some situations, such as what Friedman terms "healthy neuroticism" (Friedman, 2000), or the combination of high neuroticism with high conscientiousness.

Healthy neurotics may be particularly vigilant about their health (Friedman, 2000). Though healthy neurotics likely have lower subjective well-being, more doctor visits, and more psychosomatic symptoms, they may be more willing to engage in health protective behaviors. Healthy neuroticism may also have a particularly profound effect in stressful situations. For example, conscientiously neurotic individuals diagnosed with diseases most related to smoking were more likely to quit smoking after disease diagnosis, but did not show any smoking differences before disease onset (Weston & Jackson, 2015). In the Terman sample, neuroticism predicted lower health and increased mortality risk for women, but decreased risk for widowed men (Taga et al., 2009). That is, men who lost their wives and were particularly anxiety prone lived longer than the carefree men who lost their wives. Together, these studies suggest that when experiencing a stressful situation, high levels of neuroticism may induce increased anxiety, and conscientiousness may make one more successful at channeling that anxiety into health-promoting behaviors.

Neuroticism is a good example of the importance of using a lifespan perspective to study the relationship between personality and health, as neuroticism can also be the outcome of illness. For instance, neurological conditions and inflammatory responses may cause depression. When depression is the outcome of disease, high neuroticism may cause a negative spiral when the individual fails to enact adaptive coping mechanisms.

There is limited evidence that decreasing neuroticism reaps objective health gains. Recall that though treating depression decreases the risk of a secondary cardiac event, it does not reduce mortality risk (Rutledge, Redwine, Linke, & Mills, 2013). The association between depression and mortality may often be confounded by hostility (Lemogne et al., 2010). Treating depression may only deter or delay disease so far as it motivates individuals to adopt healthier behaviors (such as increased physical activity), social networks, or coping skills. As neuroticism is health protective for some individuals, intervening on neuroticism may be risky, thus highlighting the importance of targeted interventions that understand the full causal chain.

Interventions and Future Directions

Interventions that address personality to improve health should simultaneously target individual, community, and societal levels in order to launch people onto healthy paths and maintain their adherence to these healthy pathways. Because early character affects social relationships, careers, and environmental choice, all of which relate to health in later years, we need further understanding of how to shift people onto these healthy trajectories early and how to maintain these pathways, rather than intervening on short-term stressors at any instance throughout life. Such interventions need to be rigorously tested over time to determine their impact on well-being, disease, and, ultimately, mortality.

The most promising trait for health intervention is conscientiousness. We know that having a high level of conscientiousness is healthy, and we know many key pathways from high conscientiousness to longevity. Can we increase conscientiousness and sustain these changes? Personality is relatively stable but shows patterns of meaningful change across the lifespan, suggesting that change is possible. Different facets of conscientiousness may change differentially, as well. For instance, industriousness has been found to change early in life, impulse control and reliability changes across the lifespan, and orderliness is relatively stable (Jackson et al., 2009). Whether change is possible may also depend on contextual factors, such as age or stage of life. It may, for instance, be most effective to intervene during transitionary phases of life, when a person is shifting habits and behaviors.

Conclusion

Understanding who gets sick and who stays well is an integral part of healthcare. By identifying which individuals are more susceptible to illness, we may be more likely to prevent illness and intervene in a more targeted manner appropriate to a specific demographic. After people fall ill, understanding personality influences can be important in predicting who will cooperate with treatment and stay on pathways that maximize chances for recovery.

In disentangling the effects of personality on health and longevity, it is important to remember that personality interacts with psychosocial contexts. We cannot say that, for everyone, neuroticism is bad or that agreeableness is good. We must consider each individual as embedded in his or her environment across time and the ways in which personality traits interact with each other. In doing so, we can address how to shift people onto healthy life trajectories.

Author Biographies

Dietlinde Heilmayr is an assistant professor of health psychology at Moravian College. She earned her BA from Hendrix College and her PhD from the University of California, Riverside. Her service experiences with AmeriCorps, Fulbright, and Bike and Build inform her applied scholarly interests broadly focused on nature-based health interventions. In particular, Heilmayr focuses on the rigorous assessment and exploration of community gardening as a health intervention. She teaches a variety of courses including health psychology and experimental methods and data analysis and was the recipient of the Distinguished Graduate Teaching Award in 2017.

Howard S. Friedman is a distinguished professor of psychology at the University of California, Riverside. His book, *The Longevity Project: Surprising Discoveries for Health and Long Life from the Landmark Eight-Decade Study*, summarizes his 25-year scientific study of the pathways to health and long life. His major scientific awards include the James McKeen Cattell Fellow career award from the Association for Psychological Science and the "Outstanding Contributions to Health Psychology" senior award from the American Psychological Association (Div. 38).

Personality Hardiness

Salvatore R. Maddi

Department of Psychological Science, University of California, Irvine, Irvine, CA, USA

Introduction

Some psychologists consider resilience to emphasize how people can remain the same despite the imposition on them of stressful circumstances. One conclusion from this position is that it is helpful to avoid stressors. In contrast, personality hardiness emphasizes resilience as the process of change, growth, and development that is provoked by dealing with rather than avoiding stressful circumstances (e.g., Maddi, 2002; Maddi & Khoshaba, 2005).

In this regard, an assumption behind personality hardiness is that life is by its nature changing and stressful, so involving oneself in this process helps one grow and develop toward greater fulfillment. This assumption derives from the existential position (Kierkegaard, 1954) that everything we do in life is the result of making decisions. As life is an ongoing process of change, each decision with which we are faced involves choosing the unknown future or the familiar past. Although choosing the future is developmentally best, it brings anxiety because the outcome cannot be predicted in advance. But if we decide to avoid anxiety by choosing the past (i.e., what we already know and are doing), we encounter the existential guilt of missed opportunity, boredom, and emptiness of living.

Based on this dilemma, the hardiness approach assumes that, in one's ongoing life, the best way to establish a pattern of choosing the future, rather than the past, is to develop the personality pattern of hardiness. Hardiness is considered a pattern of attitudes and strategies that help one do the hard work of choosing the future rather than the past (Maddi, 2002). The more than 40 years of research, consulting, and counseling that emerged from this conceptualization has solidified this position. Early on, Maddi's (1965) work involved showing that people who express more interest in change are also likely to be more creative in their work. But in specifying the personality characteristics involved more completely and the particular effects of stressors on functioning, it seemed important to carry out a relevant experiment, rather than just doing correlational research.

The Illinois Bell Telephone Project

In the 1070s, Maddi was a consultant for Illinois Bell Telephone (IBT). At that time, the US telephone industry was a federally regulated monopoly, whose member companies only had to provide cheap and reliable telephone service and did not have to worry about their bottom lines. But it became clear that this situation had to change, as the beginning of the Internet was opening up the field and encouraging international competition. The US government made clear that the telephone industry would need to be deregulated in order to motivate competition for greater possibilities and income in the newly developing circumstances.

With the help of IBT decision makers, Maddi and his research team in 1974 began yearly testing of 450 managers in a longitudinal research study to determine the effects of the deregulation on them. Each yearly testing included not only the set of relevant questionnaires but also interviews. Also available were yearly job performance evaluations done by the company. Six years into the study (in 1980), the federal deregulation occurred, and its effects are still regarded as a major disruption on the industry and its companies. Indeed, in the year following the deregulation, nearly half of the managers in our sample were terminated. As to the research study, we continued to test the managers, whether they continued or were terminated, with the questionnaires, interviews, and job evaluations each year for the following 6 years. The study is still regarded as a classical natural experiment.

The study results showed that, in the 6 years following the deregulation of the telephone industry, nearly two-thirds of the sample fell apart in various ways. They showed clear signs of major anxiety, depression, and anger, undermining performance at work. These signs included violence, data loss, inability to make decisions, and decision-making avoidance. And in home life, they also showed signs of being undermined, such as divorces, substance abuse, and even suicides.

In contrast, the other third of the sample not only survived but also thrived following the deregulation. At work, they either rose up in the ranks, or if they were among those terminated, they found significant jobs in other organizations or even started their own companies. In all this, they were able to give and get social support with their significant others (at work or at home) and were able to grow and develop by dealing effectively with the stress of deregulation.

Of particular importance in developing hardiness assessment was the comparison of managers who reacted resiliently to the deregulation with those who did not (Maddi & Kobasa, 1984). In the 6 years before this upheaval, the managers who reacted well to the deregulation were much stronger than the others in the attitudes of *commitment*, *control*, and *challenge*. No matter how bad things might get, they wanted to stay involved with people and contexts (*commitment*), continue to struggle to have an influence on their outcomes (*control*), and learn how to grow and develop by trying to deal effectively with stressors (*challenge*). In contrast, the managers who fell apart under the deregulation had even before it showed definite signs of playing it safe by avoiding stressors and, if unsuccessful in this avoidance, by sinking into alienation and powerlessness. These results led to conceptualizing hardiness as the attitudes (the three Cs of commitment, control, and challenge) and strategies (problem solving rather than avoidance coping, socially supportive rather conflict-laden interactions, and beneficial rather than overindulgent self-care) associated with resilience. It appeared that hardy attitudes provided the courage and motivation to be able to do the hard work of hardy strategies that turned stressors into growth advantages. All of this is quite consistent with the existential view, well summarized by Nietzsche (1968, *Nietzsche's Twilight of the Idols*, p. 254) as "whatever doesn't kill me makes me stronger."

Also, the IBT data on interviews and questionnaires completed prior to the deregulation permitted a study (Khoshaba & Maddi, 1999) on the early life experiences of managers and the effects of these experiences on performance after the deregulation. Content analyses of the data showed that the managers who thrived after the deregulation had reported remembering a more disruptive, stressful early family life and having been selected by their parents as the hope of the family. They indicated having accepted this role and working hard to justify it. These results are consistent with the assumption that hardiness can be learned rather than being inborn. It also indicates that parents can help their children grow in hardiness by teaching them that life is by its nature stressful, and involving themselves in this process, rather than denying it, is the way to grow and develop toward a better life. In contrast, parents who are overprotective and controlling may be jeopardizing their children's growth toward hardiness.

Further Evolution of the Hardiness Approach

In the years since the IBT study, there have been many additional research studies and consulting work on the hardiness approach. In this process, our various versions of the hardiness questionnaire have been translated into more than 15 Asian and European languages and are also used in English in numerous countries. There have also been reviews of hardiness research (see Suggested Reading). In the research studies covered in these reviews, it has been shown that the hardy attitudes (the three Cs of commitment, control, and challenge) are positively related to each other and to the hardy strategies of problem-solving (rather than avoidance) coping, socially supportive (rather than conflict-laden) interactions, and beneficial (rather than overindulgent) self-care. This hardiness pattern has been positively associated with enhanced performance, conduct, mood, and health in samples of college and high-school students and working adults in military, firefighting, sports, and business contexts (e.g., Maddi, 2002). Some specific topics and studies are considered below.

In the process of research and consulting, there has been systematic improvement of hardy attitudes measurement. The original questionnaire for the three Cs of commitment, control, and challenge was 50 items in length. Over the years, the measure has been shortened and improved. The current version (Maddi, 2001) is the 18-Likert-item Personal Views Survey, III-R (third edition, revised). Examples of items are, for commitment, "I often wake up eager to take on life wherever it left off"; for control, "When I make plans, I'm certain I can make them work"; and for challenge, "Changes in routine provoke me to learn." Cronbach's alpha coefficients for all three Cs range in the.70's and for total hardiness are even higher. The three Cs are positively correlated, and each of them shows a high correlation with the total hardiness score. Also, consistent with hardiness theorizing, Sinclair and Tetrick (2000) have found that factor analysis of the hardiness test items yields the three empirically related first-order factors of commitment, control, and challenge and that these factors are indeed positively related to the second-order factor of hardiness. This pattern has supported the conceptually emphasized use of a total hardiness score as necessary. In another study (Maddi & Harvey, 2005), no cross-cultural or demographic differences were found in hardiness.

By now, there are many especially significant studies on the role of hardiness in various performance, conduct, and health activities. For example, in samples of bus drivers (Bartone, 1989), lawyers (Kobasa, 1982), and nurses (Keane, Ducette, & Adler, 1985), hardiness was found to be positively correlated with measures of performance and satisfaction and negatively correlated with anxiety and depression. There are also similar findings in American employees experiencing the culture shock of work missions abroad (Atella, 1989) and in foreign immigrants to the United States (Kuo & Tsai, 1986). In a study of sports performance (Maddi & Hess, 1992), hardiness levels of male, high-school varsity basketball players were measured in the summer, and then their performance was obtained in the ensuing season. Hardiness predicted six out of seven indices of performance in the expected direction, even though all the subjects were varsity players.

Also, there have been studies concerning hardiness and military personnel. For example, Bartone (1999) found that soldiers high in hardiness adjusted better to health and life stressors than did those who were low in hardiness. Further, among soldiers returning from operational deployments, there was a positive relationship between hardiness and readjustment to their former lives (Britt, Adler, & Bartone, 2001). Hardiness was also a positive predictor of performance success in soldiers undergoing special forces training among Norwegian Naval Academy cadets (Bartone, Johnsen, Eid, Brun, & Laberg, 2002). Similarly, hardiness was positively correlated with both retention and performance excellence in US Military Academy cadets (Maddi, Matthews, Kelly, Villarreal, & White, 2012).

In addition, studies support a negative relationship between hardiness and conduct problems, such as alcohol and gambling abuse. For example, Maddi, Wadhwa, and Haier (1996) found that among high-school graduates about to enter college, hardiness had a negative relationship with the reported frequency with which alcohol and drugs were used. In this study, the reported frequency of alcohol and drug use was objectively validated through urine screens. Also found in a sample of college students was a negative relationship between hardiness and gambling (Maddi et al., 2015).

Comparison of Hardiness and Other Possible Predictors

Understandably, questions have arisen as to whether hardiness is little more than yet another personality variable. This concern has led to several empirical studies comparing hardiness and other possible predictors of performance.

One other possible predictor that has been proposed is negative affectivity, or neuroticism (e.g., Hull, Van Treuren, & Virnelli, 1987). Maddi and Khoshaba (1994) conducted a relevant study in which hardiness and an accepted measure of negative affectivity were entered into a regression analysis as independent variables in an attempt to predict the clinical scales of the Minnesota Multiphasic Personality Inventory (MMPI). With the effects of negative affectivity controlled, hardiness was still a robust negative predictor of the MMPI clinical scales.

Another alternative predictor that might be confounded with hardiness is optimism. To test this possibility, Maddi and Hightower (1999) conducted three related studies that compared the relative influence of hardiness and optimism with transformational and regressive coping. Studying undergraduate students, the first two studies differed in the tests used to assess transformational and regressive coping styles. Nonetheless, the results showed consistently that, by comparison with optimism, hardiness was the better positive predictor of transformational coping and negative predictor of regressive coping. In the third study, the same approach was used in a sample of women who had breast lumps and were arriving at a specialty clinic for diagnosis of whether or not the lumps were cancerous. Under this life-threatening stressor, optimism showed similar effects on coping as did hardiness, but only hardiness was a negative predictor of regressive coping. Taken together, these three studies show that hardiness is a better predictor of effective coping and that optimism, by comparison, may be laced with naïve complacency.

Another explanatory alternative to hardiness is grit, which is the courage provided by having a definite goal that affects performance under stress and will never be given up (Duckworth & Quinn, 2009). By comparison, hardiness is the existential courage to continue to learn from and change under life's stressors (Maddi, 2002). To investigate the relative predicted power of hardiness and grit, a sample of cadets at the US Military Academy were tested for hardiness and grit several weeks before their training began, and then their performance evaluations were followed during the 4 years of this intentionally stressful training. The study results showed that hardiness was a better predictor than grit of cadet retention and performance (Maddi et al., 2012, 2015).

Hardiness Practice Applications

There is a growing need for hardiness assessment and training, due to the increased rate of social, technological, and cultural change being fueled by our transition from industrial to information societies (e.g., Peters, 1988). In an effort to adapt to the pressures of change, companies are continually restructuring (e.g., decentralizing, merging, downsizing, upsizing), which influences the lives of employees. In an attempt to help individuals deal well and grow with these changes, Maddi and Khoshaba have developed hardiness assessment and training procedures that can be used in consultation with individuals and organizations.

As to hardiness assessment, there is now the HardiSurvey III-R, a valid and reliable 65-item questionnaire that measures the vulnerability factors of stress, strain, and regressive coping, along with the resilience factors of hardiness attitudes, problem-solving coping, and supportive social interactions (Maddi & Khoshaba, 2001). The vulnerability and resilience factors of the test taker are compared with each other and with available norms, leading to a wellness ratio. This test can be taken on our website (www.HardinessInstitute.com) and provides a comprehensive report concerning your resilience or vulnerability under stress.

As to hardiness training, there is now a comprehensive workbook (Khoshaba & Maddi, 2008; Maddi & Khoshaba, 2005) that includes instructions, exercises, case studies, and evaluation procedures concerning how to engage in problem-solving (rather than avoidance) coping, socially supportive (rather than conflict-laden) interactions, and beneficial (rather than overindulgent) self-care. Also shown is how to use what is learned through these procedures to deepen your hardy attitudes of commitment, control, and challenge, so that once the training is over, you will have the courage and strategies to do the hard work involved in improving your functioning in everyday living. This workbook can be used by trainees on their own, or with the supervision of a certified hardiness trainer.

There are some studies supporting the effectiveness of the hardiness training procedure. In one study (Maddi, Kahn, & Maddi, 1998), IBT managers who went through hardiness training in the year following the stressful deregulation of the telephone industry improved in their performance and felt less anxious and overwhelmed, despite the huge disruption of the company. In this process, the IBT managers also increased in their hardy attitudes and simultaneously decreased in their self-reported strain. This beneficial pattern of results was still present at a 6-month follow-up test. Further, a recent study (Maddi, Harvey, Khoshaba, Fazel, & Resurreccioin, 2009) showed that undergraduate students who went through a hardiness training course based on the workbook, by comparison with a carefully developed control group, not only increased in hardiness but also in grade-point average at graduation.

Concluding Remarks

In terms of conceptualization and empirical support, it appears that the hardiness approach has growing validity. This encourages its use in assessment and training to increase the likelihood that individuals and organizations will be able to turn stressful circumstances from potential disasters into growth opportunities instead.

Author Biography

The son of Sicilian immigrants, Salvatore R. Maddi was born in New York in 1933. He received a PhD in clinical psychology with honors from Harvard University in 1960. Having taught at the University of Chicago (1960–1986) and the University of California, Irvine (1986–2015), he has developed the hardiness approach that shows how people can develop the courage, motivation, and capabilities to turn stressful circumstances into growth opportunities. He has won many awards, the latest of which is the 2012 American Psychological Foundation Gold Medal.

[3]Karlsruhe Institute of Technology, Karlsruhe, Germany

Although behavior is central to psychology in almost any definition of the field, research on actual behavior has reached a minimum in the field of psychology. This has been criticized several times, for example, by Baumeister and colleagues' seminal paper titled "Psychology as the Science of Self-Reports and Finger Movements: Whatever Happened to Actual Behavior?" In this chapter we will focus on the assessment of actual behavior. More precisely, we will focus on the assessment of physical behavior as an important subdomain of behavior—which encompasses overt postures, movements, and physical activities in everyday life—and its resultant physiological consequences (e.g., energy expenditure [EE]).

Measurement Principles and Technology

With the technological developments of the last 20 years, ambulatory activity monitoring—defined as a measurement strategy to assess physical activity, posture, and movement patterns continuously in everyday life—has become more and more feasible and is therefore increasingly applied to various research questions and clinical (feedback) applications. Activity monitors based on accelerometry have become most popular for assessing ambulatory activity; accelerometry can be used in almost every target group with relatively low participant burden and has contributed to advanced knowledge in epidemiological activity research over recent years.

Accelerosensors measure acceleration—that is the change in velocity over time. They are built into accelerometers, devices that are specially designed to measure acceleration, and into a variety of other products, like smartphones, cars, and cameras. Accelerosensors can

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

be used to describe the frequency, intensity, type, and time of physical activity. Although not the main focus of this chapter, it is important to know that accelerometer signals can also be used to quantify movement characteristics, such as walking speed, step length, and smoothness of movement. Furthermore, most current accelerosensors also measure a component of gravitational acceleration; because the magnitude of this component depends on the angular position of the sensor, these accelerosensors can also provide information on the angular position of the body segment the accelerometer is attached to. As a result, accelerosensors can also be used to automatically detect body postures and movements (Chen, Janz, Zhu, & Brychta, 2012).

Most modern devices are based on a piezoelectric (sensing element causes displacement of seismic mass), capacitive (proof mass between two electrodes), or piezoresistive (piezoresistors in the cantilever beam and proof mass) microscopic technology (microelectromechanical systems [MEMS]). The main advantages of the new technology are increased sensitivity, reduced size and costs, expanded onboard memory, extended battery life, and wireless communication (Chen et al., 2012). Due to technological advancements, data can be collected for a longer period at higher time resolutions, and unfiltered raw data can be stored instead of integrating and filtering data across time intervals (epochs). This major improvement enhances the comparability of data assessed with different sensors and enables the reanalyzes of data with improved algorithms because the analysis is conducted offline (Chen et al., 2012).

Although technological developments rendered counts as primary accelerometer output unnecessary, many accelerometers still have counts per unit time as their main output. Counts are arbitrary units without a physical meaning, but they express the volume of movement within a defined time interval (epoch). The term “volume” indicates that the number of counts per time interval depends on the amount (or duration) of physical activity within that time interval and its intensity. Although all of the sensors measure the same underlying construct, namely, acceleration, results are hardly comparable between studies and devices from different manufacturers and even between different generations of the same accelerometer (Chen et al., 2012). Differences in outcomes are due to differences regarding transducers, sampling frequencies, amplifiers, and filtering (Chen et al., 2012). Thus, when conducting an accelerometer study, it is highly recommended to use a sensor that records unfiltered raw such as acceleration (m/s^2) or the gravitational constant ($g = 9.81\,m/s^2$). When measuring raw signals, the sampling and storage rate have to be considered carefully. For example, accelerometers should provide a sampling rate that, according to the Nyquist principle, should be at least twice the highest frequency of assessed movements (Chen et al., 2012); thus, for example, for an arm movement of 25 Hz, the sampling rate has to be at least 50 Hz. Common accelerometers have sampling rates between 1 and 100 Hz (Chen et al., 2012).

In sum, when choosing a suitable accelerometer, the choice should strongly depend on the research question, the topic or outcome of interest, and the target group’s behavioral characteristics of interest (for a comparison in accelerometers, see Yang & Hsu, 2010). For example, children’s movement behavior is spontaneous with short intense intervals of high intensity, while older adults’ movement behavior is characterized by low intensity activity and long periods of sedentary behavior. Furthermore, factors such as reliability, validity, sensitivity, range, resolution, accuracy, and the precision of a device are important in the decision regarding which accelerometer to use. Finally, aspects such as battery length, capacity for data storage, and options of wear position should be considered (Chen et al., 2012; Matthews, Hagströmer, Pober, & Bowles, 2012).

Fields of Application

Accelerometry can be applied to various fields, for example, public health, elderly/falls research, rehabilitation, and other medical specialities. For the purpose of the present entry, we will focus on exemplary applications in the field of clinical and health psychology.

The important role of decreased or increased physical activity in many psychological disorders such as attention deficit hyperactivity disorder (ADHD), schizophrenia, major depression, or bipolar disorders has been underlined by Tryon in the early 2000s. For example, psychomotor retardation is a defining criterion in major depressive disorders. Volkers et al. (2003) reported a lower level of motor activity during waking hours and a higher level of motor activity during sleep. Furthermore, the authors observed longer periods of inactivity during waking hours and decreased immobility during sleep. Reichert et al. (2015) detected motor retardation of depressed patients both in gait and gestures. Furthermore, lower levels of motor activity amplitude and frequency indicated a reduced and decelerated activity denoting that patients walked both less and slower.

In addition, ambulatory activity monitoring has advanced knowledge regarding situation-specific characteristics of hyperactivity in children with ADHD, which could not have been identified with self-report measures. For example, in the early 1980s, Porrino and colleagues have already found increased activity during structured school tasks but not during free time in children with ADHD compared with healthy children. Teicher (1995) examined the distribution of activities during the day and showed that children with ADHD generally had few periods of low-level activity. They assumed that ADHD is characterized more by the relative absence of periods of rest than the presence of extreme activity. Using an interactive ambulatory activity feedback system, Tryon, Tryon, Kazlausky, Gruen, and Swanson (2006) were able to decrease motor excess in children with ADHD during school periods.

Two systematic reviews of Reed and colleagues between 2006 and 2009 revealed that momentary and regular physical activity have been repeatedly associated with positive mood in studies using a between-subject perspective and retrospective self-report measures. By using accelerometry to assess unstructured physical activity and by using electronic diaries to repeatedly assess mood within subjects in everyday life, ambulatory assessment studies have recently contributed to advanced knowledge on the activity–affect association. For example, Schwerdtfeger's studies between 2008 and 2012 revealed that mood was associated with the preceding physical activity level and momentary mood state was associated with subsequent activity level. Furthermore, the activity–affect association appeared to be more complex in inactive people (von Haaren et al., 2013).

Objective Assessment Versus Self-Report

Although many self-report (e.g., questionnaires) and objective measures (e.g., accelerometers) aim to measure the same construct, namely, the amount or volume of physical activity, they are low to moderately correlated (Prince et al., 2008). Furthermore, the discrepancies between subjective and objective physical activity data are well illustrated in the results of studies analyzing the achievement of physical activity guidelines suggesting tremendously higher achievement of health-related exercise targets with subjective measures compared with accelerometer-based studies (Gabriel, Morrow, & Woolsey, 2012). Gabriel et al. (2012) have identified several aspects that point out why the use of self-report instruments may induce different results compared with objective measures of physical activity: social desirability, reporting bias, misclassification bias and recall bias, differences between self-reports (with respect to psychometric properties, mode of administration, recall time frame), and differences in physical activity definitions.

First, reporting bias and recall bias are relevant problems when using self-reports, as they involve problems with cognitive processes that are necessary to gather activity information stored in the memory (Gabriel et al., 2012). In general, participants tend to overestimate the amount of physical activity performed (Prince et al., 2008).

Second, misclassification bias describes the problems of methods to adequately classify participants regarding their physical activity level (e.g., an insufficiently active person is categorized as meeting the guidelines). Therefore, it can lead to the underestimation of activity–health associations (Gabriel et al., 2012).

Finally, even differences between self-report instruments may impact results. For example, an interviewer-administered questionnaire with a shorter recall time frame may be more useful and valid in older adults, although it may not be practical and valid in another target group (Gabriel et al., 2012). In addition, social desirability that characterizes the tendency to present oneself based on perceived cultural norms was associated with overreporting of physical activity in self-report measures (Prince et al., 2008).

Instead of questioning the use of self-report per se, it may be important to understand that questionnaires and objective measures derived from accelerometry sometimes focus on conceptually different aspects of physical activity (Gabriel et al., 2012). For example, “fishing” as a hobby might contribute to the amount of physical activity from the perspective of questionnaires, but will not significantly contribute to the amount of physical activity as captured by activity monitors.

Two Perspectives: Within Versus Between

In general, research in physical behavior can focus on a between-subject or within-subject perspective. This is important to mention, as there is often confusion about these two perspectives. For example, a between-subject investigation on affect and physical activity can show that persons with a higher activity level have higher mood ratings. However, it does not evidence that a within-subject relation is true also, which means that a person has higher mood ratings when performing exercise compared with non-exercise situations. Between-subject investigations often focus on the frequency, intensity, type, and time of components of physical behavior (e.g., walking or being upright) and its relationship with health targets. These studies generally consider person-specific (e.g., age, sex, cultural, and social background) and environmental (e.g., region, facilities) variables of interest. However, they completely neglect the time dependency of activity. Said more simply, if my interest is in understanding why people do physical exercise, I need to assess in which specific situations they start exercising. Examples for within-subject investigations are dose–response relations or the reciprocal associations between physical behavior and psychological variables such as stress, emotions, self-concept, motives, and barriers to being physically active. Furthermore, physical behavior is addressed and evaluated in intervention studies and in studies that examine physiological variables that depend on or are confounded by physical activity, such as heart rate or heart rate variability.

Measurement Issues

Number of Measurement Days

Although it is known that physical activity varies between days, it is unclear how many days are exactly needed to account for between-day variability. The results of studies that tried to identify how many assessment days are necessary vary from 3 to 5 days in adults and 4–9 days in children (Trost, Mciver, & Pate, 2005) or from three 24 hr periods to 10 days or 2 weeks. Because physical activity varies between weekend and weekdays, at least one weekend day is required (Trost et al., 2005). It must be noted, however, that many factors will affect between-day variability and—because of that—the number of measurement days. Examples of this are the capacity of a person to vary his/her physical behavior (e.g., due to type of work, a person's health/fitness) and the physical behavior outcome of interest; some outcomes (e.g., ratio of usage left/right arm) might be more stable between days than others (e.g., number of steps taken).

Data Processing

Current software for initializing accelerometers generally allow user-friendly setting of start and end time. Depending on the research question, some authors recommend programming the start of recording at midnight of the first day the sensor has to be worn (Matthews et al., 2012). Even though data processing of accelerometer data is much easier nowadays, it is important to realize that initializing accelerometers and analyzing data still need some time and, more importantly, requires skilled personnel (Matthews et al., 2012).

Data check

To detect problems during the course of a study and eventually be able as a researcher to repeat data collection, data should be controlled in terms of quantity and quality immediately after data recording (Heil, Brage, & Rothney, 2012). The quality of accelerometer data can be limited by implausible data (e.g., due to malfunction of the sensor, outliers exceeding specific thresholds, tampering by participants) and missing data over a predetermined time interval (Chen et al., 2012; Heil et al., 2012). Today, preset user settings of the software can support the identification of these data quality aspects.

Non-wear periods

To identify periods during which the sensor was not worn, different recommendations are reported in the literature: non-wear times can be detected based on thresholds of a predetermined number of counts (e.g., zero counts over a predetermined time period). Recommended time periods to consider for zero counts vary considerably between 10 and 90 min (Choi, Liu, Matthews, & Buchowski, 2011). The identification of non-wear periods is not trivial, as zero counts can have different reasons such as not only sleep or sitting quietly or malfunction of the sensor but also removal of the sensor without a reason, or due to specific activities that do not allow wearing the sensor, such as swimming, other water activities, or showering (sensors are not waterproof) or heavy contact sports (risk of breaking; Mâsse et al., 2005). Only removal of the sensor would be "true" non-wear time.

To be able to identify times during which the sensor was not worn (see *Data check*) and to facilitate the interpretation of the accelerometer data, we suggest that participants should record the following information depending on the research question: time at which the sensor is removed in the evening, bed/sleep time, wake time in the morning, time of attachment of the sensor in the morning, and times and activities during which the sensor was removed during the day.

Identifying a valid day

Researchers should think about how many hours of wear time they consider reasonable. Studies often require a wear time of 10 hr/day as a precondition for a valid day (Mâsse et al., 2005). In children, the required wear time for a valid day can be reduced by trend due to shorter waking times (Mâsse et al., 2005). In addition, it might be reasonable to differentiate between weekend and weekdays in terms of required wear time for a valid day (Mâsse et al., 2005). Using data imputation to account for invalid days, the values of valid days and those of partly valid days are used to extrapolate values for the invalid days (Mâsse et al., 2005).

Outcome Variables

With the development of saving unfiltered raw acceleration data, accelerometry allows generating manifold outcome variables ranging from counts to movement-specific or gait-specific variables (e.g., walking speed), energy expenditure, body posture, and movement categories such as walking, jogging, standing, climbing stairs, etc. While ambulatory monitoring is an objective technique to assess physical activity, posture, and movement, it is not automatically guaranteed that the method generates reliable and valid outcome variables. Thus, a major challenge of ambulatory activity monitoring is to operationalize parameters that truly, uniquely express the aspect of physical behavior that is of interest. For example, in a literature review in 2006 on biomechanical exposure at work, Mathiassen pointed out that an overall measure of activity level may not reflect the negative effect of repetitive operations (behavior) at work on musculoskeletal disorders. Instead, the distribution (variation) of specific activities over the day is interesting (see Suggested reading). Several categorizations exist, but Heil et al. (2012) suggest the following categorization of outcome variables:

- Movement-based volume variables are variables that are not transformed into physiological units, for example, acceleration in standard physical units (g, m/s^2), counts/min, counts/day.
- Time-based amount variables (minutes of moderate to vigorous physical activity [MVPA]/day, sedentary behavior/day).
- Energy expenditure-based variables (total EE/day, AEE/day, EE during MVPA).
- Activity-based variables (steps, walking time, jogging/week).

Influencing Factors

To account for between-day variability, we mentioned considering the minimum number of measurement days in the "number of measurement days" section above. However, there are multiple systematic factors influencing physical activity behavior in everyday life. Besides influencing factors such as age, gender, weight, sociocultural status, and many others that are assessed on the between-person level, there are also aspects that have to be considered on a within-subject level when conducting ambulatory activity monitoring. First, physical activity levels are higher or lower depending on the weather (and the temperature) and the season. Usually people are more physically active during spring and summer compared with autumn and winter. Second, physical activity levels vary between weekend and weekdays (Trost et al., 2005) and can also vary between vacations and times during which individuals have to work or go to school (Heil et al., 2012). Furthermore, the placement of the monitor is not only relevant to gather the behavior of interest but also a factor that can influence the results (Trost et al., 2005). Placement at the waist is recommended for whole body ambulatory activities of the large skeletal muscles, such as walking during everyday life, because a placement close to the center of mass is supposed (Yang & Hsu, 2010). Other placement options such as thigh (sedentary behavior/posture, differentiation between sitting and standing), wrist (detect subtle activity during sleep), or ankle (step count and gait pattern detection) can be used depending on the research question (Matthews et al., 2012; Yang & Hsu, 2010).

Reliability, Validity, and Reactivity

Ambulatory activity assessment can improve both validity and generalizability, as it enables the assessment of real behavior in the natural environment instead of assessing behavior in an artificial laboratory setting. Looking at the literature reveals, unfortunately, considerable discrepancies regarding validity and reliability. For example, the results for reliability of accelerometers obtained in laboratory settings have been reported to be high with values between 97.5 and 99.4% in studies by Tryon. However, Esliger and Tremblay (2006) examined the reliability of three common accelerometers and found high discrepancies between devices in intra- and inter-instrument variability (range: CV = 0.5 to >40%).

Results of validation studies show that accelerometers under- or overestimate energy expenditure of specific activities depending on the investigated target group, the type of devices that were used, and the activities that had to be performed in these studies (Calabró, Lee, Saint-Maurice, Yoo, & Welk, 2014; Trost et al., 2005). Accelerometers still show considerable discrepancies with the criterion measures such as indirect calorimetry in low intensity activities, a domain that is of growing interest for researchers (Calabró et al., 2014). Furthermore, postures and movement patterns are misclassified when patterns are similar such as in walking and climbing stairs and in situations involving various patterns at the same time.

From a methodological perspective, the validity outcomes of accelerometers depend on the validation protocols (how extended the protocols are; real life vs. laboratory), the population specificity, the reference instruments and outcome variables (energy expenditure, posture, activity type classification), the accelerometer device, the psychometric topic of study, and the applied statistics. Definitely, more studies are necessary to obtain a more extensive picture on these issues. Common problems regarding validity in monitoring movement behavior in everyday life are (a) a lack of insight into the setting, (b) the control of confounding variables, (c) personal background and motivation for performing or refraining from activities, and (d) sensor placement.

For example, irregular walking patterns may either represent a lack of balance while walking on a flat surface or an appropriate adaptation to an uneven pavement. In addition, an upcoming exam can cause a low activity level as can laziness of a person. Furthermore, various movements cannot be detected adequately or require additional sensors, such as arm movements, cycling, or swimming. Moreover, the assessment of static activities, the carrying of additional load, and the differentiation between sedentary behavior and activities of low intensity are problematic. For example, the differentiation between sitting and standing requires either various sensors, an integrated inclinometer or the placement of one sensor at the thigh that in turn induces less accurate data for whole body movements. Thus, the combination of accelerometry with electronic diaries to assess context information such as temperature, social contact, location, or light may help to identify situations and interpret the observed behavior (Ebner-Priemer, Koudela, Mutz, & Kanning, 2013).

The findings for reactivity to ambulatory activity monitoring are heterogeneous as well. For example, in one of Ebner-Priemer's studies in 2007, participants reported that they were minimally affected by 24-hr ambulatory activity monitoring. In addition, participants' ratings of distress and reactivity caused by the device were minimal. Several studies of Clemes and colleagues between 2008 and 2009 revealed that wearing an unsealed pedometer and displaying daily steps induced the highest reactivity compared with wearing an unsealed pedometer without displaying recorded steps or wearing a sealed pedometer. Dösegger et al. (2014) revealed an overall reactivity effect of approximately 5% in children and adolescents in response to accelerometers, while they reported no reactivity in other samples, for example, in a young active student sample. Additionally, van Sluijs, van Poppel, Twisk, and van Mechelen (2006) reported measurement effects in response to self-report but not in response to accelerometer measures in a randomized controlled trial. Furthermore, wearing a multichannel system did not affect the amount of wheelchair driving in patients with spinal cord injuries; however, patients reported some burden (Bussmann et al., 2010).

Due to the heterogeneous findings, it is not trivial to give general recommendations regarding reactivity. Allowing for at least 1 day of familiarization and a random assignment of start days, as recommended by Dösegger et al. (2014) when measuring habitual physical activity with accelerometry, it might not be feasible for a highly burdensome multiple device assessment procedure, which sometimes even lasts less than 24 hr. However, interviewing the participants after the monitoring period about burden and reactivity might be helpful.

The Future of Ambulatory Activity Monitoring in Psychology: Combining Accelerometry With Electronic Diaries

For psychology research, the association between psychological variables such as motivational processes, habits, and/or affective states is important to explain physical behavior in everyday life. Researchers often face the problem that the behavior of interest is rare: many people perform few active episodes because they are mainly sedentary. From a statistical point of view, a minimal number of active episodes are required to obtain sufficient variance or covariation. Recent studies addressing the association between affective states and physical activity in everyday life found a significant association between positive affect and physical activity but did not find an association between negative affect and physical activity. These results may be explained by different time courses of positive affect, negative affect, and physical activity, more specifically the effects on negative affective states that might not be parallel but shifted.

Activity-triggered e-diaries, sometimes also called interactive multimodal ambulatory monitoring, may be advantageous to understanding the relationship between actual physical behavior and affective states. By changing the affective state assessment strategy from a random or fixed mode to an interactive mode, interesting episodes are detected in real time and are used as triggers for the assessment of psychological variables and contextual information. Using this approach, variance can be enhanced, as affective states can be assessed during episodes of high physical activity as well as during episodes of low physical activity (Ebner-Priemer et al., 2013).

Due to the fast technological developments in information technology and telemedicine, the assessment of physical behavior using accelerometers and connecting them with other sensors, smartphones, and technical applications is in its infancy. Multiparametric sensor fusion and the use of additional signals such as skin temperature can deliver useful information (e.g., whether a sensor is worn or not) and thus enhance the differentiation between inactivity and compliance. Additional contextual information that can be obtained via smartphones or Global Positioning System (GPS) signals delivers useful information about the situation, the social interaction, or the interaction with other devices. Since some activities take place at specific locations, activity classification can be improved. The various functions of smartphones such as video and audio options will offer unlimited opportunities for researchers but will also demand a reconsideration of how participants can be protected in terms of ethical fundamentals in future studies.

Author Biographies

Birte von Haaren-Mack is a postdoctoral research associate at the Department of Health and Social Psychology of the German Sport University Cologne. The focus of her research is examining psychophysiological effects of physical activity on stress and the relationship between physical activity and affect in everyday life; to assess these constructs in everyday life, she uses the methodology of ambulatory assessment, especially electronic diaries, accelerometry, and ambulatory ECG.

Johannes B.J. Bussmann is an associate professor at the Department of Rehabilitation Medicine, Erasmus MC, Rotterdam, Netherlands. The focus of his research is understanding the consequences of chronic conditions on physical behavior, the development and validation of objective devices and outcomes related to physical behavior, and the development and evaluation of treatment strategies. He is the president of the International Society for the Measurement of Physical Behavior (ISMPB) and board member of the Society of Ambulatory Assessment.

Ulrich W. Ebner-Priemer is a professor at the Institute for Sport and Sport Science at the Karlsruhe Institute of Technology (KIT), Germany. The focus of his research is characterized by its methodological focus on ambulatory assessment. Phenomena of interest are studied in everyday life (real life) in real time using psychophysiological methods (objective) and time-sensitive analysis (dynamics). He is currently the president of the SAA.

Shared Mechanisms Between Social and Physical Pain

Pain is a multidimensional construct, consisting of sensory, emotional, and cognitive aspects. Given its complex nature, the experience of pain is subject to a variety of physical and psychological factors. Additionally, pain has a profound and mutually influential relationship with the social world. Social factors may be considered a "double-edged sword" in the context of pain. For instance, social factors have the capacity to increase vulnerability to pain-related dysfunction or to contribute to healthier responses to pain.

Recent evidence supports the model of shared neural activation between nonphysical pain arising from social causes (e.g., exclusion, ostracism, and loss) and physical pain. In a seminal study, Eisenberger, Lieberman, and Williams (2003) reported that, after being exposed to social exclusion experimentally, participants demonstrated greater levels of activation of both the dorsal anterior cingulate cortex (ACC) and the right ventral prefrontal cortex, two brain regions previously associated with pain-related emotional distress. Subsequent research has also implicated the anterior insula, which appears to play a key role in the experience of physical and social pain (Eisenberger, 2012). Craig (2015) has found substantial evidence that pain is an emotion that is indicative of the brain's self-regulatory response to disturbance in homeostasis. Like other feelings, pain has both sensory and motor components integrated within the

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.

anterior insula and adjacent neural structures. These patterns of activation have been implicated in social rejection in experimental and real-life settings. For instance, individuals who had recently been rejected by a romantic partner evidenced neural activation similar to physical pain when shown pictures of the person who had rejected them (Kross, Berman, Mischel, Smith, & Wager, 2011). Additionally, similar patterns of regional activation have been noted in individuals viewing pictures of recently lost loved ones, suggesting that social pain is not specific to social rejection and can include other socially based sources of distress, such as loss. In essence, when we refer to hurt that arises from social interactions, we are not speaking metaphorically. Social and physical pain belong within the same family of neurophysiological responses that alert the mind to modify its current status.

Researchers have explored the potential evolutionary value of social pain, suggesting that social pain may have promoted physical safety: if an organism is separated from its group, it is exposed to greater predatory and other environmental threats (MacDonald & Leary, 2005). Thus, exclusion or rejection from one's group may have developed to signal imminent danger, similar to the experience of acute physical pain, which signals potential tissue damage and serves a biologically necessary purpose. Linguistically, socially painful experiences are described similarly to physical pain, suggesting that they are often been experienced in a similar fashion. Importantly, these theoretical assertions have been supported by experimental data. For instance, social exclusion has been found to promote greater physical pain (Eisenberger, Jarcho, Lieberman, & Naliboff, 2006). Furthermore, in this same study, baseline cutaneous heat pain sensitivity was directly related to the level of social distress after exclusion. This bidirectional relationship provides further evidence that, in the evolutionary sense, prosocial ties confer safety and that the loss of social relationships is indexed neurally by the human "alarm system"—pain—to signal a threat.

The immune system is implicated in social and physical pain, thereby revealing an additional shared mechanism. Indeed, pro-inflammatory cytokines—markers of the immune system—have been associated with physical pain and may underlie mood difficulties in chronic pain. The inflammatory response is a primary biological response to tissue damage and serves to protect a wound through tissue swelling, slowing use of damaged areas with pain registers, and slowing psychomotor energy expenditures through signaling fatigue. Responding as if the body were harmed, increased circulation of pro-inflammatory cytokines has been found following social stressors such as social exclusion (Slavich, Way, Eisenberger, & Taylor, 2010). Additionally, researchers found that the pro-inflammatory cytokine interleukin-6 (IL-6) mediated the relationship between social exclusion and later feelings of depression (Eisenberger, Inagaki, Rameson, Mashal, & Irwin, 2009). Interestingly, when inflammation was induced in participants via exposure to an endotoxin, they reported greater feelings of social disconnection and depression (Eisenberger, Inagaki, Mashal, & Irwin, 2010), again underscoring a bidirectional relationship between a physiological response to a threat or harm (inflammation) and social exclusion. In fact, these authors reported that the relationships between inflammatory markers and depressed mood were fully explained by perceived social disconnection.

Recent intervention studies showed that targeting these shared underlying systems may address both physical and social pain. DeWall and colleagues (Dewall et al. 2010) found that a 3-week course of acetaminophen, a common nonsteroidal anti-inflammatory analgesic thought to act on the central nervous system, also decreased feelings of social pain in response to social exclusion through reduced activity in the dorsal ACC and anterior insula. Individuals facing chronic social stress or isolation may be vulnerable to reliance on analgesic opioids to cope with this social pain. Indeed, polymorphisms of the μ-opioid receptor gene, traditionally implicated in physical pain processes, have been found to be predictive of greater social pain in response to exclusion, as well as predicting greater ratings of physical pain unpleasantness (Way, Taylor, & Eisenberger, 2009). Accordingly, a greater emphasis on social therapeutic targets may be most effective for the dual purpose of treating pain and mitigating addiction risks.

Social Contributors to Vulnerability and Distress in Chronic Pain

Traditionally, pain studies have focused on intraindividual processes, such as cognition and emotion. However, several factors originating in the social environment may alter both the experience of pain and subsequent coping responses to pain. It has been suggested that one of the etiologic factors in chronic physical pain may be chronic social pain, caused by ostracism, rejection, conflict, or isolation. These factors may increase vulnerability to pain and heightened emotional or behavioral responses to pain. For example, feeling ostracized or rejected may contribute to greater pain intensity following noxious thermal cutaneous stimulation (Eisenberger et al., 2006). Feelings of loneliness also appear to predispose individuals to greater pain by increasing negative thoughts about pain. Similarly, individuals with chronic pain who face more frequent stressful or conflictual interactions with others tend to report greater pain intensity (Faucett & Levine, 1991). Further, specific interpersonal communications may exacerbate pain: receiving social feedback of a personal failure predicts greater pain intensity than feedback of success after an intelligence test (Hout, Vlaeyen, Peters, Engelhard, & Hout, 2000). Thus, the presence of social stress or conflict appears to have negative implications for pain perception.

The consequences of negative social factors may also have long-term consequences by altering individual trajectories of the development of pain. Perhaps the best-known example of this phenomenon is the effect of significant social stressors in early life; exposure to traumatic events, particularly episodes of abuse, predisposes individuals to risks for future chronic pain (Davis, Luecken, & Zautra, 2005) and to medically unexplained pain later in life. Although the effect sizes from meta-analytic studies are relatively modest, the effect is nevertheless robust across studies and populations (Davis et al., 2005). It has been hypothesized that early and severe social stressors may sensitize the central nervous system, thereby kindling a diathesis for poorer outcomes later in life (Rutten et al., 2013). Alternatively, early life trauma may increase exposure to future stressful social environments, thereby prolonging these negative effects (Davis et al., 2005). Though the exact mediators are unclear, exposure to early and severe social stress appears to have profound implications for pain, both immediately and in the long term.

In addition to the direct effects of social stress on pain perception, the social environment may indirectly predispose individuals to poorer pain outcomes through changes in behavior, cognition, and emotional states. Feelings of social exclusion undermine effective coping strategies and self-esteem and potentiate aggression against others. Exclusion also discourages prosocial behavior and efforts to reconnect with others after exclusion, thereby entrenching a pattern of social avoidance that compromises the potential benefits of an extant social support network (Maner, DeWall, Baumeister, & Schaller, 2007). Notably, these patterns have effects lasting beyond the initial social struggles; similar to "pain memories," the recall of a socially painful experience may be sufficient to inspire social and emotional pain, increase feelings of aggression, and lead an individual to view a social relationship less favorably (Klages & Wirth, 2014). These findings are notable, as prior evidence suggests that a possible mechanism promoting long-term vulnerability to mood disturbance in chronic pain is a heightened and persistent fear of rejection (Ehnvall, Mitchell, Hadzi-Pavlovic, Malhi, & Parker, 2009).

Social threat has been a recent focus of empirical inquiry, particularly with regard to how it affects pain-related learning and coping. At present, the evidence in this area is mixed. Some experimental studies have found that a threatening social context, defined as a situation in which environmental cues signal either social threat (e.g., angry faces) or potential physical pain, facilitates the acquisition of pain-related fear (Karos, Meulders, & Vlaeyen, 2015). However, the fear elicited from these social contexts may have domain-specific effects: in an experimental setting, fear of physical pain, but not fear of social pain, was significantly predictive of greater pain intensity ratings in response to a cold water pain induction task, while only fear of social pain was found to predict social pain ratings after a social exclusion paradigm (Riva, Williams, & Gallucci, 2014). In both of these studies, the effects of a threatening social context had indirect effects on pain perception. More specifically, it was fear of pain, rather than general perception of a threat, that predicted increased pain intensity. These studies highlight the importance of proximal factors, such as current mood states, in the pain experience.

Social problems are known risk factors for mood dysregulation, higher levels of depression, anger, and negative affect (see Sturgeon, Zautra, & Arewasikporn, 2014). In turn, these negative emotional states may increase pain perception; this effect has been noted primarily for high-activation negative emotional states such as fear, anxiety, and anger. There is also evidence for a potentiating effect of depression on pain intensity, though this effect may be due to cognitive appraisals of pain, such as viewing pain in a catastrophic light (Berna et al., 2010). The mechanisms underlying the effects of negative mood on pain remain undefined but have been theorized to include increased muscle tension and overtaxing of the endogenous opioid system, which is responsible for pain perception and control in the body.

In addition to interpersonal conflict or threat, other social risks factors, such as limited or absent social resources or relationships, contribute to worsened pain and poorer long-term health for individuals with chronic pain. Chronic pain is associated with a susceptibility to social withdrawal (avoidance) when pain is high, which may decrease exposure to potential sources of positive social engagement, worsening the emotional consequences of pain (see Sturgeon et al., 2014). Isolation is also a risk factor for several pain-relevant difficulties, such as depression and decreased physical function. More generally, there is also evidence that loneliness may affect genome-wide transcriptional activity, leading to dysregulated glucocorticoid activity and potentially predisposing individuals facing chronic difficulties with loneliness to long-term inflammatory disease (Cole et al., 2007). Given that inflammatory dysregulation may contribute to difficulties with chronic pain in some instances, social isolation may be a significant risk factor for both the incidence of chronic pain and poorer adaptive responses once chronic pain has developed. In sum, social stressors, whether due to social conflict or challenge or to a lack of positive social interactions, constitute a significant source of vulnerability for individuals facing pain in the short and long term.

Social and Environmental Factors Promoting Effective Pain Adaptation

Although challenges in one's social environment can worsen the experience of pain, there is also evidence that the social world can promote positive adaptation to pain. Resilience to pain has been defined by an individual's capacity to effectively maintain meaningful function, recover from the deleterious effects of pain, and develop new capacities or knowledge after managing pain for a period of time (see Sturgeon & Zautra, 2010). A key contributor to resilience is social relationships, and earlier definitions highlighted the importance of individuals' utilization of social resources to recover from stress. In this vein, the frequency, nature, and quality of social interactions can powerfully affect an individual's ability to cope with chronic pain. An important aspect of pain resilience is positive emotion, which is often fostered through positive and meaningful engagements with other people.

Positive affect has been shown to promote resilient coping with chronic pain, as it has demonstrated myriad benefits for individuals experiencing acute or chronic pain. Positive emotions facilitate recovery from stress, bolster immune function, and improve cognitive flexibility and problem solving under stress (Fredrickson, 2001). Positive emotions have also been found to attenuate both clinical and experimental pain and to protect against pain catastrophizing (Hood, Pulvers, Carrillo, Merchant, & Thomas, 2012). Importantly, positive affect confers enduring protection, as it may inhibit the generalization of pain-related fear, a known risk factor in the prolongation of pain from acute to chronic states. Thus it stands to reason that individuals who effectively glean positive emotions from their relationships with others may be more resistant to the deleterious effects of pain. Indeed, positive or enjoyable interpersonal events have been shown to increase positive affect and protect against later states of fatigue (see Sturgeon et al., 2014). Furthermore, extraversion, the personality trait most closely related to positive social engagement, is predictive of more effective pain coping in arthritis populations and has been shown to contribute to resilience in arthritis populations.

The positive effects of social factors may also directly influence pain experience and coping. In general, individuals who are more willing and able to seek out social support tend to exhibit greater individual resilience and report greater life satisfaction and lower levels of depression. Individuals with chronic pain also report reduced pain and show less activation of the central nervous system during a pain induction procedure when they are in the presence of their significant other (Montoya, Larbig, Braun, Preissl, & Birbaumer, 2004). These effects are observed even in the absence of a significant other: viewing a photo of a loved one has been shown to dampen ratings for experimentally induced pain (Eisenberger et al., 2011; Younger, Aron, Parke, Chatterjee, & Mackey, 2010). The potent effect of love on pain may be attributable to the attenuation of the common neural networks underlying physical and social pain, the engagement of neural networks associated with reward (Younger et al., 2010), or the interpretation of a loved one as a sign of physical safety (Eisenberger et al., 2011). Social support may also engage prefrontal cortex activity associated with prosocial behavior, which may serve as a protective factor against pain by buffering pain-relevant negative emotional states (Onoda et al., 2009). In the long term, social support also appears to have a protective effect, as individuals with rheumatoid arthritis receiving greater levels of social support report less pain and functional disability 5 years later (for a review, see Evers, Zautra, & Thieme, 2011).

The effects of social support are decidedly more nuanced than they might initially appear, however. Beyond the mere availability of friends and family who may provide support during periods of stress, an individual's perception of the quality of their social relationships may influence or determine whether such support fosters resilient coping. While both the quality and quantity of social support predict successful adaptation to pain in fibromyalgia, the quality of social support appears to play a greater role in determining physical and psychological functionality (Franks, Cronan, & Oliver, 2004). A social network that is too large or focused on aiding an individual in coping with their pain may actually reduce self-sufficiency and long-term pain coping (Franks et al., 2004). Indeed, certain individuals may value extra emotional or instrumental support over the reduction of pain or emotional distress. Thus, individuals who value social validation above continued meaningful function may successfully achieve these goals and inadvertently lead themselves to less adaptive methods of coping with pain.

Indeed, women with fibromyalgia whose primary goals relate to social validation (rather than self-sufficiency) report lower levels of perceived social support, higher levels of interpersonal conflict, and more negative life events (Hamilton, Karoly, & Zautra, 2005). Such findings point to the need to assess each individual's social values, needs, and priorities within the context of pain.

Similarly, the quality of interactions with one's social network plays a meaningful role in the promotion of effective pain adaptation. When solicitous responses to pain are more frequent (i.e., asking a spouse for help in managing pain), individuals with chronic pain commonly demonstrate greater vulnerability to disability, greater pain intensity, and poorer overall adjustment to pain. Conversely, more mindful and empathic spousal responses are associated with greater perceptions of spousal support. Though this area of research is relatively nascent, the value of emotional support may be enhanced by mutual prosocial behavior between an individual coping with pain and a loved one. This type of interaction is predictive of greater well-being, lower distress, and greater perceptions of relationship quality for both members of a romantic relationship.

Social Interventions for People with Chronic Pain

Can the troubled social relations of those with chronic pain conditions be reversed and the potential for positive social relations realized through carefully designed interventions? In some quarters the prevalent thought is that capacity for social connections is fixed in childhood, or at the latest, in early adulthood. Others have argued that social development can be advanced even into adulthood (e.g., Division of Behavioral and Social Research, National Institute on Aging, 2013; https://www.nia.nih.gov/research/dbsr). A research team led by one of the authors of this chapter (www.socialintelligenceinstitute.org) has developed an online social intelligence (SI) intervention that focuses on enhancing capacities of adults to develop the skills to sustain positive social relationships and the awareness of the value of sustainable social connections. The SI training program has been guided by the objective of the humanization of relationships, with lesson plans informed by latest evidence from social neuroscience and related fields with attention to cognitions that facilitate healthy social connections. However, the approach extends beyond cognitive models and behavioral principles to include attention to evidence of barriers to social–emotional development from adverse experiences in childhood and adult life and ways to move beyond those stressful experiences. Recent empirical evidence shows this type of program offers a promising resource for chronic pain patients and those who care for them (Zautra, Zautra, Gallardo, & Velasco, 2015).

Summary

Though models of pain have evolved over the years to incorporate a greater number of non-biological processes, including cognition, emotion, and behavior, relatively less attention has been paid to social factors that may influence perception and adaptation to pain. The social environment is a powerful influence on the experience of pain and may either promote or inhibit effective coping, depending on the circumstances. As the understanding of the neural, genetic, biological, and psychological factors at play in pain becomes more sophisticated, future models of pain and its relationships to all aspects of human functioning can be further enhanced by acknowledging the social context in which pain is experienced.

Author Biographies

John A. Sturgeon is an acting assistant professor and clinical psychologist at the Center for Pain Relief at the University of Washington Medical School. His research examines the physiological, psychological, and social factors that contribute to resilience and vulnerability in chronic pain and stress, as well as psychological interventions designed to promote effective adaptation to chronic pain.

Alex J. Zautra was a professor of clinical psychology at Arizona State University Foundation. He dedicated his career to the study of resilience and ways of enhancing adaptation to stress. His latest work included the development of interventions that further the humanization of social relations. His most recent book, with coauthors Reich and Hall, is *Handbook of Adult Resilience* by *Guilford Press.* He also authored *Emotions, Stress, and Health* published by Oxford University Press.

Beth D. Darnall is a clinical associate professor in the Department of Anesthesiology, Perioperative, and Pain Medicine in the Stanford University School of Medicine and faculty in the Stanford Systems Neuroscience and Pain Laboratory. Her research broadly focuses on psychosocial dimensions of pain, characterizing the psychophysical impacts of pain-related stressors and developing targeted psychological interventions. She is the author of *Less Pain, Fewer Pills* (Bull Publishing).

Physician–Patient Communication

Tricia A. Miller and M. Robin DiMatteo

Department of Psychology, University of California Riverside, Riverside, CA, USA

Introduction

While impressive technological advances abound in modern medicine, effective physician–patient communication remains one (if not *the*) central component in the process and delivery of quality healthcare. Effective communication plays a critical role in the physician–patient relationship; communication allows for the exchange of meaningful information and ideas in order to achieve patients' therapeutic goals (Beck, Daughtridge, & Sloane, 2002; DiMatteo, 1994). To provide the best care, physicians must communicate trust and empathy (both verbally and nonverbally) in order for patients to feel comfortable disclosing medical information and sharing their experiences of living with illness (DiMatteo, 2004; DiMatteo, Hay, & Prince, 1986). In addition, research suggests that patients prefer and are more satisfied with a patient-centered approach to care (Cousin, Mast, Roter, & Hall, 2012). Patient-centered care encompasses a communication style in which physicians seek to understand patients' perspectives, attend to patients' psychosocial needs, and involve and collaborate with patients, especially in any decision making (Cousin et al., 2012).

Numerous studies, spanning over 40 years examining physician–patient communication, suggest positive and significant associations with various patient outcomes, including adherence to treatment recommendations, satisfaction, and physical and psychological health (Mallinger, Griggs, & Shields, 2005). Despite this empirical evidence, physician–patient communication is frequently judged to be inadequate (Beck et al., 2002). Some physicians overestimate their ability to effectively communicate (Tongue, Epps, & Forese, 2005), perhaps because of the complexity of the time-limited medical interaction itself or other variables (e.g., patients' type of illness or disease) that may influence the physician–patient relationship.

This entry will highlight the published literature on medical communication, including both the benefits and challenges associated with effective physician–patient communication. In addition, the effects of communication training and strategies for improving physicians' communication skills will be discussed.

Problems in Physician–Patient Communication

The communication problems in the physician–patient relationship include problems with diagnosis, a lack of patient involvement, or the inadequate provision of information to the patient (Stewart, 1995; Williams, Davis, Parker, & Weiss, 2002). Many of these problems can arise during history taking or even during the discussion of how the patient's illness or disease should be appropriately managed (Stewart, 1995). Problems may also arise from a lack of communication skills on the part of either the physician or the patient. For patients, low levels of health literacy are particularly challenging, leading to misunderstanding of medical directives, nonadherence, and poor health outcomes (Zhang, Terry, & McHorney, 2014). Studies suggest that due to ineffective communication during the medical visit, physicians fail to recognize 50% of psychosocial and psychiatric problems that exist among their patients (Davenport, Goldberg, & Millar, 1987).

More than half of patients' problems and concerns are neither elicited by the physician nor disclosed by the patient, and about half of the time, physicians and their patients do not agree on the issue or medical problem presented during the medical visit (Starfield et al., 1981; Stewart, McWhinney, & Buck, 1979). Some studies also demonstrate that physicians interrupt their patients within 18 s of the patient beginning to speak in an effort to describe their medical issue. As a result, patients often leave the medical interaction dissatisfied with the communication and with the information they received from their physicians (Frankel & Beckman, 1989). These studies suggest that the problems in physician–patient communication are very common; research should continue to focus attention on communication skills training at all levels of medical education.

Physician–Patient Communication and Improved Outcomes

The benefits of effective communication are many. Studies examining the physician–patient relationship have found that effective communication has the potential to help regulate patients' emotions, facilitate the complete comprehension of medical information, and allow physicians to efficiently identify and understand their patients' specific needs, perceptions (including health beliefs), and treatment expectations (Ha, Anat, & Longnecker, 2010). Early research on effective physician–patient communication has identified positive and significant associations with patients' sense of control, autonomy, and ability to tolerate and adjust to pain (Roter, 1983). Some more recent studies have observed decreases in the length of hospital stays and fewer referrals and decreases in the cost of individual medical visits and malpractice litigation as a result of effective communication (Eastaugh, 2004; Little et al., 2001).

Physicians with adept communication skills can improve patient adherence. Patients typically make their health decisions based on their own beliefs, which may or may not be accurate, in the value and expected efficacy of the recommended treatment (DiMatteo, 2004). When effective communication allows physicians to be part of this evaluative process, it can be carried out in a way that is evidence based and avoids irrational or anecdotal conclusions. Additionally, interpersonal aspects of communication can affect patients' responses to medical recommendations. Rapport and the communication of emotional support through nonverbal communication skills (e.g., facial expressions, body posture and movements, touch, eye contact, physical distance and orientation, vocal cues) can also help to facilitate and ensure trust within the therapeutic relationship (DiMatteo, 1994; Mast & Cousin, 2013). Research suggests that if the verbal information being communicated by physicians does not align with the nonverbal behaviors that patients expect, the result can be a decrease in the level of support and empathy felt by patients (Ong, Visser, Lammes, & de Haes, 2000).

Effective communication is also related to physician satisfaction. Studies suggest that patients who are more satisfied (as a result of effective communication) tend to have physicians with greater job satisfaction and less work-related stress and who feel less burnout (Maguire & Pitceathly, 2002). Some researchers even suggest a possible reciprocal relationship between communication and physician–patient satisfaction. It is possible that patients who are more satisfied with the communication during the medical visit behave in ways that reflect this satisfaction and thus positively influence their physicians' overall satisfaction and vice versa.

Collaborative Partnership and Improving Communication

One of the best-known ways of improving communication in the physician–patient relationship is to ensure an exchange in which both physicians and patients collaborate and engage in shared decision making (Ha et al., 2010). This type of collaborative partnership requires physicians to offer treatment choices and allows patients to share in both the responsibility and control over any decisions made. Through the process of negotiation, care options are evaluated and tailored to the context of patients' situations and needs, rather than a standardized treatment protocol (Ha et al., 2010). Research suggests, however, that patients differ in the degree and type of participation they prefer. For example, older and/or more seriously ill emergency patients desire to be less involved in their care compared with patients who are younger and/or less seriously ill (Jahng, Martin, Golin, & DiMatteo, 2005). This research not only suggests the importance of collaborative partnership through effective communication but also highlights the need for prescreening of patients' involvement preferences in order to maximize the effectiveness of medical care delivery.

Many techniques exist to help physicians improve their communication skills. Eastaugh (2004) detailed three effective ways to improve communication. First, physicians must focus on their patients' concerns by exhibiting empathy through actively listening and making eye contact with their patients. Physicians must also engage their patients by using open-ended questions and avoiding using medical jargon or interrupting their patients; this sets the groundwork for a true collaborative partnership. Second, physicians must take the time to properly educate their patients (e.g., clearly defining and describing unfamiliar terms, using the "teach-back" method, and providing patients with written medical information in the form of pamphlets and brochures) to ensure complete comprehension of the prescribed treatment plan. This technique is especially important given some empirical evidence that suggests that physicians often overestimate the amount of information they provide. For example, physicians in one study believed that they provided at least 6 min of patient education, but after careful observation and analysis, it was found that the physicians provided only 40 s of education (Eastaugh, 2004). Lastly, physicians must seek to enlist their patients as collaborative partners in the decision-making process. Doing so can empower patients to question and voice their prior misconceptions and ultimately learn new disease management techniques (Eastaugh, 2004).

Communication Skills Training

Health psychologists and medical educators have sought to determine how best to teach communication skills to physicians and medical students in order to improve patient care (Haskard et al., 2009). Many training programs have been developed and evaluated (e.g., Communication Skills Mentors Program introduced by the Bayer Institute for Healthcare Communication), and the assessment of physicians' communication skills has recently been added to medical certification programs (Haskard et al., 2009). Effective communication may not be easy, but it is a trainable skill; intervention studies show that training in communication skills can make a significant difference in patient outcomes. Communication skills such as information giving and active listening, for example, can be enhanced through training (Fallowfield, Jenkins, Farewell, & Solis-Trapala, 2003).

In a quantitative meta-analysis, researchers found that communication skills training for physicians resulted in substantial and significant improvements in patient adherence; the odds of patient adherence were 1.62 times higher when physicians received communication training compared with when physicians were not trained (Zolnierek & DiMatteo, 2009). Additionally, training both physicians and patients to be effective communicators was related to increases in physician and patient satisfaction, willingness to recommend the physician, and the amount of health behavior counseling provided by physicians (Haskard et al., 2009). If only physicians *or* patients were trained in communication skills, however, physicians' level of stress increased, and their satisfaction decreased (Haskard et al., 2009). Currently, there is much debate over whether or not these improved behaviors may lapse over time, given that medical students' skills in talking with patients tend to decline as their medical education progresses (Ha et al., 2010). Thus, in order to deal with the challenges of shifting patient expectations, the increases in complex treatments, and the many constraints imposed by accountable/managed care, it is imperative that physicians practice optimal communication skills and seek ongoing performance feedback (Tongue et al., 2005).

Conclusion

Effective physician–patient communication fosters more positive health outcomes and a higher quality of healthcare for patients. Most complaints and malpractice suits against physicians are related to issues of communication and not necessarily clinical competency. Patients want physicians who can skillfully diagnose, detect problems early, prevent medical crises and expensive interventions, and provide better support; effective communication can help to facilitate and ensure these outcomes (Levinson, Lesser, & Epstein, 2010). Continued efforts must be made to identify the types of communication skills (or communication training interventions) that are most effective in improving communication and the degree to which communication training can reduce healthcare disparities and improve care for all patients. Policy makers and health systems leaders must recognize that in order for physicians to provide patient-centered care, they must be trained in the skills that enable them to communicate most effectively (Levinson et al., 2010). Finally, communication skills must be taught at all levels of medical education, and physicians must actively seek out, practice, and receive feedback on effective communication techniques toward the goal of better patient care.

Author Biographies

Tricia A. Miller received her PhD in psychology from the University of California at Riverside. Her research focuses on the social psychological process of health and medical care delivery including patients' health literacy. She also studies the effect of provider–patient communication on the promotion and maintenance of treatment adherence and patients' overall health outcomes.

M. Robin DiMatteo, PhD, is Distinguished Professor of Psychology Emerita at the University of California, Riverside. She received her PhD degree from Harvard University and has served as a resident consultant in health policy at the RAND Corporation. Dr. DiMatteo has been elected Fellow of the American Association for the Advancement of Science and received grant funding from numerous agencies and foundations including the Investigator Award in Health Policy Research from the Robert Wood Johnson Foundation.

Placebo and Nocebo Effects

Andrew L. Geers and Fawn C. Caplandies

Department of Psychology, University of Toledo, Toledo, OH, USA

Historical Context

Prior to the scientific era of medicine, the remedies used for medical care were largely ineffective or, worse, harmful to recipients. In the few cases in which therapeutic ingredients had value, they were inappropriately administered, given in the wrong dose, or combined with so many diluting and contrary substances that the remedies were rendered useless (Shapiro & Shapiro, 1997). Examples of early ingredients include the eating of live frogs, cast-off snake skin, spider webs, wood lice, human bones, and goat intestines and drinking the blood of an enemy. Medical interventions involved activities such as dehydration, bloodletting, magnetism, exorcism, and attaching leeches to the body. Although such treatments appear peculiar now, there was considerable belief in their utility and frequent reports of treatment efficacy. Many medical scholars have concluded that the benefits experienced in early medicine were, to a large extent, the product of what has been called placebo effects.

The word placebo entered the English language in the thirteenth century when it was translated from Latin as meaning “to please.” Between the eighteenth and nineteenth century, the word placebo developed into a term for fake treatments that are administered to placate patients. While the administration of placebos was openly viewed as the unsavory practice of disreputable practitioners, placebo treatments remained a common medical tool. Perspectives on placebos shifted in the middle of the twentieth century when concern about bias in medical research led to the scientific practice of administering inert treatments to control participants in randomized controlled trials (RCTs). The use of placebo control groups in RCTs was spurred on by an influential paper, “The Powerful Placebo,” in which Henry Beecher (1955) concluded that approximately 35% of patients in research trials benefit by simply being given a placebo. Since this time, the use of placebo control groups has become the gold standard in clinical research, and more placebos have been dispensed to participants in RCTs than any other drug or medical treatment.

Even though placebo treatments have been administered throughout recorded human history and lay theories of placebo effects abound, empirical exploration into the topic is rela-

tively recent. Initial experimentation on placebo effects began in the 1960s and has flourished during the past two decades. This increased attention can be observed in publication records, with fewer than 25 empirical publications in PubMed focused on placebo effects in the year 1992 to more than 200 in the year 2011. The interest in placebo effects likely came about for a number of reasons, including pioneering neurobiological studies linking placebo effects to detectable changes in the brain and a broader recognition of the importance of psychological mechanisms in health outcomes. With this influx of research has emerged the perspective that placebo effects, like pharmacologically active treatments, are fundamental to successful healthcare (Colloca & Benedetti, 2005). Rather than discounting placebo effects, there is now a push to find strategies to enhance them. From a broader scientific perspective, placebo effects provide a rich opportunity to study the interplay of complex psychological and neurological processes. Further, work on placebo effects is transdisciplinary and integrates diverse scholarly fields including psychology, anthropology, neuroscience, ethics, chemistry, and countless branches of medicine.

Reconceptualizing Placebo Effects

Placebo effects have traditionally been defined as the result of inert treatments. As data mounted, however, such definitions proved problematic. For example, if placebo effects are defined as the consequences of inert agents, how does this explain the genuine psychobiological changes that are observed in numerous placebo studies? Recent research supports the position that the phenomenon actually centers on expectations and the meaning ascribed to the medical situation rather than to the inertness of a treatment. Contemporary definitions of placebo effects now describe them as psychological or physiological changes that are directly attributed to receiving a substance or undergoing a procedure, but that are not the direct consequence of the inherent power of that substance or procedure (Stewart-Williams & Podd, 2004). When defined in this way, placebo effects are not only a result of the administration of inert agents. Instead, they are a component of all medical treatments—the component that can be attributed to an individual's treatment expectations and interpretations (Benedetti, 2009).

In discussing placebo effects, it is important to address three common points of confusion. First, improvements observed in placebo control conditions in RCTs are not a direct indicator of placebo effects because placebo-controlled RCTs are designed to assess treatment effects by comparing a treatment group to a placebo group. To isolate placebo effects, researchers need an additional group, termed a no-placebo control group, in which participants are not given either an active or inert treatment. The difference between a placebo group and a no-placebo control group corresponds to the placebo effect. Without this third condition, it is unclear if any improvement observed in the placebo group was the sole result of placebo effects or the result of confounding factors such as spontaneous remission, history effects, and regression to the mean.

Second, placebo effects are sometimes classified as a non-specific effect. However, research has uncovered much about the causes of placebo effects, as well as the precise psychological and biochemical mechanisms underlying placebo effects. Thus, placebo effects have demonstrated specificity and do not fit the non-specific category. Third, and relatedly, as with medical treatment effects, there is a wide array of pathways by which placebo effects emerge. As such, rather than only one placebo effect, there appear to be many types of placebo effects. This final point is notable as it speaks to the long-standing question of the extent of placebo effects' power in medical care. Attempts to estimate the magnitude of placebo effects began with Beecher's (1955) influential paper on the power of placebo effects and have been extended in more recent meta-analytic reviews. As there are various and distinct processes responsible for placebo effects, however, there is likely no single answer to this magnitude question.

Nocebo Effects

Nocebo effects refer to negatively valenced placebo effects and result from the anticipation of unpleasant treatment outcomes. As with placebo effects, contemporary research finds nocebo effects across symptom domains and in both clinical and experimental studies (Colloca, Arve Flaten, & Meissner, 2013). Because of the ethical issues involved in providing negative symptom expectations to patients, nocebo effects have been investigated less frequently than placebo effects. Although nocebo and placebo effects may involve some distinct processes, nocebo effects are often deemed a variant of the broader placebo effect phenomenon. Keeping with this perspective, much of what is discussed herein pertains to both placebo and nocebo effects.

One notable way nocebo effects diverge from placebo effects is the occurrence of unpleasant treatment side effects in patients. Researchers have found that side effect warnings provided by practitioners, direct-to-consumer medical advertising, and informed consent protocols can all produce nocebo responses. For example, Myers, Cairns, and Singer (1987) found that listing gastrointestinal side effects on an informed consent document significantly increased the frequency of gastrointestinal symptoms reported by unstable angina patients. Notably, nocebo side effects do not always manifest, and they can be moderated by variables including worry and, in pain studies, beliefs about how one reacts to pain.

Placebo Effect Research

The basic experimental procedure to test for placebo effects is to provide a treatment efficacy message to one group of participants (e.g., this pill will reduce your pain) and then compare the responses of this group with a second group who was not given this efficacy message. To isolate the impact of this manipulation on treatment outcomes, inert treatments are typically administered to all participants. Studies using this design find that the verbal information provided about a treatment is central in determining the illness experience and the symptomatic expressions of disease. Experiments have uncovered placebo effects across cultures and ages and with samples ranging from healthy volunteers to patients undergoing surgery. Although placebo effects occur in various domains, they are particularly likely to arise in studies of pain, anxiety, and depression.

Placebo effects have been found with a wide variety of dependent measures, including subjective assessments of moods, itch, sleep quality, pain, and drug cravings. Although important, findings on subjective measures are not incontrovertible evidence for placebo effects. This is because subjective measures are prone to biases including demand characteristics, experimenter expectancy effects, and response shifts. Importantly, placebo effects have been exhibited on other dependent variables including cognitive processing measures such as reaction time, word generation, Stroop interference, and implicit learning; behavioral measures such as sleep latency, alcohol consumption, talking time by socially anxious individuals, and motor performance in Parkinson's disease patients; and physiological measures including salivary cortisol, startle eyeblink reflex, bronchoconstriction in asthmatics, and beta-band frequency during sleep. The reach of placebo effects, however, is not unlimited. Placebo effects do not alter disease parameters such as the size of cancerous tumors.

In addition to treatment efficacy information altering the effects of *inactive* treatments, it also changes the efficacy of *active* treatments. For example, many researchers have studied placebo effects by using the balanced placebo design in which treatment efficacy information (e.g., stating that a pill contains caffeine or not) and treatment agency (e.g., administering caffeine pills or not) are independently manipulated. Although results from balanced placebo designs vary, many find that stating that a treatment is efficacious amplifies the effectiveness of active treatments. In a conceptually similar vein, studies employing the open–hidden paradigm (Colloca & Benedetti, 2005) compare the impact of pharmacologically active treatments when patients are aware and unaware of the timing of a treatment administration (e.g., automatic intravenous drip hidden from view). This work has revealed that when the dose of an active treatment is covertly given, its specific efficacy can be substantially reduced—that is, without the awareness of their administration, active drugs are less effective.

Despite the remarkable progress in research on placebo effects, many uncertainties remain. Perhaps most notably, the magnitude and direction of placebo effects can be unpredictable. Some of these inconsistencies may be attributable to the diversity in treatment domains, samples, verbal efficacy manipulations, and contexts used in placebo studies.

Psychological Mechanisms

Theoretical dialogue regarding psychological processes underlying placebo effects have largely focused on two factors: expectations and classical conditioning. Classical conditioning explanations posit that placebo effects can be conditioned responses, with active medications as the unconditioned stimuli and the methods or techniques used to administer or accompany treatments as the conditioned stimuli. A substantial body of human and animal laboratory work demonstrates that conditioning can produce placebo effects. Also, increasing the number of conditioning trials results in stronger placebo effects, prior experience with an effective treatment strengthens placebo effects, and placebo effects can emerge from social observational learning (Colloca et al., 2013). Even though placebo research has given considerable attention to conditioning, expectations are generally viewed as the primary psychological mechanism underlying placebo effects. In fact, theoretical and experimental work now points to the view that conditioning is an associative process by which expectancies develop.

Expectancy explanations hold that the placebo effects are driven by the belief that receiving a treatment results in a particular response or outcome. One influential approach is response expectancy theory (Kirsch, 1999), which posits that placebo effects are caused by anticipated automatic reactions. That is, expectations are said to serve a preparatory function and directly stimulate expectancy-based responses. An extensive array of work supports the position that expectancies cause placebo effects. For example, the same inert treatment can lead to arousal or sedation depending upon the expectancy message provided. Further, modifying the characteristics of an expectancy message can change the magnitude of placebo effects. For example, double-blind expectations (e.g., you may or may not be given an active drug) often produce weaker placebo effects than deceptive expectations (e.g., you have been given an active drug). Investigations also find that self-reported expectations can mediate the association between treatment efficacy messages and placebo effects (Stewart-Williams & Podd, 2004).

What are the pathways by which expectations bring about placebo effects? It appears there are at least four overlapping pathways (see Benedetti, 2009; Colloca et al., 2013; Geers &

Miller, 2014). First, expectations can produce beneficial outcomes by reducing anxiety and decreasing the activation of threat-related centers in the brain. Thus, sometimes expectations lead to placebo effects because expecting an effective treatment lessens anxiety. In the case of nocebo effects, negative expectations increase rather than decrease threat and anxiety. Second, other work suggests that anticipating improvements from a treatment increases positive feelings through opioid and dopaminergic reward mechanisms in the brain. That is, expectations engender placebo responding by activating endogenous reward processes. Third, expectations can act as an interpretive guide, directing attention, detection, weighting, attributions, behavior, and recall of somatic experiences. Finally, conditioning and nonconscious priming studies indicate that placebo effects can arise from cues activating simple associative responses.

Neurobiological Mechanisms

One of the fastest growing areas of placebo research concerns the neurobiological pathways involved in the effect. This line of work clearly overlaps with the aforementioned work on psychological mechanisms. Research in this area began with a landmark study by Levine, Gordon, and Fields (1978) in which the opioid antagonist naloxone was found to block placebo responses in a pain paradigm. These results were the first to implicate the endogenous opioid system in placebo pain relief (termed placebo analgesia). Since this time, opioid, cannabinoid, and cholecystokinin endogenous mechanisms have been connected to placebo analgesia.

Brain imagining studies have been critical in clarifying the neurobiological mechanisms underlying placebo effects (for reviews, see Benedetti, 2009; Colloca et al., 2013). For example, experimental work indicates that placebo analgesics work by decreasing activity in the same pain-processing regions of the brain (e.g., the anterior cingulate cortex and the prefrontal cortex) as pharmacological pain treatments. Thus, placebos appear to produce change through some of the same pathways as the drugs they are often tested against. Several studies have revealed that in addition to changing activity in brain networks, placebo treatments can involve the descending inhibition of spinal nociceptive processes. Other work reveals that, in contrast to placebo expectations, nocebo expectations are associated with greater activity in the anterior cingulate cortex and the prefrontal cortex and stronger pain-related activity in the spinal cord. Outside of the arena of pain, researchers have found that in patients suffering from Parkinson's disease, placebo effects in motor performance are associated with dopamine release in the striatum.

Moderators of Placebo Effects

One of the most vexing puzzles in the placebo literature has been why some people display a placebo response in a given context and others do not. In early placebo research this issue was often framed in terms of locating the "type" of individuals who responds to a treatment expectation—labeled placebo responders. The possibility that there is a placebo-prone personality has been frequently studied. Despite these efforts, few if any individual difference variables reliably predict placebo responding across contexts (Geers, Kosbab, Helfer, Weiland, & Wellman, 2007). For example, relationships between placebo effects and personality variables such as introversion, optimism, empathy, social desirability, and self-esteem occur in some contexts, but not others. Relatedly, individuals responding to one placebo manipulation do not reliably respond to a different placebo manipulation. That said, much of this research has focused on personality differences, whereas a new wave of research is assessing whether genetic and biological factors predict placebo responding (Hall, Loscalzo, & Kaptchuk, 2015).

Other lines of research have focused on situational factors that alter the success of placebo treatments. Many contextual factors alter the magnitude of placebo effects. These factors include aspects of the healthcare practitioner (e.g., white lab coat, a practitioner's belief in treatment efficacy), properties of the treatment (e.g., number, size, color, brand, cost, and taste of pills), and properties of the administration procedure (e.g., injection, oral). Another factor that appears to moderate placebo effects is whether an active or passive placebo is employed. Active placebos produce side effects that are detectable by individuals, whereas passive placebos do not. Active placebos provide cues to the recipient that a treatment is effective and may lead to a stronger belief in treatment effectiveness than passive placebos.

Recently, research has begun to consider the interactive effects of individual differences and situational factors in producing placebo effects. This work suggests that placebo effects are determined by the match between the context and the person's current motives, prior experiences, and chronic tendencies. For example, Colloca and Benedetti (2009) induced placebo effects in three groups, one through a verbal message, one via conditioning, and one via observational learning. In this study, empathy motivation predicted placebo responses, but only when the placebo effect was induced through observational learning.

Placebo Effects in Modern Times

Placebo effects may be commonplace in modern treatments for physical and mental health. For example, in controlled clinical trials, some standard treatments, including cough suppressants and dietary supplements, often do not differ from placebo controls—suggesting that they possess a strong placebo component (Moerman, 2002). There is also considerable data indicating that the benefits of many contemporary and alternative medicines, which amount to approximately 34 billion dollars annually, benefit substantially from placebo effects (Moerman, 2002). Evidence consistent with this notion comes from a series of clinical trials with chronic pain patients that compared real acupuncture with sham acupuncture. Although no differences were found between the two groups, patient beliefs about the efficacy of acupuncture were a reliable predictor of pain relief (Bausell, Lao, Bergman, Lee, & Berman, 2005). In terms of mental health, Kirsch found that approximately 70% of antidepressant effects can be attributed to placebo effects (Kirsch, 1999). Psychotherapy is another arena in which placebo effects are likely to be strong. Difficulties in developing precise placebo control groups for psychotherapy, however, leave the exact contribution of placebo effects in this domain unknown. Finally, recent surveys across a variety of countries indicate that many physicians continue to use placebo treatments in routine practice. For example, a survey of 679 practicing internists and rheumatologists in the United States found that 58% reported prescribing (mainly active) placebo treatments on a regular basis (Tilburt, Emanuel, Kaptchuk, Curlin, & Miller, 2008).

Clinical Translation

A difficulty in the placebo effect literature has been determining how to harness the placebo phenomenon to improve patient care. This problem arises because research generally employs deceptive expectation manipulations to generate placebo effects, whereas the overt use of deception is not permitted by medical codes of conduct. The fact that placebo effects can be conditioned provides some opportunities for translation. For example, researchers have paired placebos and active drugs given to participants and then removed portions of the active drug over time (Doering & Rief, 2012). These studies suggest that placebos can be used to maintain drug responses after the initial associative pairing. Another intriguing development in translation is the creation of the "open label" paradigm in which participants are explicitly informed that they have been administered a placebo and are additionally told that placebos yield beneficial effects. In open label experiments, participants have improved from placebo treatments even when they were aware that their treatment was inert (Kam-Hansen et al., 2014).

Another approach to enhancing placebo effects in medical care arises from the notion that all treatments have a placebo (e.g., expectation) component. Thus, rather than directly administering inert treatments, benefits can arise from altering contextual factors that strengthen the placebogenic portion of a standard treatment. For example, research indicates that when individuals have an opportunity to choose between placebo treatments, they may exhibit larger placebo effects compared with participants assigned a placebo treatment (Geers et al., 2013). This work suggests that in some cases physicians could increase placebo responding by encouraging greater patient involvement. The patient–provider interaction provides another opportunity for enhancing placebo effects in medical settings (Benedetti, 2009). Evidence for the importance of the therapeutic encounter in placebo responding comes from a study in which patients with irritable bowel syndrome were randomly assigned to a wait list group, a placebo acupuncture group, or a group that received placebo acupuncture with a supportive practitioner (Kaptchuk et al., 2008). The supportive practitioners were instructed to listen to participants and to be warm, confident, and thoughtful. The results revealed that participants with the supportive practitioner reported greater improvement than the other two groups 3 weeks later. These data suggest that practitioners can play a key role in strengthening the placebo component of treatments. Although aspects of the patient–provider relationship seem to alter placebo effects, more research is needed to clarify the specific factors that best enhance placebo responding in such interactions.

Conclusion

Over the last several decades, the concept of placebo effects has evolved into a topic of scientific inquiry in its own right. Research reveals that placebo effects influence meaningful physical and mental health outcomes and this phenomenon is not static but has many moderators. Research is now uncovering the psychobiological processes responsible for placebo effects. This work bridges disciplines and points to avenues by which to improve patient care, as well as our understanding of the interplay of psychological and neurological processes.

Author Biographies

Andrew L. Geers is a professor of psychology at the University of Toledo. He is interested in the advancement and application of personality and social psychology theory within health and medical contexts. His primary research interests are in the areas of placebo effects, optimism, health behavior, and assimilation and contrast models. He received his BA from the University of Cincinnati and his PhD in experimental psychology from Ohio University.

Fawn C. Caplandies is a graduate student in social psychology at the University of Toledo. She received her BA from Hartwick College in 2013. Her primary research interests are in placebo effects, expectations, and the psychophysiology of stress and coping.

Positive Affect

Brooke N. Jenkins, Amanda M. Acevedo,
and Sarah D. Pressman

Department of Psychological Science, University of California Irvine, Irvine, CA, USA

Positive affect (PA), such as feelings of happiness or joy, has been tied to many health and physiological benefits. For example, a meta-analysis of the benefits of PA on mortality found that individuals high in PA were 18% less likely to die within the follow-up periods of over 20 years (Chida & Steptoe, 2008). This effect size is similar in magnitude to the effects of smoking cessation programs for smokers on mortality indicating that it may be critical to uncover the dynamics of the PA–health relation. This entry will start by outlining the methodological issues when studying PA, briefly review the literature, and then discuss potential mechanisms connecting PA to health. Finally, we end with a discussion of positive psychology interventions (PPIs) in a health context and future directions for this field.

Methodological Themes and Issues in the Study of PA and Health

Definitions of PA vary with an array of adjective and question types utilized to assess this characteristic. Thus, it is critical for researchers to think carefully about which types of PA are assessed by their measurement tools. The Positive and Negative Affect Schedule (PANAS) (Watson, Clark, & Tellegen, 1988) and the Profile of Mood States (POMS) questionnaire (Curran, Andrykowski, & Studts, 1995) are popular self-report methods used to assess PA in health studies. These measures assess either state or trait affect by asking participants to report on how they have felt in a recent period of time or how they generally feel, respectively. In the case of large medical studies, researchers often rely on alternative methodologies to assess PA. Because of time constraints, for example, some researchers use single-item measures of happiness or similar emotions. While these measures are not preferred, since they do not capture the full spectrum of the PA experience, they have been tied to future health outcomes. An alternative self-report measurement approach, especially in archival data approaches, is to use the positive items from depression scales as a source of PA (e.g., Center for Epidemiological

Studies Depression Scale [CESD]). While this approach has proved useful in predicting future health such as risk of AIDS mortality and stroke (e.g., Moskowitz, 2003), it is difficult to interpret what forms of positivity are most beneficial in these studies. The CESD PA items assess other positive constructs beyond PA (e.g., optimism, self-esteem), and since these have also been tied to wellness, we are left with a question as to what the active ingredients for good health are in these studies.

Related to this issue of "active ingredients" is the question of which types of items should be assessed and/or included in measures of PA and whether these components should be considered independently. The PANAS and POMS discussed above measure high arousal feelings of positivity to a large extent (e.g., vigor, excitement, interest). While these specific subcomponents have been tied to better health (e.g., longer lifespan, decreased cold infection; Cohen, Alper, Doyle, Treanor, & Turner, 2006; Pressman & Cohen, 2012), in excess, they can be harmful. In contrast, low arousal feelings of calm and peacefulness may be helpful for populations experiencing pain or high stress. Recent research has also examined specific positive emotions like love, desire, amusement, pride, and awe and shown that these do have distinct physiological profiles as well as distinctive behavioral correlates and signals. Although there is little research on the types of PA most helpful to different health outcomes at this point, there are many reasons to think that PA type matters and that, in some cases, examining broad measures of PA might obscure interesting subtype differences in predictions (Pressman, Jenkins, Kraft, Rasmussen, & Scheier, 2017).

Another consideration when picking a PA measurement tool in the context of health is *duration*. Instructions for affect assessment are often not considered carefully when scales are chosen, but how long PA lasts may have important implications for the health or physiological outcome at hand. For example, strong changes in state PA (i.e., transient emotions and moods) may influence physiology, for example, when assessed in a laboratory setting with acute challenges or manipulations of affect. Trait (i.e., stable, dispositional) PA, on the other hand, is likely the stronger predictor of future longevity and disease because it indicates how an individual *typically* feels. With that said, there is a high correlation between state and trait PA, which is likely responsible for studies showing state PA ties to survival. Of possible future interest, although not assessed in the literature broadly at this point, is the possibility that variability in state PA (i.e., fluctuation as opposed to average levels) may also be important.

Also of interest in measurement is the issue of whether there are limitations to the reliance on self-reports in this field, given that there are known response biases and social desirability concerns, among other possible problems. To address this, some researchers use alternative methods like obtaining writing and audio samples and coding positive words and laughter as markers of emotional style (Pressman & Cohen, 2012). Others have relied on observable expressions of positivity by coding facial expressions in photos or in person and have found them to be tied to mortality and disease outcomes. While there are limitations to these methods as well (e.g., language and culture norm differences), they do provide convergent validity and some indication of the generalizability of PA–health findings beyond self-report.

One final important issue in the measurement of PA is the role of negative affect (NA). Negative traits have been extensively related to health and, depending on the measurement, can be strongly correlated with PA (Watson et al., 1988). Thus, it is critical for researchers to answer the question of whether these effects are distinct phenomena. While rare in the NA–health field, PA researchers broach this problem by controlling for NA in their PA studies and/or contrasting the relative effects. This can be difficult, as many trait measures of affect have highly correlated PA/NA scales, creating multicollinearity issues in analyses. Thus, many researchers choose the PANAS to resolve this, which was specifically designed to have low overlap between valence dimensions, or rely on alternative negative measures (e.g., depressive symptoms), which overlap less with PA.

There are also methodological concerns specific to the health component of the PA–health question. One important concern is the conceptual and measurement overlap that exists when assessing health by self-report. Many health studies rely on participants to self-assess their health using questionnaires like the 36-item Short-Form Health Survey (SF-36). While known to be a good and valid predictor of objective health, the SF-36 actually includes items about happiness within it creating some clear overlap and interpretation problems. Researchers should therefore be cautious when picking self-report health scales. This is especially important when comparing self-report health scales with PA scales that assess energy (e.g., vigor, active) since these types of PA scales may tap elements of physical fitness and health. This can be partly addressed by controlling for these types of outcomes in analyses. Finally, it is important to remember that physiological and behavioral outcomes are not equivalent to health. While assessments of cortisol, blood pressure, and immune function as well as health behaviors (e.g., sleep, exercise) are key hypothesized mediators in the broader PA–health relation, when interpreting these outcomes, it is important to not reach too far since the level of change in parameters may not reach clinical significance.

PA–Health Review

The following sections consider the impacts of PA on the health outcomes most studied in conjunction with PA. When examining the influence of PA on future health, the gold standard is to survey participants on both PA and health (e.g., medical records, physicals, medications, fitness) at baseline and then follow up with them after a period of time has passed. While this prospective longitudinal design does not allow us to infer causality, it does give us more confidence that PA *may* be leading to future health if we control for health and its connection with baseline PA as best we can.

Longevity/Mortality

It is well established that PA is related to lower rates of mortality (e.g., Chida & Steptoe, 2008; Diener & Chan, 2011; Pressman & Cohen, 2005). A typical study design can be found by Kawamoto and Doi (2002) who evaluated older adults on baseline self-rated happiness and then assessed mortality rates 3 years later. Similar to other studies, individuals reporting higher happiness and cheerfulness at baseline were more likely to still be alive at follow-up. Beyond the typical self-report strategy, studies coding positive words in writing samples from autobiographies as an indication of PA have also found years of extended life benefit especially among those using more activated words. Similarly, coding of positive facial expressions in baseball player cards found a 7-year lifespan benefit for those with the most intense smiles even after controlling for relevant demographic variables. Although these non-self-report studies could not assess baseline health, attempts to do so by coding health words did not cancel out this effect, and we can assume that baseball players in their prime were in similarly good health given their professional athlete status. Thus, across numerous studies and PA measurement approaches, we see PA-related lifespan benefits.

While the consistency is impressive, there are some studies that have not shown these benefits. However, these studies are typically different from the above in some way. For example, studies that do not find such links assess child cheerfulness, middle-aged women, and older adults in assisted living facilities. Thus, PA does not hold equal benefit at all life stages, and perhaps other factors are more important predictors of longevity in these groups (e.g., current health status and/or health behaviors). However, given the paucity of research on these groups, more research is needed before making any firm conclusions.

Survival

PA–health researchers have also investigated the effects of PA on survival in populations with life-threatening disease. For example, one study assessed women with HIV for positive expectations, finding meaning, and PA using words adapted from the POMS and found PA was related to longer survival. However, this study did not separate the effects of PA from expectations and meaning, which made it difficult to know what drove these benefits. Related, Moskowitz (2003) found that for every standard deviation increase in PA (based on the CESD subscale), HIV+ men were 28% less likely to die during follow-up. These results were independent of CESD, NA, and other health-related factors relevant to this population. These results are consistent with other positive findings in samples undergoing heart surgery or with congestive heart failure.

Despite these benefits, the effects of PA in unhealthy populations are mixed. For example, the PA subscale of the NEO-PI (Neuroticism, Extraversion, Openness Personality Inventory) predicted 11-year survival in people with coronary artery disease after accounting for relevant demographic and health factors. However, the effect of PA became nonsignificant when the NEO-PI depressive subscale was added into the model. Similarly, PA assessed using the Mood Adjectives Checklist did not predict 1-year survival in recently diagnosed cancer patients with varying levels of cancer type, stage, and severity while depression (assessed with the CESD) did. It has been previously hypothesized that these mixed results are due to the limits of PA (Pressman & Cohen, 2005). That is, early-stage diseases that can be benefited by healthy behavior, support, and lower stress may be helped by high PA, whereas diseases that are far along (e.g., failing kidneys, late-stage cancer) may not benefit since at that point the pathways connecting PA to better health may be less potent. There is also the possibility that too much PA may be indicative of a failure to realistically cope with the negative aspects of a life-threatening disease, in which case affect balance may be a useful pursuit to examine in future studies.

Morbidity

Prospective studies assessing PA at baseline and then following up on rates of morbidity find that individuals higher in PA less frequently develop illness. For example, high PA is associated with a decreased likelihood of future coronary heart disease, injury, and stroke. While most studies are observational, experimental studies that exposed participants to cold viruses found that individuals with greater PA (averaged over 2 weeks) were less likely to develop a cold or flu (Cohen et al., 2006). These results were independent of NA. This study's objective illness measures (e.g., mucus weight, viral cultures) and experimental design are instrumental in clarifying that even when high PA individuals get exposed to a virus, they are less likely to get sick (as opposed to the alternative explanation that high PA individuals are less likely to be exposed to a virus). Together with the naturalistic findings, these results support that PA may confer resiliency to illness and disease. The strength of this literature is the impressive consistency (i.e., studies support an array of morbidity benefits). The weakness is that few morbidity outcomes have been replicated, calling for future studies to generate more data and increase our confidence regarding these positive associations.

Symptom Report, Severity, and Pain

PA is consistently associated with an array of self-reported health outcomes such as decreased symptom report, reduced reports of symptom severity, and less pain (e.g., DuBois et al., 2015; Finan & Garland, 2015; Sturgeon & Zautra, 2013). While most studies are cross-sectional, studies manipulating PA through, for example, loving-kindness meditation training (Fredrickson, Cohn, Coffey, Pek, & Finkel, 2008) or smiling (Pressman, Acevedo, Aucott, & Kraft, under review) in healthy samples have shown reductions in illness symptoms and perceived pain, respectively. Similar results have been found in studies of patient populations, such as those suffering from chronic pain (e.g., Finan & Garland, 2015; Sturgeon & Zautra, 2013) and cardiovascular disease (e.g., DuBois et al., 2015). These findings are more consistent across populations than the findings reviewed in previous sections. However, there may be reason to think PA can bias self-reports in a way that might not match underlying objective symptoms. For example, individuals high in trait PA who got sick following experimental exposure to an influenza virus reported fewer subjective symptoms than was expected given the objective markers of disease (e.g., mucus weight) suggesting a symptom reporting bias (Cohen et al., 2006). This study highlights the importance of measuring and reporting both subjective and objective markers of symptoms and/or pain when possible to clarify whether the relationship between PA and health is due to biased subjective reports or actual, biological resilience.

How Does PA "Get Under the Skin" and Benefit Health and Well-Being?

Main Effect Model of PA

Most researchers studying PA and health presume that PA benefits health through behavioral (e.g., better sleep, diet, exercise, medication adherence; Boehm & Kubzansky, 2012; Pressman & Cohen, 2005), physiological (e.g., cardiovascular, immune), and social (e.g., more social support and integration) pathways. These pathways are multidirectional (e.g., more social support may lead to better health behaviors, better health behaviors lead to healthier physiology). Newer studies in this area of research explore important pathways like inflammation, diet, and vagal tone (e.g., Kok et al., 2013) revealing consistent evidence that PA has direct connections to many of these pathways that provide a compelling explanation for *how* PA could influence health.

Stress-Buffering Model of PA

In contrast to the main effect model, PA may improve health by improving an individual's ability to handle stress, either by altering stress perceptions, reactions, or recovery (Pressman & Cohen, 2005). Under this model, PA is beneficial to health because it counters the negative health sequelae and physiological arousal tied to stressful experiences. For example, high PA individuals may have resources to help them cope better with stressors and recover faster. Although evidence supports that PA is beneficial during stress, it is unlikely that it is *only* beneficial during these times and, as explained with the main effect model, that PA even during non-stressful times has health-enhancing benefits.

Broaden-and-Build Theory

The broaden-and-build theory suggests that the evolutionary advantage of PA is to allow us to expand our resources by facilitating approach behaviors (Fredrickson, 2001) in contrast to NA, which narrows focus to dispel danger. For example, emotions such as joy, interest, and excitement may lead to actions like exploration, creativity, or play. These behaviors can build resources such as skills, knowledge, or social ties that will endure after the positive emotion has passed (Fredrickson, 2001) and benefit individuals during future situations. In the context of health, the broadened behaviors and cognitions experienced as a result of PA may provide individuals with physical resources, knowledge, or social connections that enable them to perform better health behaviors or reduce stress.

Taken together, these models show that happiness is not a black box that pushes out health, but that there are many reasons why PA should be good for an individual. Importantly, many of these paths do not make sense when considering the argument that PA is simply the lack of NA. For example, *not being negative* (but also not being positive) would not confer protection or recovery against stress. Similarly, the absence of NA would not encourage individuals to explore and build resources, while the presence of PA would. Certainly, further work is necessary with well-designed experimental and longitudinal studies to help us unpack these pathways; however, there are already several detailed conceptual models to build off of that will allow us to better understand the PA–health link.

Does Increasing PA Improve Health?

Now that we understand the multitude of interconnections between PA and health, we can ask the question: Can increasing PA improve health? This may be difficult given that many researchers consider PA (especially trait PA) to be relatively stable due to genetic factors and/or unchangeable circumstances (Lyubomirsky, Sheldon, & Schkade, 2005). Nevertheless, evidence also indicates that a reasonably large portion of PA may be unfixed (Lyubomirsky et al., 2005), and a meta-analysis of over 50 PPIs revealed that, overall, PPIs have a small-to-medium effect on increasing PA (Sin & Lyubomirsky, 2009). So, if we can successfully increase PA, will this initiate improvement in health? While there are only a few studies on this topic to date, they are promising. For example, researchers found a simple positive writing intervention led to fewer health center visits and better self-reported health and health behavior, even when the writing intervention was only 2 min each day for 2 days. A randomized controlled trial provided an educational intervention or an education plus PA induction intervention to a hypertensive African American sample. Individuals in the latter group had significantly higher medication adherence. While not typically assessing PA as an outcome, studies on mindfulness (which likely increases low arousal PA) have shown immunological, cardiovascular, and neurological changes (Kok et al., 2013). Similarly, increased PA after a loving-kindness meditation intervention led to increases in perceived social connectedness, which, in turn, increased vagal tone (Kok et al., 2013). While studies have not yet tested major differences in mortality, morbidity, or survival from PPIs, research has shown that these methods are acceptable for diseased populations. Although more research is needed to establish the benefits of PPIs, current results are promising. One important unknown, however, is what the active ingredients are that are responsible for health improvements. PA is a multifaceted construct, and it is likely that different kinds of PA are more or less helpful for future health and for those facing disease. Thus, researchers should take a nuanced and cautious approach as they enter this new territory.

Conclusion

The PA–health relationship is multifaceted and requires refined knowledge of how to measure and conceptualize both PA and health. Understanding these complex issues allows us to investigate how PA influences health outcomes like longevity/mortality, morbidity, and survival, as well as symptom report, severity, and pain. Several pathways, theories, and models can explain this PA–health link, and researchers can use this knowledge to fine-tune the effectiveness of interventions to target specific health outcomes. Future research in the area of PA–health will make great strides in our understanding of the role affect can play in health in particular by examining how different arousal components of PA influence health differentially, expanding research on the types of illnesses PA may impact, refining our understanding of the pathways of the PA–health link, and testing the bounds of the health benefits of PPIs.

Author Biographies

Brooke N. Jenkins is an assistant professor at Chapman University. Her work examines the effects of emotions on health. She is interested in methods for assessing emotions over time and how emotion variability influences physiological and behavioral health outcomes. She investigates new methods for assessing this variability, and in her research she works with a number of different populations including healthy children undergoing surgery and children with cancer, as well as healthy adults.

Amanda M. Acevedo is a graduate student at the University of California, Irvine. Her research program lies at the intersection of culture, emotion, and health. She is interested in how positive emotions and cultural factors might confer resilience during stress in general and in the context of pain in particular. She uses cardiovascular stress reactivity/recovery methods to examine how emotions and cultural factors might buffer stress in the lab.

Sarah D. Pressman is an associate professor of psychology and social behavior at the University of California, Irvine. Dr. Pressman's work examines how positive emotions are beneficial for physical health and the pathways by which positive psychosocial factors "get under the skin" to influence biology. She is especially interested in the role of positive psychosocial factors in protecting individuals from the harmful effects of stress and whether specific emotions confer resilience in the face of adversity.

The Precaution Adoption Process Model

To understand why many young adults put themselves at risk for AIDS, it seems logical to assess their beliefs about HIV and AIDS. A questionnaire based on some popular theories of health behavior might ask them about the likelihood that they will have sexual contact with someone who is HIV positive, their chance of becoming infected by this person, the effectiveness of various precautions, the social consequences of taking precautions, and other related topics.

This research strategy makes sense today. But in 1987, when the public was first hearing about AIDS, young adults would be completely unable to answer most of the questionnaire. The riskiness of their behavior would vary: some would have had many sexual partners; others would have had few or none. Some would use condoms, and others would not. Yet, these behaviors could not be explained or predicted by their beliefs about AIDS. *They had not yet formed such beliefs.*

As this example shows, theories that try to explain health behavior by focusing on beliefs about the costs and benefits of particular actions are relevant only to people who have been engaged sufficiently by the health threat to have formed such beliefs. The precaution adoption process model (PAPM) seeks to identify the stages that people need to pass through in order to commence health protective behaviors—including stages prior to being engaged by the issue—and to determine the factors that cause people to move from one stage to the next.

How Stage Theories Approach the Issue of Explaining and Changing Behavior

Many theories of individual health behavior, such as those focusing on the perceived pros and cons of action, specify and use a single equation to predict behavior. These theories acknowledge

General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

quantitative differences among people in their positions on different variables and, consequently, in their likelihood of action. The goal of interventions is to maximize the variables that increase the value of the prediction equation. Any action-promoting variable that has not already reached its maximum value is an appropriate target for intervention.

Advocates of stage theories, like PAPM, claim that there are *qualitative* differences among people and question whether changes in health behaviors can be described by a single prediction equation. They suggest, in effect, that we must develop a series of explanatory equations, one for each stage transition. This is a much more complicated goal than finding a single prediction rule, but it offers the possibility of improving prediction, accuracy, and intervention effectiveness and efficiency.

Stage theories have four principal elements and assumptions (Weinstein, Rothman, & Sutton, 1998):

1 A category system to define the stages

Stages are theoretical constructs. An ideal or "prototype" must be defined for each stage even if few people perfectly match this ideal. Furthermore, stages can be useful constructs even if the actual boundaries between stages are not as clear-cut as the theories suggest.

2 An ordering of the stages

Stage theories assume that before people act, they usually pass through all the stages in order. Forward progression, however, is neither inevitable nor irreversible. There is no minimum length of time people must spend in a particular stage. In fact, people may sometimes progress so rapidly that, for practical purposes, they can be said to skip stages (e.g., when a doctor recommends a new vaccine and the patient gets the shot without any further deliberation). Some stages may lie outside the route to action. An example is a stage representing people who have decided not to act.

3 Common barriers to change facing people in the same stage

Knowing the stage of an individual or group is helpful in designing an intervention program only if people at that stage must address similar types of issues before they can progress to the next stage. Thus, interventions can be tailored on the basis of stage.

4 Different barriers to change facing people in different stages

If factors producing movement toward action were the same regardless of a person's stage, the same intervention could be used for everyone, and the concept of stages would be superfluous.

A completely specified stage theory would include both the criteria that define stages and factors that govern movement between stages. Although stage definitions are meant to apply across behaviors, the specific barriers to progress may be behavior or hazard specific. Factors that enter into decisions to lose weight, for example, may be quite different from those that affect decisions to use condoms. A model that proposes a particular sequence of stages in the change process could be correct about these stages even if it has not identified all the determinants of each transition from one stage to the next. At present, the PAPM does not provide detailed information about barriers at each stage. It is a conceptual framework or skeleton that needs to be fleshed out with information about why each stage transition occurs.

The Precaution Adoption Process Model

Description of the Model

The PAPM attempts to explain how a person comes to a decision to take action and how he or she translates that decision into action. Adoption of a new precaution or cessation of a risky behavior requires deliberate steps unlikely to occur outside of conscious awareness. The PAPM applies to these types of actions, not to the gradual development of habitual behaviors, such as exercise and diet, in which health considerations may play little role (though it would apply to the initiation of a new exercise program or a new diet). Nor does the PAPM explain the commencement of risky behaviors—such as a teenager accepting her first cigarette—which seem to be better explained in terms of a "willingness" to act than in terms of any decision to act (Gibbons, Gerrard, Blanton, & Russell, 1998).

All PAPM stages prior to action are defined in terms of mental states, rather than in terms of factors external to the person, such as current or past behaviors. Neither are PAPM stages defined by criteria that are salient only to health professionals. For example, having less than 20% of calories in one's diet come from fat might be a behavioral goal of importance to a dietician, but laypeople are unlikely to be aware of or be able to track their progress toward such a goal. Their goals, and the appropriate definitions of stages for them, are more likely to center on particular foods, such as increasing the consumption of fish to three meals a week, and PAPM stages are defined in terms of goals that reflect lay objectives.

The present formulation of the PAPM (Weinstein & Sandman, 1992) identifies seven stages along the path from lack of awareness to action (see Figure 1). At some initial point in time, people are unaware of the health issue (stage 1). When they first learn something about the issue, they are no longer unaware, but they are not yet engaged by it either (stage 2). People who reach the decision making stage (stage 3) have become engaged by the issue and are considering their response. This decision making process can result in one of three outcomes: They may suspend judgment, remaining in stage 3 for the moment. They may decide to take no action, moving to stage 4 and halting the precaution adoption process, at least for the time being. Or they may decide to adopt the precaution, moving to stage 5. For those who decide to adopt the precaution, the next step is to initiate the behavior (stage 6). A seventh stage, if relevant, indicates that the behavior has been maintained over time (stage 7).

The stages have been labeled with numbers, but these numbers have no more than ordinal values. They would not even have ordinal value if stage 4 were included, since it is not a stage on the path to action. The numbers should never be used to calculate correlation coefficients, the mean stage for a sample, or conduct regression analyses with stage treated as a continuous variable. Such calculations assume that the stages represent equal-spaced intervals along a single underlying dimension, which violates a fundamental assumption of stage theory. Although

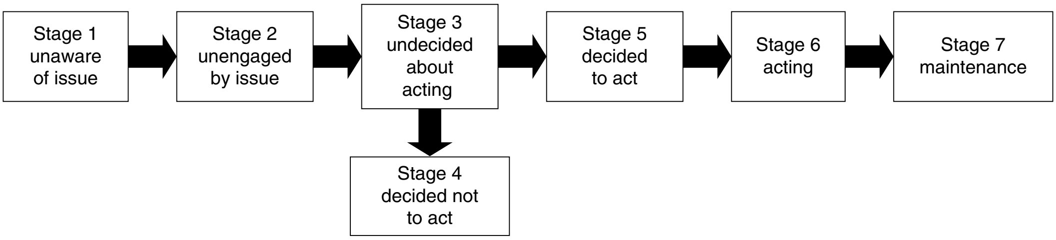

Figure 1 Stages of the precaution adoption process model.

not shown in Figure 1, movement backward toward an earlier stage can also occur, without necessarily going back through all the intermediate stages, although it is not possible to go from later stages to stage 1.

On the surface, the PAPM resembles another stage theory, the transtheoretical model developed by Prochaska and DiClemente (1983). However, even those stages with similar names in the two theories are defined according to quite different criteria. For example, the PAPM refers primarily to mental states, whereas the TTM emphasizes days or months until intended action. We are not aware of any research directly comparing the two theories.

Justification for the PAPM Stages

There should be good reasons to propose the separate stages that make up a stage theory. What is the justification for the stages in the PAPM?

Stage 1 (unaware)

Much health research deals with well-known hazards, like smoking, AIDS, and high-fat diets. In such cases, asking someone about his or her beliefs and plans is quite reasonable; most people have considered the relevance of these threats to their own lives. But if people have never heard of a hazard or a potential precaution, they cannot have formed opinions about it. The reluctance of respondents to answer survey questions about less familiar issues suggests that investigators ought to allow people to say that they "do not know" or have "no opinion" rather than forcing them to state a position. Participants in many health behavior investigations are not given this opportunity. Even when participants are permitted to say that they "do not know," these responses are often coded as missing or are collapsed into another category. To say "I do not know" indicates something important and is real data that should not be discarded.

Media often have a major influence in getting people from stage 1 of the PAPM to stage 2 and from stage 2 to stage 3 and much less influence thereafter. This and other factors that may be important in producing different transitions are given in Table 1 and in Weinstein (1988). These are suggestions for consideration, not core assumptions of the PAPM.

Table 1 Factors likely to determine progress between stages.

Stage transition	*Factor*
Stage 1 to stage 2	Media messages about the hazard and precaution
Stage 2 to stage 3	Media messages about the hazard and precaution Communications from significant others Personal experience with hazard
Stage 3 to stage 4 or stage 5	Beliefs about hazard likelihood and severity Beliefs about personal susceptibility Beliefs about precaution effectiveness and difficulty Behaviors and recommendations of others Perceived social norms Fear and worry
Stage 5 to stage 6	Time, effort, and resources needed to act Detailed "how-to" information Reminders and other cues to action Assistance in carrying out action

Stage 2 (unengaged) versus stage 3 (undecided)

Once people have heard about a health precaution and have begun to form opinions about it, they move out of stage 1. However, so many issues compete for their limited time and attention that people can know a moderate amount about a hazard or a precaution without ever considering whether they need to do anything about it.

We believe that this condition of awareness without personal engagement is quite common. In a 1986 survey of radon testing (Weinstein, Sandman, & Klotz, 1987), for example, 50% of respondents in a high-risk region said they had never thought about testing their own homes even though all indicated that they knew what radon was, and most correctly answered more than half of the questions on a knowledge test.

The PAPM suggests further that it is important to distinguish between people who have never thought about an action and those who have given the action some consideration but are undecided. There are several reasons for making this distinction. People who have thought about acting are likely to be more knowledgeable. Also, getting people to think about an issue may require different sorts of communications (and entail different sorts of obstacles) than getting them to adopt a particular conclusion. Thus, whether a person has or has not thought about taking action appears to be an important distinction.

Stage 3 (undecided) versus stage 4 (decided not to act) and stage 5 (decided to act)

Research reveals important differences between people who have not yet formed opinions and those who have made decisions. People who have come to a definite position on an issue, even if they have not yet acted on their opinions, have different responses to information and are more resistant to persuasion than people who have not formed opinions (Cialdini, 1988; Ditto & Lopez, 1992; Nisbett & Ross, 1980, chapter 8). This widely recognized tendency to adhere to one's own position has been termed "confirmation bias." It manifests itself in a variety of ways. According to Klayman (1995), these include overconfidence in one's beliefs, searches for new evidence that are biased to favor one's beliefs, biased interpretations of new data, and insufficient adjustment of one's beliefs in light of new evidence. For these reasons, the PAPM holds that it is significant when people say that they have decided to act or have decided not to act and that the implications of someone saying that they have decided not to act are not the same as saying it is "unlikely" they will act.

We believe that cost–benefit theories of health behavior, such as the health belief model, the theory of reasoned action, protection motivation theory, and subjective expected utility theory, are dealing mainly with factors that govern how people who get to stage 3 decide what to do. Factors these theories focus on are certainly important, but they relate mostly to this one phase of the precaution adoption process. These theories also overlook another possibility that people faced with a difficult decision might get stuck and quit trying to make up their minds, moving back to stage 2. Determinants of this regression to an earlier stage might be different from the factors that lead people toward stages 4 or 5.

Perceived susceptibility is one factor that can influence what people decide and is included in most theories of health behavior (Connor & Norman, 1995). People are reluctant to acknowledge personal susceptibility to harm even when they acknowledge risks faced by others. Consequently, overcoming this reluctance is a major barrier to getting people to decide to act.

Stage 5 (decided to act) versus stage 6 (acting)

The distinction between decision and action is common to most stage theories. For example, Schwarzer's health action process approach (Schwarzer, 1992) distinguishes between an initial motivation phase during which people develop an intention to act, based on beliefs about risk, outcomes, and self-efficacy, and the volition phase in which they plan the details of action, initiate action, and deal with the difficulties of carrying out that action. Even Ajzen's (Ajzen, 1985) theory of planned behavior, which is not a stage theory, separates intentions from actions. Protection motivation theory (Rogers & Prentice-Dunn, 1997) is also not a stage theory, but its developers implicitly recognize the need for sequencing interventions. According to these authors "[Protection Motivation Theory] experiments always present information in the same order: threatening information followed by coping information" (p. 116). These researchers also speak of first developing motivation and then developing coping skills.

A growing body of research suggests that there are important gaps between intending to act and carrying out this intention and that helping people develop specific implementation plans can reduce these barriers. The PAPM suggests that detailed implementation information would be uninteresting to people in early stages. Yet, for people who have decided to act, such information is often essential to produce the transition from decision to action. This claim is echoed by temporal construal theory (Trope & Liberman, 2003), which asserts that decisions about action are based initially on abstract construals of the options but become more focused on concrete details as the actual choice approached.

Stage 6 (acting) versus stage 7 (maintenance)

For any health behavior that is more than a one-time action, adopting the behavior for the first time is different from repeating the behavior at intervals, or developing a habitual pattern of response. Once a woman gets her first mammogram, for example, she will have acquired both more information in general and personal experience (perhaps both positive and negative). These will influence the decision to be rescreened. Similarly, a man who stops smoking or loses weight must deal with the acute withdrawal experience and/or the glow of success in the early stage of taking action but must address different challenges in the maintenance stage. The distinction between action and maintenance is widely recognized (e.g., Marlatt & Gordon, 1985; Meichenbaum & Turk, 1987).

Stages of inaction

One value of the PAPM is its recognition of differences among the people who are neither acting nor intending to act. People in stage 1 (unaware), stage 2 (unengaged), stage 3 (undecided), and stage 4 (decided not to act) all fit in this broad category. Those in stage 1 need basic information about the hazard and recommended precautions. People in stage 2 need something that makes the threat and action personally relevant. Individualized messages and contact with friends and neighbors who have considered action should help these individuals move to the next stage. Another powerful influence on the transition from stage 2 to stage 3 is the awareness that others are making up their minds and that one is obliged to have some opinion on this current issue of the day.

As stated earlier, people who have thought about and rejected action, stage 4, are a particularly difficult group. Evidence shows that they can be quite well informed (Blalock et al., 1996; Weinstein & Sandman, 1992) and, as noted earlier, they will tend to dispute or ignore information that challenges their decision not to act.

Criteria for Applying Stage-Based Interventions

A variety of issues should be considered to determine the practical utility of the PAPM or any other stage theory.

Superiority Over Unstaged Messages

The value of a stage theory depends on the extent to which it leads to interventions that are more effective than generic messages.

One might ask, "Why not just employ combination treatments that contain elements for people at each stage?" There are several problems with this suggestion. First, a combination treatment will be much longer than a stage-matched treatment. Media time is expensive, speakers usually have a limited length of time for their presentations, and audiences have a limited attention span. Thus, attempting to replace a stage-focused intervention with a multifaceted combination treatment would involve substantial costs.

Second, people are most likely to be engaged by a treatment that matches their stage, and a mismatched treatment may lose their attention. Thus, members of the general public who have already decided to act may be put off by basic risk information and may fail to attend to the subsequent, detailed procedural information describing what they do need. Nevertheless, if only a single message can be given to a mixed-stage audience, a combination intervention would probably be the most appropriate.

Stage Assessment

A second criterion is the ability to identify stages accurately and efficiently. The PAPM requires only a simple process to assess a person's stage, so it can be used easily in individual and small-group settings. Clinicians could integrate this assessment without disrupting their practices. Similarly, a filtering question on a website can assess stage and send visitors to the page most relevant to their stage. Even in a large audience, a show of hands might be used to determine the distribution of stages present.

Delivery of Stage-Targeted Messages

The feasibility of delivering stage-targeted messages in different situations varies greatly. If communication is one on one, delivering the message appropriate for an individual is relatively easy. In group settings, messages can be chosen to fit the overall audience, though not individual members. In mass communications, a stage approach is more often practicable with print than with broadcast media. Within print channels, pamphlets and magazines offer more opportunities for stage targeting than newspapers; within broadcasting, cable offers more opportunities for stage targeting than networks. The Internet makes it possible for individual users to choose different information pathways depending on their self-perceived information needs. This should provide unprecedented opportunities for low-cost message targeting, though evidence on the cost of such tailored messaging is scanty. There is evidence, though, that people in different PAPM stages perceive themselves as needing different types of information (Weinstein, Lyon, Sandman, & Cuite, 1998).

The ability to deliver targeted messages to members of a group also depends on the range of stages present in that group. The greater the range of stages, the more difficult it is to choose a single message. For a mass audience, the most efficient way to encourage a new health protective action may be with a comprehensive broadcast message that ignores stage or assumes everyone to be at a very early stage. As the issue matures, however, distinctive audiences, separable by stage, merit distinctive messages, and print or "narrowcasting" becomes the medium of choice for mass communications.

The Difficulty of Behavior Change

A final important criterion concerns the difficulty of the action being advocated and the expected resistance of the audience to the behavior change recommendation. When a behavior is easy and resistance is low, stage may matter little. In such situations, interventions and messages needed to help people progress from stage to stage can be brief, and several may be combined into a single comprehensive treatment. In contrast, when change is difficult and resistance is high, there is a greater need to have separate messages for each stage. Note that although some precautions—such as changing to a fluoride-containing toothpaste—are easy to carry out, the ease of others may vary greatly from one person to the next. Health professionals should never assume that a behavior is easy without considering carefully the obstacles that may exist.

Using the PAPM to Develop and Evaluate Behavior Change Interventions

Blalock and colleagues used the PAPM in three studies conducted from 1994 to 2000 that focused on osteoporosis prevention (Blalock et al., 2002). Osteoporosis is a metabolic bone disorder that results in decreased bone density and increased susceptibility to fracture (Riggs & Melton, 1986). Precautions recommended to reduce the risk of developing osteoporosis include adequate calcium intake and weight-bearing exercise (Kling, Clarke, & Sandhu, 2014). Their research was designed to better understand the factors that (a) discriminate among women in different stages with respect to calcium intake and exercise and (b) predict different types of stage transitions (Blalock et al., 1996). This information was used to develop stage-based educational interventions. These studies provide examples of the necessary steps in using the PAPM to develop and evaluate behavior change interventions.

The first step involves identifying and clearly defining the behavior of interest. Although the PAPM focuses on the adoption of specific health behaviors (e.g., "daily walking for at least 30 min"), it may also be used to intervene at a broader behavioral category level (e.g., "increasing exercise"). In either case, care should be taken to define the target behavior(s) in terms that are meaningful to laypeople. Although Blalock and colleagues defined the target behavior in terms of a specific daily calcium intake, a value that has little meaning to most laypeople, they overcame this problem by providing study participants with feedback that informed them of their current calcium intake. This step would not have been needed if the behavior criterion had been simpler, such as "using a calcium supplement."

Second, a system must be developed to classify individuals according to their current stage. The stage classification system allows health professionals to assess the distribution of stages within a target population at a particular point in time, guiding the design of both individual and community-level interventions. As described in the AIDS example at the beginning of this chapter, if awareness and knowledge of a health threat change over time, the effectiveness of different types of interventions is likely to change as well. Thus, monitoring temporal changes in the distribution of people across stages makes it possible to design dynamic interventions that accommodate the dynamic nature of the behavior change process.

Third, it is necessary to have at least a preliminary understanding of the factors that influence different types of stage transitions. This understanding is needed to tailor interventions to people, or groups of people, who are in different stages of change. Early work by Blalock et al. (1996) suggested that to move people, or groups of people, from stages 1 and 2 (unaware, unengaged) to stage 3 (undecided), interventions should focus on increasing awareness of the health problem of interest, behavioral recommendations to minimize risk, and potential benefits associated with adopting the behavioral recommendations—including the effectiveness of the recommended behaviors in terms of risk reduction (i.e., precaution effectiveness).

The cross-sectional and prospective research carried out by Blalock and colleagues examined between-stage differences. Significant differences between stages on particular variables suggest that these variables are worthy of additional attention—and of inclusion in interventions at early stages of research—but they are not proof of causation. Furthermore, if interventions succeed in altering these variables but fail to move people to stages closer to action, this does not prove that the stages themselves are invalid. The variables that actually cause each stage transition must be identified empirically.

Fourth, intervention strategies are needed to address variables associated with different stage transitions. For example, media campaigns and informational materials may be able to increase awareness of a health problem, behavioral recommendations, and the benefits associated with action. However, more intensive interventions are often needed to help individuals acquire the skills and resources needed to support behavior change efforts. The intensity of the intervention required will depend on the behavior of interest and what barriers need to be overcome. For example, Blalock and colleagues used a combination of written materials and telephone counseling focused on helping women identify potential barriers to action and develop strategies to overcome the barriers identified. This approach led to a significant increase in calcium intake among women who were thinking about or trying to increase their calcium intake at baseline. However, a similar intervention focused on exercise had no effect on exercise level. Fifth, health educators must specify how the effectiveness of the intervention will be determined. Will it be considered effective if it results in stage progression, even if the proportion of people in the action and maintenance stages remains the same? Or, is success contingent upon behavior change in the target group? If a behavior is difficult to change and people are in early stages, the PAPM suggests that a single, one-shot intervention—especially an intervention that focuses on movement to the next stage—should not be judged solely by whether it changes behavior.

Finally, educators must determine the timeframe for follow-up assessments. The PAPM and other stage theories suggest that the behavior change process is dynamic. Intervention-induced changes in beliefs and behavior may be transient, so intervention effects may be missed if only long-term follow-up assessments are used. Although long-term behavior change is generally desired, a stage model perspective raises the possibility that even transient changes may be steps in the right direction, helping us to understand the barriers at different stages and increasing the success of subsequent behavior change attempts.

Research Using the PAPM

The PAPM has been applied to many types of health behaviors, including osteoporosis prevention (e.g., Blalock et al., 1996), cancer screening (e.g., Glanz, Steffen, & Taglialatela, 2007), hepatitis B vaccination (Hammer, 1998), home radon testing (e.g., Weinstein, Lyon, et al., 1998), smoking cessation (Borrelli et al., 2002), and red meat consumption (Sniehotta, Luszczynska, Scholz, & Lippke, 2005). As discussed earlier in this chapter, stage theories—with their numerous assumptions about stages and about the changing barriers between stages—are complex. Given the limited, though growing, number of studies relating to the PAPM and the variety of behaviors examined, it is not yet possible to reach firm conclusions about the model's validity or its helpfulness for designing interventions. For further information on the ways in which the PAPM is being used, the problems researchers encounter in these investigations, and a detailed analysis of stage-matched field study to encourage home radon testing, see Weinstein, Sandman, and Blalock (2008).

Conclusion and Future Directions

Most other (non-stage) theories of individual health behavior regard adoption of new precautions as involving only one step, from inaction to action (or, perhaps, inaction to intention), and the variables typically claimed to produce this step clearly characterize it as a judgment about the relative costs and benefits of action. The PAPM does not reject the variables identified by these theories. Rather, it sees the theories as describing just one part of the precaution adoption process, the stage when people are actively weighing options and deciding what to do. The PAPM, however, shows that other issues important to behavior change arise before people ever think seriously about action and still different issues arise after people have decided to act.

Because the PAPM is not composed of a short list of variables, it does not offer a simple process for designing interventions. Rather, it is a framework that can be used to guide interventions by identifying barriers that inhibit movement from one stage to the next. As additional research is conducted, we will learn more about barriers at each stage and will see how consistent these barriers are from one health behavior to the next.

Author Biographies

Neil D. Weinstein is a professor emeritus of Rutgers, The State University of New Jersey, where he was a member of the Departments of Human Ecology and Psychology. His major areas of scholarship include risk perception, unrealistic optimism about personal risk, communication of risk information, stage theories, the precaution adoption process model, smokers' understanding of the risks of smoking, the relationship between perceived personal risk and health behavior, and theory testing.

Peter M. Sandman was a Rutgers University professor from 1977 to 1995 and is one of the preeminent risk communication and reputation management speakers and consultants in the world today. Dr. Sandman works in three risk communication venues: helping arouse concern when people are insufficiently upset about serious risks, helping diminish concern when people are excessively upset about small risks, and helping guide concern when people are appropriately upset about serious risks.

Susan J. Blalock is a professor in the Eshelman School of Pharmacy at the University of North Carolina at Chapel Hill. A hallmark of her research involves the application of behavioral science theories to understand the mechanisms through which intervention effects are obtained. Her current research focuses on how patients process information concerning medication risks and benefits and the effect this type of information has on patient judgments and decisions regarding medication use.

Prejudice and Stereotyping in Healthcare

Elizabeth S. Focella

Department of Psychology, University of Wisconsin Oshkosh, Oshkosh, WI, USA

In the social psychological literature, stereotypes are defined as beliefs, usually overgeneralizations, associating particular traits and attributes with members of a particular group (e.g., "members of this group are lazy"). Prejudice, in contrast, is an attitude (usually unfavorable, e.g., dislike) toward a person based solely on that person's presumed group membership. Both stereotyping and prejudice may be considered a form of bias. Literature in social psychology has long been interested in the concepts of stereotyping and prejudice as a way to understand intergroup relations. More recently, stereotyping and prejudice have been studied in the context of healthcare to help explain the apparent health disparities between groups, particularly between Whites (a term that will be used hereafter to refer to a diverse group of people who identify as White, Caucasian, or European American and people of European descent who may or may not be American) and Blacks (a term that will be used hereafter to refer to a diverse group of people who identify as Black or African American and people of African descent who may or may not be American).

Researchers in a variety of disciplines, including psychology, medicine, and public health, find that even when controlling for factors such as access to healthcare, low socioeconomic status (SES), and disease severity, members of low-power groups (Blacks in particular) still have worse health outcomes, including increased risk of mortality. Among the potential sources for this disparity, some research documents the presence of differential treatment in numerous areas of healthcare, including medicine, surgery, primary care, and mental health, and for a variety of conditions and procedures, including coronary artery disease, renal disease and kidney transplantation, stroke, cancer, HIV/AIDS, medication for pain management, and advice for smoking cessation (e.g., see Geiger, 2003). Among a number of explanations for these disparities in treatment and outcomes, stereotyping and prejudice in healthcare has received compelling empirical support (for a review, see Chapman, Kaatz, & Carnes, 2013; Dovidio & Fiske, 2012).

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

A substantial portion of literature concerning stereotyping and prejudice in healthcare examines racial/ethnic bias, particularly against Black patients (van Ryn & Burke, 2000). This is likely due to the fact that Blacks have poorer health outcomes, including risk of mortality, than other racial and ethnic groups. Hence, the literature on bias against Blacks represents a large portion of our empirical knowledge on the topic of bias in healthcare. The literature examining stereotyping and prejudice in healthcare does, however, document prejudice and stereotyping for other racial and ethnic groups, including Hispanic and Native American patients, and exists beyond examination of racial and ethnic bias, including bias toward other low-power groups including people who identify as lesbian, gay, bisexual, or transgender (LGBT), women, the elderly, and people who are overweight, are diagnosed with mental illness, and abuse drugs and alcohol.

At times, people are able to consciously access and report their feelings (prejudice) and beliefs (stereotypes) about particular groups of people. In such cases, prejudices and stereotypes are conscious, or *explicit*. In the past few decades, however, research has shown that in some cases, people hold stereotypes and prejudices that they are not consciously aware of (i.e., nonconscious), or are *implicit*. The literature on prejudice in healthcare examines both *explicit* and *implicit* stereotyping and prejudice among clinicians.

Explicit Stereotyping and Prejudice

In the context of healthcare, the literature documenting clinicians' explicit bias is comparatively less robust than literature documenting implicit bias. This may be the case because most physicians and other healthcare providers intend to treat their patients fairly and may not wish to endorse stereotyping or prejudice directed at these groups, thus making the prevalence of explicit stereotyping and prejudice less pronounced among healthcare providers. When explicit stereotypes are documented, they are typically directly related to concerns about compliance and adherence to treatment. Explicit negative attitudes (i.e., dislike) are typically less reported than stereotypes and are often expressed toward groups for which bias is more socially accepted (e.g., people who are overweight, people who are drug users).

The literature finds that racial and ethnic groups including Blacks, Hispanics, and Native Americans, as well as members of other groups, including persons who are overweight and former injecting drug users, are explicitly stereotyped by healthcare providers as noncompliant. For example, one study found that medical and nursing students reported awareness of stereotypes associating Hispanics and Native Americans with noncompliance (Bean et al., 2014). Similarly, other studies show that healthcare providers stereotype Blacks, people who are overweight, and former injecting drug users as less likely to adhere to treatment. Further, the aforementioned study of medical and nursing students found that medical and nursing students reported awareness of stereotypes associating Hispanics and Native Americans with risky health behavior and difficulty understanding and/or communicating health-related information.

While the stereotype of noncompliance is associated with several groups, other stereotypes are more group specific. In particular, overweight patients face more unique stereotypes in addition to noncompliance, including perceptions that they lack motivation and are lazy, self-indulgent, and physically exhausting to care for. Other more general negative stereotypes toward overweight patients include being lower in social attractiveness, as well as physically unattractive.

Other well-documented explicit stereotypes in healthcare relate to perceptions of controllability, blame, and fault for the patient's health state. These beliefs are often associated with patients who abuse drugs and alcohol, are overweight, are diagnosed with mental illness, and are current or former injecting drug users. Interestingly, these negative attitudes toward those who abuse substances may be influenced by beliefs about controllability and social mores. Literature on healthcare providers' beliefs about overweight patients, as well as those coping with mental illness (e.g., those with schizophrenia) and substance abuse, shows that a portion of healthcare providers express the belief that those patients are responsible for their current state. For example, as documented in some literature, nurses have expressed the belief that their overweight patients' failure to lose weight can be attributed to noncompliance with treatment recommendations and lack of motivation. Further, the literature suggests a link between these negative stereotypes and the clinician's preexisting beliefs about personal responsibility. One study shows that clinicians who identify as conservative, as opposed to liberal, may have more negative attitudes toward patients who are injecting drug users. Mediation analyses indicated that conservative clinicians' negative attitudes toward injecting drug users are due to the belief that injecting drug use is in the patient's control (Brener, Hippel, Kippax, & Preacher, 2010). Taken together, the literature suggests that negative attitudes toward these groups of patients can be characterized by negative personal attributions for the patients' state.

In relation to stereotyping, literature documents the possibility that healthcare providers may, at times, overly attribute their patients' physical ailments to the patients' more salient condition. For example, studies show that nurses in particular express the belief that their overweight patients' ailments are likely the result of their patients' weight and that nurses caring for patients who are injecting drug users express the belief that their patients' ailments are caused by their injecting drug user status. Importantly, this occurs regardless of whether the ailment is in fact due to the patients' obesity or drug use. The tendency to overly rely on a patient's group membership when making a determination about their treatment and diagnoses is a form of stereotyping and presents a potential for diagnostic overshadowing, in which a patients' symptoms and ailments are blamed on another, more obvious condition. In diagnostic overshadowing, a disease or otherwise harmful or life-threatening condition is not detected because it is "overshadowed" by a more obvious and more salient condition—a circumstance that delays treatment for the true cause of the patient's ailments and possibly an increased likelihood of death. Diagnostic overshadowing occurs for people with a variety of conditions including people who are overweight, have intellectual disabilities, have physical disabilities, and are diagnosed with mental illness.

In addition to explicit stereotyping of patients, the literature also documents the existence of prejudice. In a study about prejudice toward schizophrenic patients, researchers found that healthcare providers showed greater desire for social distance from a schizophrenic, compared with a non-schizophrenic patient. Other research documents some evidence of explicit prejudice against Black patients, including physicians' lower feelings of affiliation with Black, compared with White patients. Further, prejudice toward those who are overweight among healthcare providers is widely documented, including some healthcare providers' feelings of disgust, repulsion, and pity for their obese patients. Physicians also express embarrassment at the prospect of discussing sexuality and sexually related healthcare with LGBT patients. The literature also documents more general negative affective responses of healthcare providers toward those who abuse drugs and alcohol, as well as those with mental disorders.

Implicit Stereotyping and Prejudice

Implicit bias can be assessed in a number of ways including psychophysical reactions, neuroimaging, and computerized reaction time tasks that measure participants' associations of particular groups of people with certain attributes as well as general evaluative concepts like "good" or "bad." Implicit bias is most often assessed through a particular reaction time task known as the Implicit Association Test (IAT). The IAT is administered on a computer, in which participants are asked to categorize a set of words or images. The IAT measures the strength of associations between particular concepts (typically groups of people such as Blacks and Whites) and evaluations (such as good or bad) or stereotypes (such as noncompliant). The notion behind the IAT is that when a person holds an implicit association between a group of people and a stereotype or evaluation (e.g., bad), they should be able to categorize that group of people with words related to the stereotype or evaluation more quickly and with greater accuracy compared with when they are asked to categorize that stereotype or evaluation with other groups of people. For example, if a clinician holds an association between Blacks and noncompliance, they should be able to more easily categorize Blacks with words related to noncompliance compared with when they are asked to categorize Whites with noncompliance.

The literature documenting implicit stereotypes and prejudice among healthcare providers documents a number of empirical findings. First, numerous studies on implicit bias in healthcare show that both physicians and other clinicians such as nurses hold an implicit, and often strong, preference for Whites relative to Blacks. The literature also documents a similar bias against those who are overweight. On a "fat–thin" IAT, healthcare providers show an implicit preference for thin, compared with fat, people. The literature also finds a similar preference among physicians and nurses toward people who are higher, compared with lower, in SES, and there is some discussion in the literature about physicians' implicit as well as explicit bias against LGBT older adults (e.g., see Foglia & Fredrikson-Goldsen, 2014). Interestingly, the implicit bias that physicians and nurses exhibit toward Blacks and those who are overweight is similar to that of the larger population, suggesting that current medical education does little to reduce implicit bias.

The literature on implicit bias toward patients also shows evidence of stereotyping. Often, these implicit stereotypes pertain to noncompliance. Numerous studies show that physicians, nurses, and medical students implicitly associate Blacks, for example, as being noncompliant, medically uncooperative, and uncooperative generally. Literature shows that Hispanics are also implicitly stereotyped as noncompliant, as well as implicitly associated with health risk (Bean, Stone, Moskowitz, Badger, & Focella, 2013). Notably, the literature also shows that Blacks are not only implicitly associated with diseases that are epidemiologically relevant for Blacks (e.g., sickle cell anemia) but that they are also implicitly associated with conditions and social behaviors with no inherently biological or genetic relationship with Blacks including obesity and drug use (Moskowitz, Stone, & Childs, 2012).

The Influence of Stereotyping and Prejudice on Clinical Decision Making and Interactions with Patients

Some recent empirical studies not only document the existence of prejudice and stereotyping among clinicians but also show that these biases influence their clinical decision making, including treatment, as well as their interactions with patients. In a landmark study by Green et al. (2007), physicians read a clinical vignette of either a Black or White patient presenting to the emergency department with an acute coronary syndrome. These physicians were later asked to make recommendations of whether to treat the patient with thrombolysis. Green et al. (2007) found that while physicians reported no explicit preference for Whites relative to Blacks or differences between Whites and Blacks on perceived cooperativeness, they did exhibit an implicit preference favoring Whites over Blacks as well as implicit stereotypes of Blacks as less cooperative with medical procedures and less cooperative more generally. Importantly, they identified a link between physicians' implicit bias and their treatment recommendations—as physicians' implicit pro-White bias increased, the lower their likelihood of treating Black patients with thrombolysis.

Other studies show similar findings, providing evidence that bias influences clinical decision making. For example, literature shows that implicit bias against the mentally ill can predict overdiagnosis, while explicit bias predicts more negative prognoses (Peris, Teachman, & Nosek, 2008). Additionally, research finds that perceptions of cooperativeness are predictive of treatment recommendations. This may disadvantage members of minority groups including Blacks, Hispanics, people who are overweight, and people who are mentally ill, who are stereotyped (implicitly as well as explicitly) as being less medically cooperative relative to Whites, the thin, and those not labeled as mentally ill.

Further, it is widely observed that White patients are more likely to receive pain treatment than non-White patients. This disparity in treatment, research indicates, can be predicted by physicians' implicit pro-White bias. For example, as pediatricians' implicit pro-White bias increases, the lower their likelihood of prescribing narcotic medication to Black patients (Sabin & Greenwald, 2012). To explain why pro-White bias influences pain treatment, some research has explored the possibility of an empathy gap—namely, that physicians with a stronger implicit pro-White bias are less able to empathize with their non-White patients. One study in particular (Drwecki, Moore, Ward, & Prkachin, 2011) showed that the more participants (including undergraduate students, physicians, and nurses) empathized with Whites compared with Blacks, the less pain treatment participants gave to Blacks relative to Whites. This work suggests that the widely observed disparity in pain treatment between Whites and Blacks is due, in part, to clinicians' lowered ability to empathize with, and thus assess, their Black patients' pain.

Stereotyping and prejudice not only influence treatment recommendations, but they also impact the way that clinicians interact with their patients. For example, some research shows that nurses who have implicit prejudice against those who are overweight are less likely to make eye contact with an overweight patient (Persky & Eccleston, 2011). Other studies show that healthcare providers' (including physicians' and genetic counselors') pro-White bias predicts using less emotionally responsive communication when counseling non-White patients and, when interacting with Black patients, more clinical verbal dominance, lower patient positive affect, and poorer ratings of interpersonal care. When interacting with White patients, in contrast, physicians and other healthcare providers exhibit lower levels of verbal dominance, receive more positive ratings of nonverbal effectiveness, and have higher ratings of interpersonal care.

With regard to patient stereotyping, race and compliance stereotyping is associated with longer visits, slower speech, less patient-centeredness, and poorer ratings of interpersonal care with Black patients. When interacting with White patients, in contrast, physicians exhibit less verbal dominance and typically have shorter visits, faster speech, and higher clinician positive affect. Importantly, several studies show that medical visits with minority patients compared with White patients are less patient-centered, which is predicted by implicit pro-White bias. The more pro-White bias on the part of the clinician, the less patient-centered their care of their minority patients (e.g., see Cooper et al., 2012).

Other sophisticated research on the topic of stereotyping and prejudice in healthcare finds interesting nuances and implications of the physician–patient interaction on patient health. For example, research exploring patients' perceptions of discrimination on the part of their clinicians finds that the more patients' perceive discrimination and bias from their healthcare providers, the lower their adherence to their clinicians' treatment recommendations, which may have negative impacts on their health (e.g., see Bird, Bogart, & Delahanty, 2004).

In addition, research in social psychology finds that while people might be low in explicit prejudice, they could nonetheless harbor nonconscious, or implicit, bias. In the context of healthcare, clinicians who possess egalitarian beliefs (i.e., who have low explicit prejudice), but who have implicit prejudice (termed aversive racists), may have particularly poor interactions with their patients. Notably, research shows that many healthcare providers, including physicians, tend to have low explicit bias, but nonetheless hold implicit biases. In interactions with a minority group member, people who are aversive racists tend to send mixed messages—while their low explicit prejudice tends to express itself in overt behavior (e.g., positive verbal content), their high implicit prejudice tends to "leak out" in their nonverbal behavior (e.g., less eye contact, distancing nonverbal behaviors). Since the minority interaction partner attends to the nonverbal cues in making judgments about the quality of the interaction, the minority person tends to have more negative ratings of the interaction and of their interaction partner. In fact, a study by Penner et al. (2010) found that Black patients even had more positive interactions with physicians who were high in both explicit and implicit bias than physicians who had low explicit but high implicit bias (i.e., aversive racists). Taken together, the work on explicit and implicit bias suggests that the conscious (explicit) and the unconscious (implicit) bias held by clinicians interact to influence clinical decision making, the quality of clinicians' interactions with patients, and patients' perceptions of bias.

Failures to Show a Link Between Stereotyping/Prejudice and Clinical Recommendations

While several studies have documented that stereotyping and prejudice influence physicians' treatment of patients, some have failed to find a direct effect of biases on treatment recommendations. For example, while several studies find that clinicians explicitly and implicitly stereotype their overweight patients as less adherent to treatment, some of these studies find that the extent to which clinicians hold this noncompliance stereotype has no predictive influence on treatment recommendations. Further, a subset of studies documenting explicit and implicit bias toward Black, Hispanic, and mentally ill patients failed to find effects of these biases on clinical decision making including physicians' treatment recommendations. This literature that documents bias but shows no impact of bias on treatment suggests that further study is needed to understand the specific conditions under which bias may be predictive of clinical decision making, as well as the more nuanced impact of bias on healthcare.

For example, although several studies do not show a direct effect of race (or other low-power group status, e.g., mental illness) on clinical recommendations, several show that clinicians' perceptions of uncooperativeness and doubts about adherence alter treatment recommendations. Namely, they show that lower perceived adherence is predictive of lower likelihood to recommend treatment. These results suggest that differences in treatment are not necessarily directly influenced by race or other group status but that they may be indirectly influenced through stereotypes, including lower perceptions of cooperativeness and adherence.

In addition, in the studies that fail to show a link between stereotyping and prejudice and treatment recommendations, there is often a standard of care that is typically followed. With little ambiguity and thus less discretion, it might be difficult to capture bias. Further, authors of some studies that fail to show a link between explicit or implicit bias and treatment recommendations note that participants might have been aware and/or were suspicious of the study's purposes. With greater attention paid to race as a variable of interest, participants may have been particularly sensitive to make sure that their minority patients were given treatment as opposed to not. In Green et al.'s (2007) study, for example, 67 physicians were excluded from the analyses because they expressed awareness of the nature of the study. Yet, when these 67 "aware" physicians were included in the results, Green et al. found an interaction effect. As unaware physicians' pro-White bias increased, their likelihood of recommending thrombolysis to Black patients decreased. In contrast, increase in pro-White bias among aware physicians was associated with more thrombolysis recommendations for Black patients.

When Are Stereotyping and Prejudice More Likely?

The extant literature suggests situations in which stereotyping and prejudice are more likely to bias clinical decisions. First, situations marked with ambiguity are more likely to elicit bias. Research shows that in cases with clinical uncertainty, where a medical procedure is discretionary, or treatment guidelines are not well defined, the likelihood of clinician bias is greater. In addition, previous research shows that being under high cognitive load makes people, including physicians, more likely to behave according to stereotypes and prejudice. Similarly, when people are in time-pressured situations, which necessitate that they simultaneously attend to numerous tasks, they tend to be more likely to engage in stereotyping and to act according to their biases. Unfortunately, the medical context, which is often one marked by limited time and high cognitive load, may be especially likely to elicit bias.

Reducing the Occurrence and Impact of Stereotyping and Prejudice in Healthcare

To ameliorate the impact of stereotyping and prejudice in healthcare, the extant literature suggests several solutions. First, hiring a more diverse set of physicians may alleviate some of the observed disparities. Previous research finds that racially concordant medical interactions (those in which the physician and patient are the same race) are marked with less perceived discrimination, greater trust, greater satisfaction, and more effective communication (e.g., Cooper et al., 2003). Hence, increasing racial minority patients' access to racially concordant physicians may help to produce more productive medical visits for racial minority patients. The literature also suggests that workshops may help by making physicians, nurses, and medical students aware of their implicit bias and how it may influence their clinical decision making and their interactions with patients. Finally, bias-reduction strategies that have been successful in laboratory and some field settings may also be effective in the context of healthcare to reduce prejudice and stereotyping. These include taking the perspective of the minority patient (i.e., perspective taking), perceiving the patient as an individual as opposed to a member of their minority group (i.e., individuation), fostering a sense of common identity between the provider and the patient (i.e., common identity), and considering the ways in which the patient does not fit with stereotypes of his or her minority group (i.e., counterstereotyping). Individuation and perspective taking in particular have been shown to reduce biases in medical treatment, including pain treatment (see Chapman et al., 2013). Specifically, this research finds that inducing perspective taking increases physicians' empathy for their minority patients, improving their ability to assess their patients' pain and, consequently, increase the provision of treatment. Importantly, these bias-reduction strategies may have a place in medicine to alleviate the impact of prejudice and stereotyping in healthcare.

Suggestions for Future Research

There are several directions for future research that will enhance our understanding of stereotyping and prejudice in healthcare. For example, while some bias-reduction strategies have been shown to be effective, further research is needed to understand how, and under what circumstances, these known strategies may be useful specifically in the healthcare context. In addition, given that some literature has failed to find a link between stereotyping and prejudice and clinical recommendations, further research is needed to determine the specific conditions under which stereotyping and prejudice will influence providers' recommendations and interactions with patients and the instances in which it will not.

Future research may also examine the role of clinicians' expectations on patient health outcomes. For example, if a clinician has low expectations (based on existing prejudice and stereotypes) that a patient will commit to therapy or treatment recommendations, some research suggests that they may be less likely to counsel the patient or to suggest a more challenging, yet perhaps more effective, course of treatment. As a result, the patient may experience worse health outcomes. Future research should more thoroughly examine the extent to which these expectations influence interactions with patients and how they influence the type and quality of treatment recommendations.

Further, research has focused more on the existence of stereotyping and prejudice among clinicians, but less on examining patients' own lived experience of stereotyping and prejudice. Not only would it be beneficial to obtain a qualitative understanding of these experiences, but it would also be beneficial to understand the cumulative effect of these experiences on patients, how these experiences may influence patients' perception of and participation in healthcare, and how these experiences impact patients' subsequent interactions with clinicians. Given that a great deal of work examines stereotyping and prejudice in short-term studies, future work may also include more long-term studies that examine how negative interactions with clinicians, and the healthcare system more generally, may influence patients' subsequent participation in healthcare.

Importantly, a more thorough investigation of patient–provider communication is warranted. Medical decisions are not made in a vacuum—rather, they derive from an interaction between the clinician and the patient. Future work may investigate how the nuances of these interactions shape the patients' attitudes and behavior toward the physician and how these interactions may influence the physician's clinical decision making. Research that investigates the more nuanced and reciprocal nature of patient–provider interaction (e.g., using non-obtrusive observation methods such as the Electronically Activated Recorder; Mehl & Robbins, 2012) may be particularly effective at understanding prejudice and stereotyping in the dynamic, and multifaceted, context of healthcare.

Author Biography

Dr. Elizabeth S. Focella is an assistant professor of psychology at the University of Wisconsin Oshkosh. Her research examines attitudes and behavior change, chiefly in the context of health promotion. One major focus of her research examines prejudice and prejudice reduction, particularly in healthcare. Another line of her work, in cognitive dissonance, examines how people are motivated to change when they are made aware of the discrepancy between their pro-health attitudes and their unhealthy behavior.

The Prototype-Willingness Model

Frederick X. Gibbons[1], Michelle L. Stock[2],
and Meg Gerrard[1]

Washington, DC, USA

Basic Components

The prototype-willingness model (PWM) (Gerrard, Gibbons, Houlihan, Stock, & Pomery, 2008; Gibbons, Gerrard, & Lane, 2003; Gibbons, Stock, Gerrard, & Finneran, 2015) was created with a goal of improving the predictive and explanatory power of existing health behavior theories but with a specific target in mind: health *risk* behavior among *adolescents.* It is a modified dual-process model. Like other dual-process theories, the PWM maintains that health decision making involves two kinds of information processing. The two types are operative in the two pathways to health behavior described in the model.

The reasoned pathway involves analytic processing. It is the deliberative route to behavior reflecting the fact that some risky behaviors are the result of a consideration of options and expected outcomes associated with those behaviors. The proximal antecedent in this path is behavioral intention, which is defined as an intention (plan) to engage in a particular behavior. *The social reaction path* reflects a belief that certain behaviors, especially among adolescents, are more reactive than reasoned—that is, a response to a set of circumstances that may not have been sought or even anticipated. This path involves more heuristic processing: Deliberation is truncated, especially consideration of consequences; affect has more impact, and cognition less impact; images are influential; and heuristics play an important role. Both pathways include attitudes and subjective norms as distal antecedents; the social reaction path, however, also includes two constructs that are unique to the model, willingness and prototypes.

Behavioral willingness is defined as an openness to risk opportunity. It captures the reactive aspect of behavior, which is considerable for adolescents. It differs from an intention—it is not a plan of action or a goal state. Very few people plan on driving under the influence of drugs, for example, but some are willing to do so. Whether the behavior happens, then, is largely

dependent on whether the risk opportunity occurs (Gibbons et al., 2004). Willingness is influenced by affect and social influence (Gibbons et al., 2004), as well as heuristics (e.g., prototypes). Outcomes associated with the social reaction path typically have included risky health behaviors. However, there is no theoretical reason why the behavior has to be negative; as long as the behavior has a reactive component and an associated image, the PWM is potentially appropriate.

Assessment of willingness includes a hypothetical scenario; for example, "Imagine you're at a party sometime in the next month and there are some drugs there you can have if you want. We're not suggesting you would ever be in this kind of situation, but try to imagine it happening." Next, the respondent is asked how *willing* she/he would be under these circumstances to do each of several behaviors that increase in risk (e.g., "try some … use enough to get high … take some to use later"). Responses are aggregated. A basic assumption behind the construct of willingness is that many adolescents are curious about risky behaviors. Peer pressure can be important, but there is more to substance use or risky sex than an inability to "just say no"; willingness is different from resistance efficacy. When individuals are asked about their willingness, various heuristics are instantiated. This happens quickly, but it does require some thought. Thus, the social reaction pathway—and this is true for much health decision making—relies heavily on heuristics, but it is a conscious more than an unconscious process, and it is seldom automatic.

Prototypes are the images that individuals have of the type of person who engages in a behavior. They include two primary dimensions: favorability and similarity. The most common method of favorability assessment involves adjective descriptors. For example, wording for adolescents (age ~12–14) would be:

> We want to ask about your images of people who do different behaviors. We're not talking about any particular person, and we're not saying these people are all alike. We want to know what you think these people are like. Please think about the type of person your age who____. How much do you think each of these adjectives describes that type of person?

This prompt is followed by a list of adjectives, preferably a mix of positive and negative (e.g., popular, selfish, considerate). These prototype (and willingness) items have consistently produced valid and reliable indices, even among children as young as 8 (Andrews, Hampson, Barckley, Gerrard, & Gibbons, 2008).

Research: Age and Experience

Two recent meta-analyses have reviewed some of the studies prompted by the PWM. One provided an analysis of the general model (Todd, Kothe, Mullan, & Monds, 2016), whereas the second examined a more specific issue: prototype similarity versus favorability (van Lettow, de Vries, Burdorf, & van Empelen, 2016). Both analyses reached essentially the same two general conclusions: PWM constructs, specifically prototypes and willingness, add significantly to the prediction of health behaviors, and the model has utility and potential in terms of interventions. Below are some issues raised in those meta-analyses.

Adolescents

A number of studies have indicated that willingness is usually a better predictor than intention among adolescents for risky behaviors, including substance use (e.g., cigarettes and drinking).

This varies with age, however. Two prospective studies examined the relative predictive power of willingness versus intention annually from age 12 through 18 and found the anticipated pattern for smoking: controlling for previous behavior, willingness exceeded intention through age 16, at which point the smoking became more intentional for the next 2 years (Pomery, Gibbons, Reis-Bergan, & Gerrard, 2009). From then on, smoking was mostly habitual, and neither willingness nor intention predicted significant variance beyond previous behavior. However, another analysis in the same paper with nonsmokers age 12–19 showed that *initiation* of smoking was also predicted better by willingness up to age 19. Consistent with these results, Todd et al. (2016) found that age moderated the prototype-to-willingness and willingness-to-behavior relations, leading them to conclude that the PWM works better for adolescents than adults.

Adults

Some behaviors are risky or rare enough that the image associated with them is pronounced and impactful; consequently, they are less likely than drinking or smoking to become intentional or habitual, even into adulthood. These behaviors include sexual "cheating," drunk driving, and heavy drug use, among others. More generally, many risk behaviors are intentional up to a certain level, but people have their limits, and risk above that threshold often becomes willingness based. More PWM studies with adults are likely in the future.

Type of Behavior

Health Risk

Todd et al.'s list of behaviors examined in PWM studies included health promotion (e.g., exercise, vaccination) and health risk. The model did best in predicting substance use: Willingness accounted for 20% of the variance in behavior, whereas intention accounted for only 8%. As Todd et al. suggested, substance use is a risky behavior with a significant social reaction component. On the other hand, willingness explained less variance than intention in cigarette use, which has much less of a social component. This pattern varies considerably by age, however—much more reactive in early adolescence and then more reasoned in late adolescence and early adulthood (Pomery et al., 2009).

Health Promotion

Gerrard et al. (2002) examined the prospective effects of a healthy prototype, the adolescent *nondrinker*, and the more common, unhealthy prototype, the adolescent drinker, on adolescents' willingness to drink and their actual consumption. As expected, the drinker image predicted drinking indirectly, via willingness to drink, and the abstainer image predicted directly. However, there was also an indirect path from the abstainer image to drinking through an image contemplation measure ("How often have you thought about this type of person?"). These results are consistent with a dual-process account. First, nondrinkers had a favorable nondrinker image, and that image directly predicted their abstinence, suggesting that the nondrinker image was a goal for them. Second, a favorable nondrinker image was associated with more image contemplation, which also suggests more reasoned processing; in contrast, the drinker image involved heuristic processing. Other healthy images that have been examined include condom users, exercisers, healthy eaters, sun protectors, and (substance) abstainers.

Comparing Willingness and Intention

The distinction between willingness and intention is central to the PWM and to its status as a dual-process model. Clearly, many health behaviors have a reasoned component to them, and although the intention–behavior correlation is often less than predicted, it is reliable. For this reason, the PWM maintains that for many risky behaviors, analyses that include both willingness and intention are more likely to effectively predict behavior than intention alone. By the same token, for many health-related behaviors, willingness is not relevant, especially among adults (e.g., drinking or smoking).

Antecedents

In spite of their overlap, intention and willingness have distinct antecedents. In survey research, for example, Gibbons et al. (2004) found that parents' substance use predicted their children's intentions and especially their behavioral *expectations* to use substances (e.g., "My parents smoke, I probably will also"), but it did not predict willingness to use. Social influence (i.e., perception of friends' use) and risk images, on the other hand, predicted both willingness and intention, but the relations were stronger for willingness. Other studies have found that endorsement of the heuristic "If it's illegal, it must be effective" predicted willingness but not intention to use performance-enhancing drugs and also that positive and negative alcohol portrayals by actors in movies affected adolescents' willingness to drink but not their intentions (Gibbons et al., 2016).

Manipulations

Several studies have also demonstrated differences in how intention and willingness are affected by experimental manipulations. Two such studies examined a behavior with a significant willingness–intention distinction: casual sex. One study found that men who initially reported no intention to engage in casual sex increased in willingness (but not intention) to engage in the behavior after exposure to tempting photos (women posing provocatively in bikinis; Roberts, Gibbons, Kingsbury, & Gerrard, 2013). A second study replicated this effect for "cheating" using supraliminal primes (provocative photos interspersed with control photos). This study found that those in committed relationships reported lower willingness to engage in casual sex than those who were single, as expected, but these committed men and women had significantly higher willingness than intention. Apparently, for some people with no intention to cheat but some willingness, whether that willingness turns into casual sex behavior may depend on "risk opportunity."

Prototypes

Dimensions

Both favorability and similarity are important aspects of risk images (prototypes); when both are high, willingness is most likely. In their meta-analysis, van Lettow et al. (2016) found that in a majority of studies that assessed both prototype similarity and favorability, similarity was a stronger predictor for willingness. However, studies that also included a similarity by favorability interaction term showed that the interaction was a stronger predictor than either dimension by itself. In fact, the "diagonals"—those who are high in similarity but low in favorability, or vice-versa—are an interesting group. Presumably, those in the latter category are considering starting the behavior ("contemplators"). On the other hand, those in the high-similarity/low-favorability category clearly do not approve of the behavior and, presumably, are either concerned they may start engaging or are already engaging and want to stop.

Relations With Intention and Willingness

Some studies have found evidence of a prototype-to-intention path. Although rare when both willingness and intention are included in analyses, this relation is not inconsistent with the model. Health behavior often is goal based, and one goal can be image acquisition. Exercising is an obvious example of a healthy behavior with an image that can act as a goal. But (normatively) negative images can also be goals: admission into a desired social group, "dirts" or "druggies," for example. In this case, the group has a negative image that can be attractive (for some) and therefore increase the image-to-intention relationship. Finally, prototype influence is moderated by social comparison tendencies. Those who compare a lot are more responsive to images, so the prototype/willingness relationship is stronger for them.

Subjective Norms and Attitudes

Norms

Some form of subjective norm construct can be found in most health behavior models, sometimes divided into *descriptive* and *injunctive* (people's perceptions of what others are doing versus what others want them to do). We have found that peer pressure (injunctive norms) is often not a significant factor in terms of health risk willingness, whereas perceived prevalence (descriptive norms) usually is. The model describes paths from subjective norms to both intention and willingness, but that may not be true for both types of norms. Engaging in a behavior because you believe others want or expect you to do it requires some thought and reasoning (what do they want? will this please them?), whereas doing a behavior mostly for conformity reasons (i.e., "everyone's doing it") requires less reasoning and more reacting. Future research examining whether injunctive norms lead to intentions whereas descriptive norms lead to willingness would be informative.

Attitudes

A similar dual-process argument could be made for attitudes. Using perceived risk as an example, perceptions of danger (e.g., "driving after drinking is dangerous") are usually higher than perceptions of personal vulnerability, which often reflect some optimistic bias (e.g., "I could have several drinks and drive home; I've done it before"). Perceived danger should be more strongly related to intention, and personal vulnerability more to willingness. Similarly, attitudes include both cognitive and affective components; the latter should be more strongly related to willingness than the former.

Interventions: Laboratory Studies

Perceived Risk

The PWM has been the theoretical basis for several interventions and preventive interventions as well as laboratory analogue studies examining the utility of components of the model, mostly prototypes and willingness, for possible future interventions. One recent example of this involved the "absent-exempt" heuristic, which is a perception that some people develop if they have been engaging in a risk behavior for some time and nothing bad has happened to them that they may be somehow immune to the consequences. A series of studies showed that absent-exempt thinking is enhanced among high-risk individuals by (downward) social comparison with a low-risk individual who *has* experienced the associated negative consequence (e.g., an STD), even though they had engaged in very little risk behavior (Stock, Gibbons, Beekman, & Gerrard, 2015). Most important, this increase in absent-exempt thinking was accompanied by an *increase* in willingness to have casual sex among high-risk individuals. This finding has intervention implications: PSAs that include the theme "It only takes once!" are common (especially for sexual behavior), which creates a real possibility of iatrogenic effects—increases in risk-taking after the intervention, due to absent thinking, among those already at high risk.

Dual Processing

There was also evidence of dual processing in these studies. Risk willingness increased significantly in all three studies, but risk intention did not change. Also, when reasoned processing was instantiated before the comparison opportunity, it eliminated the absent-exempt effect. Most interesting, however, was the fact that in addition to reporting lower perceived vulnerability and higher willingness (but not intention), high-risk participants also reported significantly more intention to get tested for an STD. In other words, the absent-exempt heuristic was associated with an increase in risk willingness ***and*** an increase in health promotion intentions—an example of reasoned action accompanying social reaction in the same individuals simultaneously.

Manipulating Prototypes

Safe Sex Images

Many studies have manipulated components of the PWM to test prototype malleability and the impact of these manipulations on willingness and behavior. They have addressed a range of behaviors besides substance use and UV exposure, including exercise, diet, sleeping, safe sex, and nonprescription drug use. Most have focused on risk prototypes, but a sizable number were prompted by Gerrard et al. (2002) in showing that images of people who engage in healthy behavior can also motivate change. In the first prototype manipulation study, college students read a bogus newspaper article reporting the results of a personality survey, indicating that the typical person who does not use condoms (experimental group) or does not vote (control) is "more selfish" and "less responsible" than those who do (Blanton et al., 2001). As expected, students in the condom condition reported less willingness to have unprotected sex than did those in the voter condition.

Prototype Visualization

Another prototype paradigm uses a visualization strategy. Ouellette, Hessling, Gibbons, Reis-Bergan, and Gerrard (2005) had participants write about typical exercisers and non-exercisers. As expected, exerciser prototypes were much more favorable; more important, a follow-up revealed that those in the exerciser condition significantly increased their exercising, relative to those in the non-exerciser condition. An extension of this study based on terror management theory employed a mortality salience induction to examine *why* prototypes affect behavior and found that making mortality salient, combined with contemplating an exerciser prototype, increased the extent to which participants said they valued exercising.

Interventions

UV Protection

A series of UV protection lab studies has also successfully altered prototypes. These studies employed a UV filter camera that produces a facial photo that graphically depicts existing skin damage due to previous UV exposure. The prediction was that the photos would make images of tanning and tanners more negative. Thus, the same motivation behind the risk behavior (appearance) was used to motivate abandoning it. One study showed that the photographs reduced prototype favorability and tanning willingness while increasing perceived vulnerability to skin damage; these changes mediated subsequent declines in tanning booth use among those who received the photos (Gibbons et al., 2005). A more recent study examined the impact of the UV photos from a dual-processing perspective by asking women to focus on either their thoughts or their feelings when they viewed the UV photos in order to encourage analytic or heuristic processing about the risk (Walsh, Stock, Peterson, & Gerrard, 2014). As expected, older women in the cognitive focus condition had lower sun exposure willingness and higher perceived skin cancer vulnerability than those in the affective focus group, suggesting that altering type of processing regarding risk can lead to a reduction in risk behavior. Another UV intervention focused on a high-risk population: road maintenance workers (Stock et al., 2009). Participants were shown UV facial photographs and then watched an educational video on UV risk and protection. There were two significant paths from the intervention to the outcome measures (changes in self-reported UV protection and tanning assessed objectively with a spectrophotometer): a direct path *and* an indirect path mediated by changes in risk cognitions suggested by the PWM. Thus, the most effective strategy for this high-risk population included both reasoned (educational) and heuristic components.

Strong African American Families (SAAF)

Work on family process by Gene Brody and colleagues led to the development of the SAAF Program, which is a family-centered alcohol preventive intervention based partly on the PWM. It includes two components. One component, which involved the parents, targeted the reasoned path by promoting parent–child communication. The second, more heuristic, arm was directed at the children. It was designed to make their drinker images more negative and educate them on the differences between planned and reactive behavior, thereby reducing their willingness to drink. The intervention was successful in decreasing the favorability of the children's drinker images and their intention and willingness to drink while increasing reports of parent–child communication. The desired effect on alcohol consumption at a 24-month follow-up also was significant (Gerrard et al., 2006).

Dual Processing

The SAAF intervention also demonstrated the efficacy of combining a heuristic *and* an analytic approach to shaping adolescents' decision making. In the reasoned path, the effect of changes in parenting on adolescents' drinking was mediated by changes in their intention; in the social reaction path, the effect of changes in the children's prototypes on their drinking were mediated by changes in willingness. The social reaction path was stronger, mostly because the willingness/behavior relationship was stronger than the intention–behavior relationship. Importantly, however, a structural equation model that included both the reasoned *and* the social reaction paths provided a significantly better fit of the data than models with either path alone, once again illustrating the utility of a dual-processing approach to intervention.

Smoking Prevention

Click City is an online prevention program that targets adolescents' prototypes and willingness and intentions to use tobacco. One study demonstrated that the intervention was most efficacious for children who were most at risk, that is, those who had tried smoking at baseline and/or had a family member who smoked. A follow-up replicated these results: Students in the program reported smaller increases in the favorability of their smoker prototypes and their willingness and intentions to smoke than those in the control condition (Andrews et al., 2014).

Future Research Directions

Smoker Prototypes and Smoking Cessation

The first PWM prototype study examined the relation between smoker images and success at smoking cessation (Gibbons, Gerrard, Lando, & McGovern, 1991). Results indicated that smokers' images of other smokers became more negative during the course of their quit group, and the more negative they became, the more likely the smokers were to quit. A subsequent study found that a negative smoker image was a better predictor of quitting than was a positive *former smoker* image (Gibbons & Eggleston, 1996). Along similar lines, overweight images have been shown to be stronger predictors of weight loss efforts than are thin images, and negative smoker prototypes are more motivating for nonsmokers to avoid smoking than positive smoker prototypes are for nonsmokers to start. These results suggest the desire to stop being, or avoid becoming, a negative exemplar may be a stronger motivator than the desire to become a positive (healthy) exemplar. More such cessation studies are needed.

Willingness and Prototype Development

Finally, examining factors that affect the development of images and willingness would have value from both an applied and theoretical perspective. We know that risk images are influential for children as young as 8, and we know that the media (especially movies) are an important source for these images (Gibbons et al., 2010). We also know that by age 13 or 14, adolescents can articulate the difference between intention and willingness. Further examination of this developmental process is called for; the same is true for the study of factors that can effect change in willingness and prototypes.

Conclusion

Several conclusions can be drawn from the PWM literature. First, willingness and intention are clearly related, but there is considerable evidence suggesting that they are different constructs, with discriminable antecedents and consequences. Second, analogue studies have demonstrated that risk and nonrisk prototypes are malleable and that reducing risk prototype favorability and/or increasing nonrisk prototype favorability can reduce risk willingness and actual risk behavior. Finally, there is evidence of increasing acceptance of the dual-processing perspective upon which the PWM is based, along with enthusiasm for the utility of this perspective for explaining, predicting, and changing health behavior, especially among adolescents.

Author Biographies

Frederick X. Gibbons is a health–social psychologist and a professor in the Department of Psychological Sciences at the University of Connecticut. He received his PhD in psychology from the University of Texas. His research interests focus on the application of social psychology theory and principles to the study of health behavior. This research has examined disparities in health status and factors associated with onset and cessation of health risk behavior. It has included survey and lab (experimental) studies, along with interventions and preventive interventions.

Michelle L. Stock is an associate professor in the Department of Psychology at The George Washington University. She received her PhD in psychology from Iowa State University. Her program of research includes a focus using the prototype-willingness model to provide a framework for understanding cognitive (heuristic and reasoned), affective, and situational factors that influence risky health decisions.

Meg Gerrard is a research professor in the Department of Psychological Sciences at the University of Connecticut. She received her PhD in psychology from the University of Texas. Throughout her career, her research has focused on the prediction of adolescent risk behaviors (i.e., alcohol and substance use, risky sexual behaviors, and smoking) and the prevention of these behaviors. She and her colleague (Rick Gibbons) developed the prototype-willingness model of adolescent health behavior in an effort to explain and explore non-intentional adolescent risk behavior.

Psychosocial Factors in Coronary Heart Disease

Elizabeth J. Vella

Department of Psychology, University of Southern Maine, Portland, ME, USA

Cardiovascular disease represents the leading cause of death globally, which includes mortality due to stroke and coronary heart disease (CHD); of these two forms of cardiovascular disease, CHD accounts for more deaths annually (World Health Organization, 2015). The primary features of CHD include plaque development in the coronary arteries (atherosclerosis), heart attack (myocardial infarct), and acute chest pain (angina; Labarthe, 1998). The traditional risk factors for CHD include age, obesity, high cholesterol, high blood pressure, inactive lifestyle, smoking, excessive alcohol consumption, and family history of the disease (World Heart Federation, 2015). Epidemiologic evidence suggests that traditional risk factors of CHD may account for 58–75% of new cases (Beaglehole & Magnus, 2002). Other predictors of CHD may include stress-related psychosocial factors at a person level (e.g., dispositional hostility and depression) and/or environmental level (e.g., chronic work-related stress and lack of social support; Albus, 2010).

What Is a Psychosocial Risk Factor?

Simply stated, a psychosocial risk factor should be conceptualized as a psychological attribute that impacts social behaviors in a way that elevates likelihood of illness, such as emotion dispositions of anger that increase antagonistic social interactions, thereby leading to exacerbated stress levels and social isolation, eventually giving rise to disease onset. The impact of psychosocial risk factors on illness onset is often both direct (e.g., stress-induced elevations in markers of inflammation that hasten atherosclerotic plaque formation) and indirect (e.g., stress-induced changes in lifestyle behaviors that contribute to unhealthy diet, smoking, and excessive alcohol consumption as maladaptive means of coping). When studying psychosocial risk factors for CHD, researchers must measure and control for the presence of traditional risk factors in their

General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

statistical models to effectively be able to ascertain that the psychosocial risk factors in question are predictive of CHD above and beyond the traditional risk factors aforementioned.

Early Research on the Type A Behavior Pattern and Trait Hostility

In the 1950s, cardiologists Friedman and Rosenman began to take notice that a pattern of personality characteristics seemed to typify their CHD patients. These physicians termed the personality style as the Type A behavior (TAB) pattern, characterized by a strong sense of time urgency, hard-driving competitiveness, ambitiousness, hostility, and tendencies to experience anger and become aggressive. They conducted a wide-scale assessment of TAB entitled the Western Collaborative Group Study (WCGS) to determine if a reliable relationship exists between this set of personality traits and the severity of coronary dysfunction; 3,154 men aged 39–59 were administered the structured interview to assess TAB and then followed for 8.5 years (Rosenman et al., 1975). Results indicated that Type A individuals were more than twice as likely to subsequently develop clinically significant CHD symptoms than Type B (essentially calm demeanor, even tempered) counterparts.

However, the Multiple Risk Factor Intervention Trial (MRFIT) called the TAB construct into question by failing to replicate WCGS results. Reliable differences in the administration and coding of the structured interview to assess TAB have been reported between WCGS and MRFIT, which may account for these discrepant results (Sherwitz & Brand, 1990). Further, the multifaceted nature of the Type A construct may increase the probability of inconsistencies in the literature. Importantly, subsequent analyses of data from WCGS and MRFIT indicated that the structured interview-derived subscale score entitled "potential for hostility," an interactive style of expressive speech and experience of anger, was a better predictor of CHD in both datasets than the global Type A score (Dembroski, MacDougall, Costa, & Grandits, 1989; Hecker, Chesney, Black, & Frautschi, 1988). Therefore, the toxic elements of TAB appear to concern a particular interactive style separate from the qualities of ambitiousness, competition, and time urgency.

More recently, evidence suggests a reliable association between trait hostility/anger and CHD outcomes. For example, a meta-analytic report across 21 articles longitudinally examining 71,606 initially healthy participants and 18 articles longitudinally studying 8,120 CHD patients found that elevated ratings of anger/hostility were linked to an average 20% increase in disease risk, in terms of risk of eventual diagnosis amid initially healthy participants and risk of additional coronary events/CHD mortality for the patient samples (Chida & Steptoe, 2009). Interestingly, the risk profile was more pronounced amid the latter samples of participants already diagnosed with CHD, suggesting that the mere diagnosis and experience of CHD as a condition may promote bouts of anger and hostility in a way that contributes to poorer prognosis. Specifically, anger/hostility ratings predicted a 24% increased risk of additional coronary events/CHD mortality amid patients compared with a 19% increased risk of CHD diagnosis amid initially healthy participants.

Currently, the hostility construct remains a point of controversy as a risk factor for the development of CHD, yielding a mixture of results claiming significant and insignificant associations. A clear problem in the literature that may explain many of these discrepancies across studies concerns the multidimensionality of the hostility construct (cognitive mistrustfulness, emotional anger, and behavioral aggression). This problem is compounded by variability in measurement instruments: some assessment tools for measuring hostility are more reliably predictive of disease onset than others (e.g., cynical mistrustfulness and the experience of anger versus anger expression through aggression), a quality that adds confusion to the medical science literature.

Depression

Clinical depression is diagnosed based upon criteria specified in the Diagnostic and Statistical Manual published by the American Psychological Association, including such symptoms as depressed mood, feelings of worthlessness, fatigue, changes in sleep patterns, and suicidal ideation. The relationship between clinical depression and CHD diagnosis/mortality is more reliable and robust than the associations apparent for hostility/TAB. For example, a recent meta-analysis across 30 prospective cohort studies including a total of 893,850 participants indicated that depression was associated with a 30% increased risk of CHD diagnosis (Gan et al., 2014). Similar to the hostility construct, the timeframe of depression onset has been found to be meaningfully related to CHD prognosis: patients who experienced recurrent–persistent depression pre-CHD diagnosis and maintained depression levels post-CHD diagnosis were 1.5–2 times more likely to be re-hospitalized for a coronary event or experience coronary mortality, respectively, than their non-depressed counterparts (Leung et al., 2012). These findings indicate that clinically depressed adults are at an elevated risk for CHD diagnosis and that they furthermore exhibit poorer CHD prognoses compounded by a higher mortality risk due to coronary complications.

Environmental Factors: Work Stress

A long-standing history of research has illustrated work-related stress to contribute to disease outcomes, ranging the full gamut from acute bouts of insomnia to chronic medical conditions, such as CHD (Ganster & Rosen, 2013). A variety of theoretical orientations have been offered to organize research assessments, including the job strain model, the effort–reward imbalance model, and the organizational injustice model (e.g., Kivimäki et al., 2006). The job strain model proposes the demand–control hypothesis that occupations characterized as high demand–low control represent a toxic combination in terms of giving rise to chronically elevated stress levels that degrade immune function and lead to adverse health outcomes. In short, this model stipulates that employees who are burdened with oftentimes unpredictable waves of high volume responsibilities (elevated demand) without appropriate decision latitude for managing the workload (poor control) are at risk for work-related illness and eventual burnout. Along similar lines, the effort–reward imbalance model stipulates that work environments whereby employees are disproportionately challenged relative to compensation and recognition are likewise at risk for stress-induced illness. Finally, the organizational injustice model argues that stress-induced illnesses may arise in workplaces whenever employees reliably report being treated unfairly by their supervisors. Each model grapples with different ways by which workers may experience heightened stress levels on a daily basis.

Evidence supports all three models of conceptualizing the work stress–CHD relationship, as indicated by a meta-analytic report of 14 prospective cohort studies involving 83,014 employees, whereby elevations in work stress predicted an average 50% increase in CHD diagnosis/mortality (Kivimäki et al., 2006). Although all three models were supported in this meta-analysis, the evidence was significantly stronger in support of the effort–reward imbalance and organizational injustice models relative to the job strain model, after controlling for the variance pertaining to traditional CHD risk factors. Irrespective, there is a clear and strong pattern of evidence that elevated stress in the workplace predicts adverse coronary outcomes over time.

Environmental Factors: Social Support

Having the opportunity to discuss stressful life experiences with a trusted confidant can be helpful in reducing emotional strain and promoting problem-focused coping, envisioning potential resolutions to the circumstances underlying the challenge/threat in question. Social support resources elicit the tendency to perceive that a weight has been lifted from one's shoulders through self-disclosure, thereby enhancing the sensation of self-efficacy (ability to effectively handle the stressful situation) and reducing the maladaptive tendency of catastrophizing (rumination of difficulties that leads to perceived hopelessness—common when people feel overwhelmed by their life stressors and alone in their path of coping). If chronically elevated stress levels increases risk of CHD diagnosis/mortality, it stands to reason that stress-reducing social environments would confer protective benefit.

Sources of social support are typically defined in the health sciences literature in terms of being "functional" or "structural" in scope. Types of functional support include the following categories: emotional, informational (e.g., receiving advice), financial, appraisal (someone helping to evaluate a situation), and instrumental (e.g., receiving assistance in completing a project), whereas structural support pertains to the number of individuals in one's social network in terms of marital status, proximity of friends and family, community memberships, and the frequency of social contacts (e.g., number of times visiting with friends per month).

The pattern of evidence in both etiologic (initially healthy samples) and prognostic (samples of CHD patients) longitudinal studies has been significant for functional social support but insignificant for structural social support, whereby low functional support predicted elevated relative risk of heart attack amid initially healthy samples and, in particular, a 59% increased risk of mortality amid CHD patients after controlling for traditional risk factors in a meta-analysis (Barth, Schneider, & von Känel, 2010). These findings highlight the prominence of functional social support with regard to the quality of supportive social interactions, rather than the structural quantity of social interactions, when predicting health outcomes.

Environmental Factors: Socioeconomic Status

Typically assessed by annual income and/or years of education, socioeconomic status (SES) represents an environmental attribute worthy of consideration as a psychosocial risk factor for CHD. There are a variety of putative mechanisms that may connect low SES to CHD outcomes, such as indirect effects of inadequate resources to maintain a healthy lifestyle and direct effects of stress-induced influences on coronary dysfunction. For example, individuals of a lower class standing may consume a cheaper, highly processed diet conducive to the development of obesity, type 2 diabetes, hypertension, and elevated cholesterol. Likewise, the economic burden of poverty often compels individuals to work two to three jobs to make ends meet, thereby exacerbating perceptual stress levels as a function of workload and reducing time spent with family and friends—effectively degrading social support resources for stress management. Thus, lower SES tends to co-occur with elevated work stress and poor social support, eliciting potential synergistic effects on disease outcome, suggesting a need for theoretical orientations designed to guide research investigations involving psychosocial risk factors for CHD morbidity and mortality.

Meta-analytic evidence involving 70 studies has indicated significant effects across income, occupation, and education whereby individuals in the lowest socioeconomic positions exhibited elevated risk of incident heart attack relative to their more affluent counterparts, with the effects most apparent in terms of income (a staggering 71% increase in relative risk of heart attack; Manrique-Garcia, Sidorchuk, Hallqvist, & Moraldi, 2011). Further, prospective evidence following 66,500 initially healthy adults across 8 years found low SES predicted CHD mortality after controlling for traditional risk factors. SES was measured in terms of three occupational classes (professional/managerial, skilled manual/non-manual workers, and semi-routine/unskilled workers) with each step down from professional/managerial associated with a 24% increase in CHD mortality (Lazzarino, Hamer, Stamatakis, & Steptoe, 2013). Moreover, a synergistic effect was observed whereby psychological distress augmented the adverse effects of low SES: the combination of low SES and high psychological distress was linked to a 33% increase in CHD mortality relative to high SES and low psychological distress counterparts (Lazzarino et al., 2013).

Piecing Together the Puzzle: Integrative Theoretical Frameworks

The evidence to date reveals that a variety of psychosocial risk factors predict elevated CHD morbidities and mortalities to a varying degree after controlling for the presence of traditional risk factors, including dispositional factors such as hostility and depression (e.g., Chida & Steptoe, 2009; Gan et al., 2014) and environmental factors such as occupational strain and low social support (e.g., Barth et al., 2010; Kivimäki et al., 2006). However, emergent findings increasingly show that these psychosocial risk factors do not exist in a vacuum, but rather dynamically interact with one another, thereby requiring more comprehensive theoretical models to guide future research. For example, the transactional model of hostility stipulates that the cynical mistrustfulness associated with this disposition serves as a driving force to create a social environment conducive to antagonistic behaviors that degrade social support resources and exacerbates emotional strain (e.g., Vella, Kamarck, Flory, & Manuck, 2012). Finally, the reserve capacity model was designed to explain associations between SES and health outcomes, whereby lower SES directly increases perceptual stress levels while simultaneously reducing social support resources for coping (the reserve capacity); in turn, both of these SES-induced developments of increased stress and decreased coping reserve are thought to directly elevate daily negative emotions/cognitions and reduce positive emotions/cognitions, collectively altering physiological processes that underlie CHD risk (Gallo & Matthews, 2003).

Numerous issues pervade this literature and are worthy of mention as limitations for consideration to improve subsequent research. First, whether dispositional or environmental in scope, all psychosocial risk factors reviewed here feature the same common denominator of elevated stress levels that may impact upon health status via direct and indirect pathways. As such, researchers should focus their attention on incorporating standardized measures of perceptual stress levels in concert with the psychosocial risk factors in question to disentangle the pathways leading to CHD outcome. Second, most of these psychosocial risk factors are multifaceted in scope, suggesting a need to concentrate efforts on measurement issues to reliably delineate the relative degrees to which psychosocial risk factor attributes predict the development and prognosis of CHD. Finally, just as it is known that functional social support may improve one's ability to effectively cope with stressful life experiences, reducing risk of CHD morbidity and mortality, researchers should also counterbalance their investigations by incorporating other psychosocial "protective" factors that may confer significant health benefit as part of their theoretical models (e.g., frequency of positive emotions and trait optimism). Future research on psychosocial risk factors of CHD should make targeted efforts to ascertain interactive pathways that include traditional risk factors to maximally predict health outcomes and enhance scientific understanding of these provocative associations.

Author Biography

Dr. Elizabeth J. Vella is an associate professor of psychology at the University of Southern Maine. Her research interests include the link between psychosocial factors and cardiovascular risk and the physiological mechanisms that may explain these associations, as well as the implications for stress management interventions in improving quality of life and reducing physiological responses to stressors among at risk populations. She has authored numerous articles in scientific journals and presented her research at academic conferences.

Relationship Dissolution and Health

Karen Hasselmo, Kyle J. Bourassa, and David A. Sbarra

Department of Psychology, University of Arizona, Tucson, AZ, USA

Humans are inherently social beings, and intimate relationships are a particularly important part of our lives. The beneficial effects of intimate relationships may operate directly by encouraging healthy behaviors (e.g., high-quality sleep or a healthy diet) or more indirectly by buffering against the effects of psychological stress. Conversely, the absence of relationships, or being in a low-quality relationship, is associated with a variety of negative health outcomes. This entry focuses on health outcomes associated with romantic separations. Specifically, we report on the epidemiological data connecting romantic separations with morbidity and mortality, explore the potential behavioral physiological mechanisms linking these outcomes with the dissolution of the relationship (e.g., cardiovascular and immune system processes, health behaviors), and consider the psychological variables that may explain the associations of interest, including forgiveness, rumination, and psychological distancing. We end with future directions for research and intervention development.

When intimate relationships end, most people are resilient and cope well over time. The end of an intimate relationship can, however, set the stage for adverse effects on well-being—whether it is divorce after decades of marriage or the breakup with a first love.[1] For the subset of people who *are* affected negatively by a separation experience, these effects can exert their negative influence across a range of health-relevant physiological systems.

Morbidity and Mortality Following Dissolution

The bird's-eye view of intimate relationship dissolution offers one perspective on the connection between separations and poor health. In large samples of separated and/or divorced people, average findings indicate an increased risk for all-cause morbidity and mortality (Sbarra, Law, & Portley, 2011). For example, in a long-term study of the Uppsala birth cohort, being divorced placed both men and women in the highest risk groups for early mortality, with a 46 and 27% higher relative mortality risk than their married counterparts, respectively (Donrovich, Drefahl, & Koupil, 2014).

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

Research has begun to connect specific disease processes to marital status changes. In a sample of over 3.5 million participants, for example, married participants had lower odds of any cardiovascular disease (OR = 0.95), whereas divorced participants had higher odds (OR = 1.05) relative to single adults (Alviar, Rockman, Guo, Adelman, & Berger, 2014). Losses in bone density are also connected to divorce or separation; divorced men, relative to those who are married, demonstrated a 0.33 standard deviation reduction in lumbar spine-bone mass index. This number was similar (0.36) even for those men who remarried.

Infectious diseases are also associated with marital status. In a cohort of over 5.5 million men and women followed for hospital contacts over three decades, divorced participants had a 48% greater chance of contracting a hospital-diagnosed infectious disease when compared with married participants (Nielsen, Davidsen, Hviid, & Wohlfahrt, 2014). This increased infection risk was sustained in a 15-year follow-up. Other research demonstrates that rates of illness peak around the time of divorce and may not return to their baseline levels. Beyond physical health, marital status is predictive of mood and anxiety disorders across the world. In a study conducted by the World Mental Health Survey Initiative on a sample of 35,500 participants, the odds ratio of any mood or anxiety disorder increased 23% for divorced participants relative to married adults, and this effect was much stronger for women (OR = 2.6; McDowell et al., 2014).

These epidemiological findings demonstrate the importance of studying health outcomes following a separation but offer few hints regarding what processes might underlie the association between dissolution of intimate relationships and negative health outcomes.

Health-Relevant Responses to Relationship Dissolution

A thorough account of how relationship breakups can ultimately affect physical health links psychological responses to separations with biologically plausible mechanisms of action (cf. Miller, Chen, & Cole, 2009). Physiological responding can be studied to investigate emotions and emotional responses, as well as an intermediate health-relevant index used to link emotional reactions with long-lasting, systemic changes in the body. For example, cortisol may play a role in the distress response following a social stressor, but it may also function as the mediator of the relationship between stress and a pathological inflammatory response. Thus, care must be taken in discussing physiological responses in general versus physiological responses that have clear implications for health.

Miller et al. (2009) have advanced a conceptual approach to studying how biobehavioral responses to life events are associated with and may regulate (and be regulated by) disease-relevant molecular and cellular responses. This approach highlights the role of biological intermediaries, or, as Miller et al. (2009) stated, “Once a robust linkage between a psychosocial factor and a clinical health outcome is identified, the next step is to determine what biological processes convey those effects into the physical environment of disease pathogenesis” (p. 504).

Related to divorce, Miller et al.’s (2009) first criterion is satisfied. Beyond the meta-analytic findings we described above, other studies demonstrate that divorce can result in a proliferation of stress that mediates the association between the end of marriage and poor self-rated health up to a decade later. We do not yet know, however, the biological intermediaries that translate the psychosocial stress of divorce into poor physical health. We have some clues as to how these effects might operate but lack clear-cut, disease-relevant pathways. In the following sections, we review what is known with respect to cardiovascular, immune, and endocrine outcomes. We also discuss the role of relationship dissolution in shaping people’s health behaviors, as these behaviors are associated with changes in each of these systems.

Cardiovascular Responding

Cardiovascular processes are one possible link between intimate relationship dissolution and negative health outcomes. A dysregulated cardiovascular response to stress is thought to be an indicator of—if not causally linked to—the development of cardiovascular disease. It is well established that an exaggerated response to environmental stress leads to rises in future blood pressure, and there is evidence to suggest hyperreactivity is reliably associated with a host of other cardiovascular issues, such as atherosclerosis (i.e., buildup of plaque in the arteries) and increased cardiac hypertrophy (i.e., thickening of heart muscles; Chida & Steptoe, 2010). Conversely, hyporeactivity, or a blunted response to stress, is also linked with negative health outcomes, including obesity, depression, and poor self-rated health, possibly due to its association with behaviors driven by disordered motivation, such as heightened focus on rewarding stimuli. As a result, both hyper- and hyporeactivity may indicate health risk following a stressful separation experience. For example, when asked to reflect over their relationship history and recent separation experience, divorced adults who scored high in anxious attachment style and who spoke in a verbally immediate way (i.e., indicating a pattern of continual engagement with the dissolved relationship) evidenced significantly higher blood pressure at the start of a divorce-related experimental task (Lee, Sbarra, Mason, & Law, 2011). In a similar investigation, high levels of divorce-related emotional intrusion were associated with elevated blood pressure, and men who find thinking about their separation especially difficult evidence substantial blood pressure increases when asked to do so (Sbarra, Law, Lee, & Mason, 2009).

Heart rate variability, as indexed by respiratory sinus arrhythmia (RSA) (Porges, 1995), is a second active area of research in cardiac responding. RSA represents the action of the vagus nerve, which exerts inhibitory control over the heart. Higher RSA is adaptive in certain situations, as it helps prepare the body to free-metabolic resources for coping responses driven by the sympathetic nervous system. Low RSA is predictive of greater cardiovascular disease risk; moreover, context inappropriate changes in RSA are thought to index poor self-regulation (Porges, 1995). Regarding RSA reactivity in divorced adults, Sbarra and Borelli (2012) found that adults who reported having avoidant attachment styles, conceptualized as an ability to achieve emotional distance from their relationships, and who were successful at regulating their emotions during a divorce-related task, as indexed by high levels of RSA reactivity during the task, evidence the greatest improvements in their self-concept over the course of three months (Sbarra & Borelli, 2012). Further research involving RSA and adults' adjustment following divorced considered a genetic polymorphism in the serotonin transporter gene (SERT). The "short" variation of this allele results in less available serotonin in the brain, and adults with the genetic polymorphism who also reported difficulty adjusting to their separation experience had significantly decreased levels of RSA during a task that asked them to reflect on their divorce experience (Hasselmo, Sbarra, O'Connor, & Moreno, 2015).

Immune Functioning

A second health-relevant psychophysiological pathway through which the end of an intimate relationship may exert its negative effects is via the immune system. Much like the cardiovascular pathway, the immune system has important functions for survival and health, and higher levels of social support are generally associated with an increase in physiological functioning in both the cellular and humoral divisions of the immune system (Uchino, Cacioppo, & Kiecolt-Glaser, 1996). Conversely, divorced/separated adults experience higher rates of mortality due to infectious diseases compared with their married counterparts. Psychoneuroimmunologists investigate the immune correlates of social influence by looking at both numbers of important immune cells and functionality of the system itself, both of which are required to mount an appropriate immune response (Uchino et al., 1996). Intimate relationship dissolution may influence the immune system through both of these routes. For example, when compared with married adults on various measure of immune system functioning, recently divorced participants showed decreased functioning on several immune parameters (Kiecolt-Glaser et al., 1987). A weakened immune system following the chronic stress of divorce or separation may lead to the higher rate of infectious diseases in this population. The mechanism that links the psychosocial effects of divorce or separation and the immune system is not yet understood, but two candidate pathways have emerged.

One route through which the stress of separation from a partner influences immune parameters is the endocrine system, specifically the various hormones this system releases in response to stress. Cortisol, a steroid hormone, has a particularly diverse range of effects within the body, including the ability to bind to the white blood cells of the immune system and regulate both their distribution throughout the body and their functional responses (Segerstrom & Miller, 2004). Cortisol plays an important role in preparing the body to respond to stress, but if levels are elevated chronically, it can lead to the development of chronic inflammatory diseases such as arthritis and asthma, among others. Preliminary data from Powell et al. (2002) investigated 20 women who were undergoing a separation event and 20 who were in stable marriages. They found that separating women had elevated salivary cortisol, suggesting a link between relationship dissolution and cortisol levels. Although this data is encouraging, more specific studies linking the cortisol pathway to divorce in particular are needed.

An exaggerated cortisol response can be deleterious in and of itself, but it can also set the stage for other problematic immune responses. In particular, it can permit inflammation over time. Similar to the hyperactivation of the cardiovascular system following the dissolution of an intimate relationship, the immune system can be over-activated in response to the chronic psychological stress associated with a breakup. The immune response to stress often initiates with the release of chemical messengers, known as cytokines, which alert the rest of the body to the presence of an intruder. If these cytokines are pro-inflammatory, they set off a cascade of processes in the body that promote inflammation. Although these pro-inflammatory cytokines are adaptive at first, they can become dysregulated during the chronic stress following a distressing event. One model suggests that glucocorticoid receptors in the brain, which receive the inflammatory message of these cytokines and then downregulate the signal, become desensitized to the pro-inflammatory cytokines when they are chronically proliferating (Miller, Cohen, & Ritchey, 2002). Without this glucocorticoid regulation, the inflammatory response persists, elevating risk for a range of chronic inflammatory diseases, including Type 2 diabetes, various autoimmune diseases, and cardiovascular disease. This pro-inflammatory pathway receives considerable attention in the broad literature on stress and health but has yet to be studied as people adapt to a divorce or a romantic breakup.

Health Behaviors

Although it is possible that the psychological stress of divorce is associated directly with changes in the aforementioned physiological systems, it is important to recognize that lifestyle habits following a breakup also play a powerful role in shaping the responses in these systems. In this way, health behaviors may be important in understanding the intermediate steps from relationship dissolution to morbidity and mortality. For example, social relationships promote important behaviors like seeking medical care and adherence to care while also encouraging self-care like exercising, healthy eating, and avoiding illicit drug use. A recent study of adherence to doctor-provided cancer prevention guidelines noted that the number one indicator of reductions in all-cancer incidence and cancer mortality was following the prescribed guidelines (Kabat, Matthews, Kamensky, Hollenbeck, & Rohan, 2015). As being married increases adherence to medical advice, this may affect health at multiple levels for divorced or separated adults. Similarly, the loss of this social pressure in the form of a spouse or partner may disrupt these healthy lifestyle behaviors. Furthermore, there is epidemiological evidence that divorce or separation promotes the adoption of unhealthy habits like substance abuse. Women in particular are vulnerable to decreases in body mass, increased likelihood of smoking relapse, and decreases in the amount of healthy fruits and vegetables consumed following divorce. The cessation of positive health behaviors and the development of unhealthy ones result in an increased risk for the promotion and maintenance of cardiovascular problems and deleterious changes in the immune functioning.

Sleep is an additional lifestyle factor that may affect health following the end of marriage. Disturbances in sleep can lead to dysregulated endocrine and autonomic nervous system functioning and even directly to higher mortality risk. Research suggests that divorced people have a higher incidence of sleep disturbance than partnered individuals. An early study of 70 subjects undergoing a separation period revealed these participants exhibited less delta wave sleep during their separation experience than their age-matched, married counterparts, indicating lighter overall sleep (Cartwright & Wood, 1991). Epidemiological studies reveal that being separated or divorced is associated with an elevated risk for severe insomnia and sleep maintenance problems (Hajak, 2001). Another study focusing on 367 middle-aged women's relationship histories over 6–8 years noted that continuously married or cohabitating participants have better sleep quality (measured both by self-report and a number of objective measures) than women who were unpartnered or gained/lost a partner during this same time period (Troxel et al., 2010). More recently, research on divorced adults suggests that sleep disturbances following separation predict future increases in blood pressure (Krietsch, Mason, & Sbarra, 2014). These increases were especially noteworthy in participants who continued to report disturbances 10 weeks after the separation and who evidenced the greatest increases in future blood pressure (Krietsch et al., 2014). Sleep highlights another pathway through which cardiovascular functioning may increase morbidity and mortality following a separation experience.

Integrating Across Multiple Domains: Allostatic Load

If the presence of indicators of health risk across a variety of health-relevant physiological systems are chronic and/or severe enough, their effects may accrue to produce accumulated wear and tear on the body, termed allostatic load (McEwen, 2000). Allostasis describes a physiological or behavioral adaptation to environmental changes in order to restore normality, or homeostasis (McEwen, 2000). Excessive cardiovascular, neuroendocrine, and immune activations in response to stress can promote vascular remodeling, initiate atherosclerotic plaque growth, and alter gene expression in a manner that contributes to disease pathogenesis (Miller et al., 2009). These processes may lead to the increased morbidity and mortality rates noted among populations affected by divorce and separation, though this area requires future research. To the extent that the cardiovascular and immune systems stay activated over time, that wear and tear may lead to illness and early death. What psychological processes are associated with the prolonged, hyperactivation of these physiological systems? We consider this question in the final section of the chapter.

Psychological Processes and Health Outcomes

In terms of psychological characteristics associated with adjustment to divorce, it is well known that individual differences in attachment anxiety are associated with poor outcomes when people perceive a threat to their relationship and/or their security within the relationship. In a study mentioned above in relation to blood pressure responses, Lee et al. (2011) studied language as a behavioral manifestation of attachment-related hyperactivation. People higher in attachment anxiety who spoke about their separation experience in a highly immediate, experiential, and self-focused manner demonstrated greater increases in systolic and diastolic blood pressure when thinking about their relationship history and separation experience relative to those people lower in attachment anxiety. People at high risk for poor outcomes following marital separation appear to employ coping strategies that are associated with a high degree of physiological activation, and this study, focused on blood pressure reactivity, provides an example of the ways in which emotion regulation strategies around attachment themes can provide insights into processes that confer risk for poor distal health outcomes.

Other research on emotion regulation following divorce supports this idea. For example, an intervention for recently divorced people (Sbarra, Boals, Mason, Larson, & Mehl, 2013) focused on the use of expressive writing (EW; writing about emotional feelings) compared with control writing (continuously writing about nonemotional issues). The results indicated that EW increased distress related to the divorce 3-month follow-up for people high on rumination when compared with low ruminators who were in the EW condition and all people in the control writing condition. After 8 months, however, all people in the EW condition and low ruminators in the control writing condition were equivalent in their distress, whereas high ruminators, purportedly at the most risk for negative outcomes following divorce, evidenced the lowest distress. The results suggest that allowing people who are at risk for rumination to focus on actively structuring their time (rather than "digging more deeply" into the emotions associated with their separation) reduces their psychological distress following marital separation.

Together, the findings related to attachment anxiety and rumination suggest potential psychological mechanisms linking marital separation to poor health outcomes. People who have a hard time distancing themselves from their psychological experiences show excessive cardiovascular responding, which, as noted above, is associated with the development of cardiovascular disease. Conceptually, this work fits well with the larger literature on self-distanced reflection and evidence indicating that people who *recount* their experiences in a blow-by-blow manner rather than *reconstrue* their experiences to find meaning are at heightened risk for mood disorders (see Kross & Ayduk, 2011).

In addition to attachment anxiety and rumination, forgiveness is another important psychological variable associated with adults' recover from divorce. Rye et al. (2005) developed an intervention focused on facilitating forgiveness for an ex-spouse using previous research indicating that forgiveness predicted improved well-being, as well as reduced depressive symptoms and both state and trait anger. The intervention was based on a prior intervention designed to increase forgiveness for previous wrongs in a romantic relationship in college women, which resulted in higher levels of forgiveness and well-being for participants. Among divorcing adults, this team tested two versions of their forgiveness intervention (secular versus religious forgiveness) and a no-treatment control using a randomized control trial (RCT) over 8 weeks of treatment and a 6-week follow-up period. Participants in both the secular and religious intervention conditions showed improvements in forgiveness of their ex-partner compared with control, though only the secular condition evidenced decreased levels of depression. This program of research and evidence from a laboratory experiment that less forgiveness results in higher skin conductance, heart rate, and blood pressure compared with baseline (van Oyen Witvliet, Ludwig, & Vander Lann, 2001) suggests that interventions designed to target forgiveness following divorce and romantic breakups may yield benefits in health outcomes.

Beyond self-distanced reflection and forgiveness, other variables and processes may serve as potential explanatory pathways leading to health-relevant biological changes. In a prospective study of breakups following nonmarital dissolution (Mason, Law, Bryan, Portley, & Sbarra, 2012), improvements in self-concept clarity (knowing who you are as a person after a separation) were associated with increases in future psychological well-being. There was no evidence in this study that people begin to feel better, who then report a greater sense of who they are after their breakup; instead, the direction of the effect seems to operate from self-concept clarity to improved psychological well-being. In a recent experimental study, Larson and Sbarra (2015) found that people who simply reflected on their separation experience multiple times over nine weeks increased their sense of self-concept clarity, which, in turn, explained decreases in loneliness and breakup-related emotional distress over the entire study period. Self-concept clarity was a key variable in early accounts of the psychological response to divorce (Weiss, 1975), yet no studies to date have examined this variable with respect to biomarkers of interest.

Conclusions

Intimate relationships are an important part of people's lives and can be beneficial for psychological and physical health. When relationships end, however, people are broadly vulnerable to morbidity and mortality from all causes, potentially due to changes in cardiovascular and immune responding. Alterations in these so-called biological intermediaries appear to be the result of changes in health behaviors, including sleep, medical adherence, self-care, healthy eating, and exercise. There are several potential psychological mechanisms that may link the end of an intimate relationship to distal health outcomes. Examples provided in this entry include experiential over-involvement, rumination, forgiveness, and self-concept clarity. Because of the health risks conferred by romantic separations, it seems essential to target those most at greatest risk for poor outcomes. Future interventions after romantic separation and divorce should focus on affecting the health behaviors and psychological processes proposed to mediate the link between romantic separation and health outcomes, with the goal of reducing the health burden associated with separation. In short, romantic separation and divorce are common stressful events, and these experiences are associated with negative, health-relevant consequences for a subset of people.

Author Biographies

Karen Hasselmo, MA, is a doctoral candidate at the University of Arizona, and her research centers on psychological and physiological outcomes of relationship dissolution.

Kyle J. Bourassa, MA, is a doctoral candidate at the University of Arizona, and his research centers on dyadic processes in intact relationships, as well as how prior relationship characteristics might affect people's well-being following romantic separation.

David A. Sbarra, PhD, is an associate professor of psychology at the University of Arizona. His research focuses on social relationships and health, as well as how people recover from difficult social transitions.

Note

[1] Although there are obvious differences between the end of marriage and a nonmarital breakup, in this entry, we consider literatures relevant to both. Where the category matters, we make the distinction clear.

Risk Perception

Vera Hoorens

Center for Social and Cultural Psychology, Katholieke Universiteit Leuven, Leuven, Belgium

Risk perception is people's judgment of future outcomes that may occur if they or other people follow a given course of action. Although risks may involve desirable as well as undesirable outcomes, the term is mostly used to describe undesirable outcomes such as health and safety hazards or natural or man-made disasters. Some researchers distinguish between risk perception and risk evaluation. By risk perception they mean the estimation of the risk's magnitude; by risk evaluation they mean judgments of risk acceptability, assumed to depend not only on the perceived magnitude of the risk but also on other risk characteristics. Other researchers use the term "risk perception" in a broader sense, including judgments of risk magnitude as well as of any other characteristic that might affect the risk's acceptability. Risk perception in both senses is to be distinguished from risk assessment, which is a formal and systematic risk analysis undertaken by risk experts (such as actuaries) in the context of financial or policy decisions.

Understanding how people perceive and evaluate risks is important to understand health and safety behavior and responses to risks of man-made and natural disasters. To explain why people are willing (or unwilling) to pay for insurance, for instance, or to explain why they freely enter objectively dangerous situations but feel unsafe in objectively non-dangerous ones, one needs to understand how people perceive the risks involved. Not surprisingly, risk perception and evaluation have been studied by researchers from a wide variety of disciplines, including psychology, economics, criminology, and sociology.

Early research often started with the assumption (sometimes implicit) that people intuitively follow normative statistical or logical rules while judging risk magnitude. From a normative point of view, the magnitude of a given individual's risk is a joint function of the perceived valence and extremity of the outcomes that he or she may experience (in more technical terms, outcomes' expected subjective utility) and these outcomes' perceived likelihood. Although many studies have focused on such individual risk perception (e.g., a vacationer judging her risk of skiing accidents), people may also form impressions of collective risks (e.g., a travel guide judging the risk of skiing accidents in her group of vacationers). Normatively, judgments

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

of the magnitude of overall risk should then also depend on the number of individuals who are likely to be affected. Assuming that people can and sometimes do intuitively follow normative rules, researchers in the domain of individual risk perception have studied how people estimate event likelihoods, how they arrive at expected subjective utilities, and how they combine likelihood and utility information toward an overall judgment of a risk's magnitude. In addition to these questions, researchers in the domain of collective risk perception have also examined how people perceive the number of individuals affected and how they integrate this information in their general risk perception.

More recent studies on risk perception are rooted in the view that people can apprehend reality in two fundamentally distinct manners: in an analytical manner, or in an experiential manner. From this perspective, people are thought to sometimes base their evaluation of the risks that are associated with a given activity on a systematic consideration of the associated outcomes and their likelihoods, but in other cases they base their risk evaluation on the affective state they experience while considering the activity. The analytical manner is deliberative, verbal, systematical, and slow, whereas the experiential manner is affective, nonverbal, intuitive, and quick. Although researchers who support the dual-process approach continue to value research on likelihood estimation, expected subjective utility, and the combination of the two, they also examine how affective states determine risk perception and strive to identify the circumstances in which either systematic risk analysis or affect-driven risk perception occurs. Among the circumstances that have been shown to favor affect-driven risk perception are strong emotional reactions, time pressure, and reduced cognitive resources (e.g., Finucane, Alhakami, Slovic, & Johnson, 2000).

Likelihood Estimation

One can estimate the likelihood of an event by observing how often, out of the cases in which it might have occurred, it has indeed occurred. People sometimes try to engage in this exercise, but in many cases they do so incompletely or use a totally different approach.

When relative frequencies are used to estimate probabilities, one should weight each nonoccurrence as heavily as each occurrence. Five occurrences of an infection clearly represent a different likelihood of infection if 20 individuals were exposed than if 200 individuals were exposed. However, people focus on occurrences to the neglect of nonoccurrences. When likelihood or frequency information is presented to them in the form of a proportion or a fraction (e.g., a 1 out of 100 chance, a 10 out of 1,000 chance), they tend to focus on the numerator (in the examples just given, 1 or 10, respectively) to the neglect of the denominator (in the examples just given, 100 or 1,000, respectively). Thus, a 10 out of 1,000 chance seems larger than a 1 out of 100 chance even though the probability is identical in each case. One implication of this phenomenon is that likelihoods that are expressed in a probability format (i.e., as a value from 0 to 1 or as a percentage) seem smaller than likelihoods that are expressed in a frequency format with a denominator above 1.

One impressive demonstration of this phenomenon was produced by Slovic, Monahan, and MacGregor (2000). They asked mental health professionals to judge if a given patient should be released from the hospital given the risk of the patient committing acts of violence. Half of the participants read that according to another expert, "20 out of 100" comparable patients committed acts of violence, whereas the other half read that according another expert, comparable patients had a "20% likelihood" of committing acts of violence. Participants were much less willing to release the patient in the former case than in the latter, indicating that they considered the likelihood of violent actions higher in the former case than in the latter.

Even if people try to follow normative statistical rules, their estimates of how often events happen versus not happen is relatively easy to influence. For instance, support theory implies that people derive an estimate of an event's likelihood from the support that they can find for the hypothesis that the event will occur relative to support for the alternative hypothesis that it will not occur (Rottenstreich & Tversky, 1997). The support for the focal or the alternative hypothesis depends, among other variables, on the ways in which people can imagine that the event will happen (or not happen). Events seem more likely when specific instances are provided (when the events are "unpacked") than when the event is merely described through a general label. For instance, when people estimate their likelihood of contracting a disease on their vacation, their estimate will be higher when they consider Dengue, typhoid fever, cholera, diarrhea, hepatitis, and malaria than when they merely consider the general condition of "diseases that one may contract while on vacation."

One robust finding in the domain of likelihood estimation is that people often disregard normative rules of probability estimation and instead use simple rules of thumb, generally called heuristics (Furnham & Boo, 2011; Nisbett & Ross, 1980; Tversky & Kahneman, 1974). The availability heuristic implies that people base their judgment of the likelihood of an outcome on the ease with which they can remember or imagine that outcome. The representativeness heuristic implies that people base their judgment of the likelihood of a given action leading to a given outcome on the resemblance between the action and the potential outcome. For instance, people tend to believe that extreme or impressive actions provoke severe outcomes and that small, simple actions provoke no more than mundane outcomes.

A third heuristic, the anchoring-and-adjustment heuristic, implies that people start from an initial value (the "anchor") that they adjust to accommodate the specific risk information they may have. The anchor is whatever numerical value is active in working memory and hence may or may not be related to the specific risk at hand. Heuristics allow quick likelihood estimations that in many cases are sufficiently accurate to allow well-balanced decisions. In many other cases, however, they lead to systematic error. These errors tend to occur when factors other than outcome frequency critically determine an outcome's availability or its representativeness for the action under consideration, or when the anchor that is being used is unrelated to, or no more than remotely related to, the risk under consideration. Outcomes do not always resemble the actions that provoke them (e.g., seemingly unimpressive actions may have weighty consequences), such that the resemblance between actions, and outcomes does not reflect the strength of the association between them. Similarly, the ease by which people can remember or imagine an outcome depends on a variety of outcome characteristics, such as the vividness and the extensiveness with which they have been covered in the media or in the arts. People therefore overestimate the likelihood of outcomes that receive vivid media coverage. Finally, the anchor may be unrelated to the risk at hand. Because adjustments from initial anchors tend to be insufficient, irrelevant values may thus unduly affect likelihood perceptions.

Expected Subjective Utility

People do not judge events by comparing their valence and extremity to some absolute zero level, but to a psychological reference point. The choice of a particular reference point thus crucially determines if, and to which extent, an outcome will be experienced as a loss or as gain. The reference point may be the current state of affairs, a previously experienced or expected state of affairs, or any other baseline that happens to be cognitively available. "Objective" gains may even be perceived as losses and "objective" losses as gains if they fall below the reference point that happens to be active. For instance, a patient suffering from a chronic disease may view the need for further treatment as a loss when comparing it the status quo but as a gain when comparing it to the deterioration that may occur without any treatment or when comparing it to the health status of other patients who are even worse off.

The expected subjective utility of an outcome is not a strictly increasing monotonic function of the distance between that outcome and the reference point. The further an outcome is from the reference point, the less a further departure will enhance the extremity of its utility. For instance, the difference between paying $500 versus $1,000 for a medical treatment "feels" larger than the difference between paying $5,000 versus $5,500. In addition, losses are generally weighted heavier than gains, and the subjective utility function of losses is generally steeper than the subjective utility function of gains. Unexpectedly being refunded $500 feels like a gain, and unexpectedly having to pay an additional $500 feels like a loss, but the expected subjective utility of the loss will be more extreme than the expected subjective utility of the gain.

One additional determinant of the expected subjective utility of an outcome is how easily people can imagine the relevant outcomes. Thus, vivid information about potential outcomes does not only enhance the subjective likelihood of these outcomes but may also make them seem more extreme. For instance, people are willing to pay more for flight insurance protecting them against losses caused by "terrorism" than for flight insurance protecting them against all losses, regardless of their cause, because terrorist attacks are easier to imagine than "any cause of loss" (Johnson, Hershey, Meszaros, & Kunreuther, 1993). The unpacking effect, which occurs in likelihood estimation, also has its equivalent in expected subjective utility, with instance-based descriptions of events leading to more extreme judgments than general event labels (Van Boven & Epley, 2003). In one study, for instance, people read about an oil refinery that released toxins in the atmosphere and thereby caused an increase in health problems in the surrounding community. The participants' task was to recommend the magnitude of compensation awarded to each victim and to advise on how long the refinery should be closed. Participants recommended larger compensations and a longer closure if the health hazards were described as "asthma, lung cancer, throat cancer, and all other varieties of respiratory diseases" rather than as "all varieties of respiratory diseases" (Van Boven & Epley, 2003, Study 1).

Combining Likelihoods and Utilities

Inspired by normative expectancy-value models, many researchers have assumed that a multiplicative function describes how people combine their estimates of outcome likelihood and outcome severity to arrive at a general estimation of risk magnitude. However, this multiplicative function has seldom been observed. One reason seems to be that people are rather insensitive to differences among relatively high probabilities. When comparing risks involving outcomes that are moderately to highly likely, they tend to solely focus on differences in severity despite differences between the outcomes' likelihood (Weinstein, 2000). Similarly, people seem insensitive to differences among very low probability events (Kunreuther, Novemsky, & Kahneman, 2001).

People seem to particularly disregard probabilities when the outcomes provoke strong emotions. In one study, participants indicated how much they would be willing to pay to eliminate a cancer risk due to arsenic in drinking water (Sunstein, 2003). The likelihood of getting cancer due to arsenic pollution was described as being either 1 in 100,000 or 1 in 1,000,000. The cancer risk was described either in nonemotional terms or in a vivid and therefore frightening manner. In the former case, the number of participants willing to pay was considerably higher in the 1 in 100,000 risk condition than in the 1 in 1,000,000 risk condition. In the latter case, the participants were equally willing to pay in both conditions.

When events seem very serious or provoke fear, people solely focus on the outcome's subjective utility to the neglect of these outcomes' probability (Sunstein, 2003). In one demonstration of "probability neglect," participants imagined an experiment involving either a chance of experiencing a painful electric shock or having to pay a penalty of \$20. Importantly, some participants were told that the chance of having to undergo the shock or to pay the penalty was 1%; others were told that the chance was 99%. When asked how much they would be willing to pay to avoid participating in the experiment, participants were willing to pay much more to avoid a 99% chance of having to pay \$20 than to avoid a 1% chance of having to pay it (\$18 versus \$1). In contrast, they were not willing to pay much more to avoid a 99% chance of undergoing a painful shock than to avoid a 1% chance of undergoing it (\$10 versus \$7).

Finally, some evidence suggests that likelihood and extremity estimations are not independent from each other. A trade-off may occur, in that people assume that rare health hazards are serious and that more common health hazards are not so serious (Jemmott, Ditto, & Croyle, 1986). Of course, this rule of thumb may in many circumstances be accurate (if extremely serious hazards were very common, little would be left of humanity by now).

Perceiving the Numbers Involved

The manner in which people consider the number of potential victims in their judgments resembles the manner in which they arrive at expected subjective utilities. Perhaps the best documented phenomenon in this context is "psychic numbing" (also called "psychophysical numbing"), meaning that the subjective value of an additional life saved or lost diminishes as more lives are involved (e.g., Slovic, 2007). For instance, if people find it reasonable to spend a fixed amount of money to save one life, they do not find it reasonable to spend X times that amount to save X lives. Saving one life feels important, but saving an additional life given many others already saved does not seem to make such a difference.

Reference points also play a role in the judgment of numbers involved. One reference point that seems to be of psychological relevance is the population to which the individuals at risk belong. A given number of individuals at risk may seem smaller when the potential victims come from a large population than when they come from a small population, so that people are less willing to take action to save the potential victims in the former case than in the latter. For instance, Fetherstonhaugh, Slovic, Johnson, and Friedrich (1997, Study 1) had people express their preference for a program that would provide drinkable water to refugee camp and thus save 4,500 lives in a camp inhabited by 11,000 refugees or in a camp inhabited by 250,000 refugees. Participants showed a clear-cut preference for the program in the smaller camp than for the program in the larger camp, even though the absolute number of lives saved was identical. Fetherstonhaugh et al. (1997, Study 3) also asked a group of participants how many lives would need to be saved to warrant an investment of 10 million dollars in life-saving medical treatments. When the population at risk consisted of, say, 15,000 individuals, the median number of lives needed was 9,000. When the population at risk consisted of 290,000 individuals, the median number of lives needed was 100,000.

From Risk Magnitude to Risk Acceptability

The role of a large variety of outcome characteristics other than severity and likelihood has been examined as potential determinants of risk evaluation. These include, but are not limited to, how voluntarily people engage in the risky course of action; how much control they can still exert on the action's outcome given that it occurs; how well the potential outcome is known to the individuals who are at risk for it, to scientists, or to society as a whole; and how many people are exposed to the risk or may fall victim to it. Risk evaluation furthermore involves an evaluation of the expected or potential beneficial outcomes of the risky action. These additional determinants of risk evaluation, above and beyond the perception of risk magnitude, explain why people sometimes respond very differently to equally large risks. For instance, people tend to find risks that they can control more acceptable than risks they cannot control and tend to find the risks of actions that benefit them more acceptable than the risks of action that do not benefit them.

Researchers in the domain of risk evaluation have tried not only to examine the influence of each of these factors on risk evaluation but also to identify the underlying risk dimensions. Their studies have yielded different risk structures, partly due to differences in the selections of risks being included, but among the dimensions that were frequently found are the number of people exposed, the familiarity of the risk, and the extent to which the outcome is dreaded (e.g., because it cannot be controlled or because it is fatal when it occurs; for a succinct review, see Breakwell, 2014, pp. 37–43). The familiarity dimension suggests that people may start out by judging new and unknown risks as unacceptable but gradually come to accept these risks as they develop a feeling of familiarity with them—even if they is no "objective" reason to assume that characteristics of the risk other than its subjective familiarity have changed (Lima, Barnett, & Vala, 2005).

Risk perception is supposed to be among the key determinants of risk, health, and safety behaviors. One debated issue in this context is whether people mainly act upon absolute risk perceptions (their perceptions of their own personal risks) or upon comparative risk perceptions (their perception of how their own personal risks compare with other people's risks).

The Affect Heuristic

As noted above, the dual-process approach suggests that people do not always engage in systematic likelihood estimations, subjective utility judgments, or judgments of other risk dimensions. Instead, they sometimes simply rely on how they feel toward a potential outcome or to the risky activity that entails the risk at hand. When the outcome provokes strong affect in them, they perceive the risk as large. When they hold favorable feelings toward an activity, they view the risks that are associated with the activity as small and/or acceptable and the benefits that are associated with it as large. When they have unfavorable feelings toward an activity, they view the risks that are associated with the activity as large and/or unacceptable and the benefits that are associated with it as small. This manner of appraising risks has been coined the "affect heuristic" (Finucane et al., 2000).

One characteristic of affect-based risk perception is that the qualitative (rather than quantitative) nature of feelings renders this type of risk perception relatively insensitive to the scope and likelihood of the relevant outcomes. Although the experiential system seems highly sensitive to the difference between the occurrence or nonoccurrence of an outcome, and to the difference between certainty and uncertainty, it is rather insensitive to further variations in utility and likelihood. Extreme cases of probability neglect may therefore also be considered evidence of risk perceptions sometimes being affect-based rather than based on a likelihood-utility calculation (Hsee & Rottenstreich, 2004). In one study, for instance, participants were asked to indicate how much they would be willing to pay for a set of second-hand Madonna CDs. People in whom a "calculation mindset" had been induced were willing to pay significantly more for a 10-CD box than for a 5-CD box, whereas people in whom a "feeling mindset" had been induced were insensitive to the number of CDs that the box allegedly held (Hsee & Rottenstreich, 2004, Study 1).

One consequence of the "affect heuristic" is that people often view risks and benefits as being negatively correlated (with higher risks associated with small benefits and lower risks associated with large benefits). This perception is remarkable because risks and benefits are in many cases positively correlated. Activities that entail large potential benefits tend to carry large risks, and activities that carry no more than small risks often produce no more than limited benefits.

Another implication of the affect heuristic is that any intervention that changes how an activity makes people feel will affect the perceived magnitude of the risks that are associated with it, as well as the activity's perceived benefits. Because this type of intervention may be related to the perceived benefits or to the magnitude of the risks themselves, enhancing the perceived benefits of an activity may reduce people's perception of the risks associated with it, while reducing the perceived risks of the activity may enhance its perceived benefits. For instance, Finucane et al. (2000, Study 2) provided participants with information stressing either the high benefit, the low benefit, the low risk, or the high risk of various technologies (food additives, natural gas, nuclear power). Before and after reading the information, participants rated the benefits and the risks of the technologies. When the information said that the benefits of the technologies were high, it lowered participants' ratings of the risks associated with these technologies. When the information said that the risks were low, it enhanced participants' ratings of the technologies' benefits. Information saying that the risks were low generally enhanced ratings of the technologies' benefits.

Coda: Your Risk and Mine Are Not Created Equal

One intriguing phenomenon in risk perception through analytical processes is that systematic differences exist between people's perceptions of their own risks and the risks of others. These differences occur both in perceptions of likelihood and in perceptions of outcome severity. Intriguingly, they seem to counteract each other. Likelihood estimations are characterized by comparative optimism, also called unrealistic optimism, with most people assuming that they are less likely than others to experience negative outcomes and more likely to experience positive events (for a brief introduction, see Shepperd, Waters, Weinstein, & Klein, 2015). Comparative optimism also occurs when people spontaneously imagine events that may happen in their or someone else's future, rather than estimating the likelihood of outcomes that are presented to them (Hoorens, Smits, & Shepperd, 2008). Severity estimations, in contrast, seem characterized by comparative pessimism, with most people assuming that if negative outcomes happen to them, they will suffer more than others would (Blanton, Axsom, McClive, & Price, 2001). It is as yet an open question whether self-other differences characterize affect-driven risk perception as much as likelihood-utility-based risk perception.

Author Biography

Vera Hoorens is a full professor of social psychology in the Centre for Social and Cultural Psychology of Leuven University, Belgium. Her research in the field of risk perception and risk communication mainly focuses on perceived self-other differences in the likelihood and experience of life events. She also studies and publishes more broadly on social comparison, verbal communication, and the perception of groups and individuals. She has a professional guilty pleasure, namely, sixteenth-century history.

Rumination

Andrew W. Manigault and Peggy M. Zoccola

Psychology Department, Ohio University, Athens, OH, USA

Interest in the role of rumination and related repetitive thought constructs in mental and physical illness and health has grown exponentially in the last several decades. Initial research focused on the role of ruminative thinking in the etiology and symptomatology of mental health disorders. More recently, researchers and clinicians have extended their focus to the physical health parameters associated with rumination, including physiological processes and biomarkers, somatic symptoms, and health-relevant behaviors. Overall, rumination can be considered a risk factor for a variety of detrimental mental and physical health outcomes. This entry first reviews several prominent theoretical models and definitions of rumination and then presents a conceptual model in an effort to organize the understanding of rumination's role in health. Afterward, we review the evidence for the relationship between rumination and health-relevant physiological systems and biomarkers, including blood pressure, cortisol, and immune functioning. The links between rumination and somatic symptoms, health behaviors, and other disease-relevant outcomes are also presented. The entry concludes with a discussion of intervention and treatment efforts aimed at reducing rumination and suggestions for future directions in research and practice.

Models and Definitions of Rumination

It is imperative that those who find themselves interested in rumination and its rich literature bear in mind that the meaning of rumination may change based upon theoretical context. Multiple theoretical models and definitions of rumination appear across disparate literatures. Among such theoretical models of rumination are the response styles theory, stress-reactive model, attentional scope model, and goal process theory. Although there are important distinctions between these models, as reviewed below, there are also important unifying dimensions and some conceptual overlap. For instance, many models highlight the repetitive nature of ruminative thought that is often past focused and characterized by negative valence or content.

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

One of the most prominent and widely adopted models of rumination is Nolen-Hoeksema's response styles theory. According to this theory, rumination is repetitive thinking about the "causes, consequences, and symptoms of one's negative affect" (p. 117; Smith & Alloy, 2009). Response styles theory posits that individuals who ruminate on the causes of their depressive symptoms tend to think more negatively, which consequently interferes with psychological functioning and maintains depressive symptoms. The theory also proposes that distraction from symptoms may alleviate the effects of rumination on depression. Supporting this account, some research shows that nondepressed individuals are more likely to experience a depressive episode if they report a tendency to ruminate over depressive symptoms relative to distraction from symptoms (Just & Alloy, 1997). Although response styles theory has received empirical support from a wide body of literature, some criticism persists. For example, rumination research grounded in this theory often makes use of questionnaires that have been criticized for their overlap with measures of depression, worry, and even positive forms of rumination (Smith & Alloy, 2009). Despite some criticism and mixed findings regarding the role of rumination in depressive symptoms, response styles theory remains one of the major approaches to health-related rumination research.

A theoretical extension of response styles theory is the stress-reactive model of rumination (Robinson & Alloy, 2003). According to this model, rumination, or repetitive thoughts pertaining to negative inferences, following a stressful life event puts individuals at risk for developing depression or having depressive episodes of longer duration. Thus, in this model, the content of rumination pertains specifically to thoughts (including negative affect) associated with a stressor. A minor departure from response styles theory, the stress-reactive model also captures ruminative thoughts before those that co-occur with negative affect. Although evidence supports the role of stress-reactive rumination in depression, this theoretical model of rumination has been criticized for being too specific (e.g., not capturing non-stressor-related ruminative thoughts; Smith & Alloy, 2009).

Inspired by cognitive findings, the attentional scope model of rumination focuses on the cognitive mechanisms of rumination that contribute to its repetitiveness and negative valence (Whitmer & Gotlib, 2013). This model suggests that negative mood can affect not only what thoughts are readily available but also how likely one is to exert control over these thoughts. Specifically, negative mood is thought to narrow one's attention such that it will be more difficult to inhibit the target of one's attentional focus or pay attention to novel stimuli. This model also makes a distinction between the cognitive impairments associated with dispositional rumination and state rumination. For example, although ruminative tendencies are associated with difficulties with inhibiting irrelevant information and updating working memory, state rumination seems to be associated with widespread deficits in cognitive control. A major advantage of this model is that it attempts to reconcile some of the seemingly contradictory findings of the rumination literature by discriminating between types of attention that may promote repetitive thinking and those that do not.

Other approaches to rumination have focused on the role of goals—in particular, frustrated and blocked goals—in prompting ruminative thinking. For example, goal process theory posits that ruminative thoughts emerge as a result of one's failure to progress toward a goal (Martin, Tesser, & McIntosh, 1993). In this framework, rumination is defined as a class of conscious thoughts concerning one's goal, which recur in the absence of immediate demands requiring the thoughts. This theory suggests that the experience or threat of failure is more important for rumination to occur than the feeling of sadness. A benefit of this approach is that it emphasizes conditions that lead to rumination as well as the cognitions that maintain it. Furthermore, goal process theory is more inclusive than other accounts;

stressful events and depressed mood may both constitute blocked goals and thus fit within this framework.

In sum, this brief review of rumination models highlights the need for a more comprehensive definition of rumination and perhaps more discriminatory use of terminology. Although the name may be shared, all types of rumination are not equivalent. The aforementioned conceptual models lack agreement with regard to the specific content and causes of rumination. Further, each model aims to predict different outcomes (e.g., response styles theory aims to predict the occurrence and duration of depressive episodes; the attentional scope model aims to identify the underlying cognitive mechanisms of rumination). Thus, they fail to provide a unified definition of rumination because they were never meant to do so. Despite theoretical discrepancies, it is important to note that the conceptual models reviewed here are not in full contradiction; across models, rumination is generally considered to be negatively valenced, repetitive, conscious, and past oriented. When considering rumination's relationship to psychological and physical health disorders, it may be useful to take a comprehensive conceptual approach while also stipulating how rumination differs from other related constructs (e.g., negative affect, sadness). A broader definition of rumination, or one that examines it across psychological disorders (and among individuals with and without psychopathology), may be valuable for identifying common causes, mechanisms, and thus points of intervention that have wider leverage.

Rumination and Health

The effects of rumination (broadly defined) extend beyond psychological processes. In particular, the link between rumination and physical health has been the subject of growing scientific interest. For example, the perseverative cognition hypothesis suggests that rumination may exacerbate or perpetuate physiological changes and symptoms that occur in response to stressors (Brosschot, Gerin, & Thayer, 2006). That is, normally occurring responses to stressors (e.g., rises in heart rate, blood pressure, and hormone secretion) may be accentuated or occur for longer periods of time if accompanied by ruminative thinking. Research on rumination and stress-related physiological parameters has yielded especially interesting results pertaining to stress recovery (i.e., a return to physiological resting states in the absence of the stressor). Given that poor cardiovascular recovery has been linked to serious health threats such as hypertension, some have proposed that the way in which one recovers from a stressful event is a better or at least equivalent predictor of long-term health outcomes than stress reactivity (i.e., the magnitude of the physiological changes that occur when the stressor is present). In other words, although it is adaptive to react in stressful situations, negative health outcomes may result from prolonged reactions in the absence of a stressor. Rumination may therefore impact health by maintaining the stress response beyond its adaptive range.

In addition, rumination may influence other cognitions, emotions, and behaviors that are critical for health and well-being. For example, if rumination maintains negative mood or depression, it may also negatively affect exercise and diet. In addition, rumination might also exacerbate the perception of negative symptoms (e.g., greater pain, poor sleep quality). In sum, the relationship between rumination and health is varied and operates through numerous pathways. A broad, conceptual overview of the effects of rumination on physical health is presented in Figure 1. The following section presents a non-exhaustive summary of studies that have tested some of the pathways outlined in this conceptual model linking rumination to physical health.

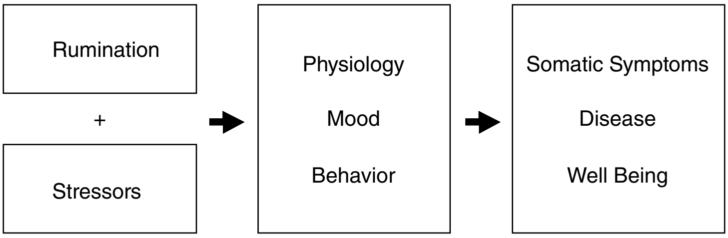

Figure 1 A conceptual model of the effects of rumination on physical health.

Rumination and Physiological Parameters

Autonomic Nervous System and Cardiovascular Activity

The study of the effect of rumination on autonomic and cardiovascular activity is robust and growing. Among others, angry, stress-related, and goal-dependent rumination measures have been examined in relation to blood pressure, heart rate, heart rate variability, and endothelin-1. Although there is some experimental and correlational evidence that rumination may lead to alterations in these parameters, empirical findings tend to vary depending on how rumination and cardiovascular outcomes are measured. Thus again, as is the case for definitions of rumination, the effect of rumination on cardiovascular outcomes depends to some degree on theoretical context. Such a relationship is logical given that any given definition of rumination may or may not capture relevant aspects of the construct relating to cardiovascular outcomes.

Several lines of research show that stress-related rumination predicts delayed cardiovascular recovery from stress. For example, undergraduates who report ruminating over a stressful arithmetic task take longer to return to baseline levels of blood pressure (Radstaak, Geurts, Brosschot, Cillessen, & Kompier, 2011). Rumination has also been linked to heart rate variability, or the variation in time between heartbeats, in some instances. Heart rate variability is a marker of physiological arousal that predicts cardiovascular health outcomes such as myocardial infarctions. In one study of heart rate variability, women without depressive rumination tendencies who engaged in state rumination following a stressful recall task had impaired heart rate variability recovery compared with those who did not ruminate following the task (Key, Campbell, Bacon, & Gerin, 2008). Thus, there is some consensus that stress-related and anger-related measures of rumination predict poor cardiovascular recovery.

Rumination may also affect other parameters that are important for cardiovascular health, including endothelin-1. Endothelin-1 is a vasoconstrictor, which can contribute to atherosclerosis, plaque rupture, and acute coronary events. For example, one study demonstrated that angry rumination tendencies predict greater increases in endothelin-1 in response to an anger recall task among individuals suffering from coronary heart disease (Fernandez et al., 2010). This finding seemingly holds after controlling for numerous other health covariates. Taken together, multiple lines of research point to an association between rumination and cardiovascular activation.

Neuroendocrine/Immune Activity

The relationship between rumination and health correlates extends to neuroendocrine and immune systems. Among other stress hormones, cortisol is often used in research because it is easy to sample (e.g., via saliva) and affects the body in a variety of ways (e.g., metabolism, analgesia, immune/digestive/reproductive function). Cortisol reallocates resources from biological processes like digestion to prepare one's body to react in a stressful situation. Although adaptive in the short term, the effects of cortisol (e.g., suppressing non-specific immune responses) can be degenerative in the long term (e.g., increasing susceptibility to infections). Thus, demonstrating an effect of rumination on cortisol responses has important implications for physiological health.

The literature on the relationship between cortisol and rumination is relatively new and inconsistent, but growing. Inconsistent findings regarding this relationship can be attributed, at least in part, to variation in measures of rumination (e.g., stress related vs. depressive, state vs. trait) and types of stressor tasks used (e.g., social evaluative vs. nonevaluative; Zoccola & Dickerson, 2012). Nevertheless, recent findings provide strong evidence in favor of a causal link between stress-related rumination and cortisol recovery (Zoccola, Figueroa, Rabideau, Woody, & Benencia, 2014). In this experiment, participants were randomly assigned to a guided rumination or distraction condition following a stressful speech task. Participants who were guided through ruminative thinking produced higher concentrations of salivary cortisol 40 min and 1 hr after the stressful speech task relative to participants who were distracted. In sum, stress-related rumination may prolong cortisol exposure, but effects seem to depend on study design issues.

Rumination may also impact the immune system, but research on this topic is in its infancy. Using a sample of older adults, one study demonstrated that rumination is positively associated with several immune measures including leukocytes count, lymphocytes count, $CD19^+$ B-lymphocyte count, and polyclonal T-cell activation (Thomsen et al., 2004). Given that high leukocyte counts are associated with increased risk of ischemic disease, rumination may negatively impact physical health via its effect on the immune system. Experimental evidence also links rumination to acute increases in inflammatory markers (Zoccola et al., 2014). Much more work is needed to confirm the role of rumination in influencing immune function.

Rumination and Somatic Complaints

The effects of rumination extend beyond physiology to symptom perception and somatic complaints. Mounting research suggests that rumination affects how one perceives, experiences, and reports health symptoms. Ruminative thinking may amplify the symptoms that one perceives and contribute to distress. For example, some research indicates that rumination is associated with health anxiety in college students, and this cognitive style predicts greater health anxiety above and beyond negative affect (as cited in Sansone & Sansone, 2012). Dispositional rumination also predicts increased somatic complaints (e.g., fatigue, nausea, and pain) in children and adolescents (as cited in Sansone & Sansone, 2012), as well as physical symptoms and overall subjective health ratings in young adults (Thomsen et al., 2004). Rumination has also been linked to hypochondriasis, which is characterized by a dysfunctional preoccupation that one has a severe illness despite medical reassurance to the contrary (as cited in Sansone & Sansone, 2012). Perceived and experienced somatic complaints can greatly influence quality of life and are highly relevant to health behaviors, such as treatment seeking and adherence, and health outcomes. Thus, the perception of symptoms can be as important as physiological processes with regard to health outcomes.

Within the pain perception framework in particular, rumination often has been integrated with other types of thoughts, such as feelings of helplessness and pessimism, which aggravate symptom perception. The sum of these aggravating cognitions is referred to as "catastrophizing." Pain catastrophizing is commonly measured with self-report questionnaires that include pain-focused rumination items or subscales. Several lines of research indicate that those who score higher on measures of pain catastrophizing report greater emotional distress, greater pain intensity, and more negative attitudes toward pain. Edwards, Bingham, Bathon, and Haythornthwaite (2006) suggest that catastrophizing leads to such outcomes by increasing attention to pain, amplifying pain processing in the central nervous system, and interfering with pain-coping behaviors.

When rumination is examined independently of the other components of pain catastrophizing, results are generally similar. For instance, findings from a recent experiment suggest that rumination is the best predictor of pain perception and distress in healthy adults (as cited in Sansone & Sansone, 2012). In this experiment, participants who scored high in pain-related rumination tendencies reported the greatest pain intensity resulting from inflation of a blood pressure cuff. In other studies, rumination predicted postoperative pain in athletes undergoing knee surgery, disability in chronic pain patients, pain levels in fibromyalgia and lower back pain patients, and psychological distress for palliative care patients (as cited in Sansone & Sansone, 2012). Thus, rumination and its related constructs (e.g., catastrophizing) are related to a wide spectrum of pain-related outcomes that are important for health and well-being.

Rumination has also been studied in relation to sleep. Sleep is a physiologic recuperative state that entails significant health repercussions when disturbed (e.g., cognitive impairments, depressed mood, impaired cardiovascular, neuroendocrine and immune function). Given that rumination is associated with an inability to disengage from irrelevant information, it is possible that those who tend to ruminate maintain high cognitive arousal before falling asleep and experience delayed sleep onset, insomnia, and lower-quality sleep. Results from several studies support this notion. For instance, one study in which participants were asked to report sleep quality and dispositional rumination demonstrated that rumination is negatively associated with sleep quality even after controlling for negative mood (Thomsen, Yung Mehlsen, Christensen, & Zachariae, 2003). In another study of college students, both state and trait measures of rumination may predict sleep onset latency, or time it takes to fall asleep (Zoccola, Dickerson, & Lam, 2009). Taken together, this body of work indicates that repetitive thinking generally predicts poor subjective sleep quality. Further, this relationship appears stable across types of ruminative thinking and thus constitutes an area of consensus for the rumination literature.

Health Behaviors

Logically, if ruminators experience more severe symptoms and are less likely to seek medical attention, then one should find empirical evidence for the relationship between rumination and healthcare utilization. Supporting this claim, Lyubomirsky, Kasri, Chang, and Chung (2006) found that individuals who ruminate may take longer than non-ruminators to seek help when experiencing symptoms of illness. In this study, women were asked to imagine finding a change in their breast and reported their intentions to seek medical attention. Women with ruminative tendencies were less likely to call a doctor immediately relative to women who do not ruminate. Furthermore, an independent sample of breast cancer survivors was asked to report the time lapse between noticing breast cancer symptoms and diagnosis. On average, women who ruminate took more than twice as long to visit a healthcare professional for breast cancer symptoms relative to non-ruminators. Given that the progression of a tumor into metastatic cancer is partly a factor of time, seeking medical attention for signs of cancer early greatly increases one's chance of survival. Thus, for diseases such as cancer, rumination may increase the likelihood of fatalities by delaying diagnosis.

Although some evidence suggests that rumination negatively affects intent to seek medical attention and delays diagnosis, the relationship between rumination and health behaviors is not consistent across age groups and physical ailments. For instance, a study by Thomsen et al. (2004) showed that, among the elderly, the tendency to ruminate predicted telephone consultations with healthcare providers but is unrelated to in-person visits. Furthermore, rumination was unrelated to healthcare utilization in the young sample. The authors suggest that the positive relationship between rumination and health behaviors is more pronounced in individuals that are likely to need medical attention (e.g., the elderly). Further, given that rumination predicted phone call consultations but not in-person consultations in the elderly sample, rumination may lead individuals to seek reassurance from healthcare providers (e.g., are physical ailments indicative of serious problems?). As such, rumination may in some cases be beneficial. For specific populations, rumination appears to increase healthcare utilization. One should note that this area of research is still in infancy and thus does not allow clear conclusions regarding the relationship between rumination and healthcare utilization behaviors. Future research in this area would gain from investigating the interplay of relevant moderators.

Beyond healthcare utilization, rumination may also affect emotion-focused coping behaviors, which can be detrimental to physical health outcomes (e.g., drug use). In a longitudinal study, ruminating adolescents were more likely to misuse substances in response to a negative event relative to non-ruminators (Skitch & Abela, 2008). Additionally, individuals who experience work-related affective rumination generally report eating more unhealthy foods after work relative to non-ruminators (Cropley, Michalianou, Pravettoni, & Millward, 2012). Taken together, this area of research indicates that rumination may impact physical health by deterring healthcare utilization and promoting unhealthy coping behaviors.

Physical Illness and Disease

Rumination ultimately may play a role in disease development. As previously mentioned, there are various pathways through which rumination may contribute to physical illness and well-being. As a result of rumination, individuals may engage in fewer pro-health behaviors, exhibit increased and prolonged physiologically stress responses, experience aggravated symptoms leading to treatment delays or avoidance, sleep poorly, or engage in unhealthy coping behaviors. All of these possible effects of rumination entail consequences of their own, which are relevant to the progression of physical illness. For example, it is thought that the prolonged stress recovery associated with rumination may lead to weakened arteries, plaque buildup, and other risk factors of cardiovascular disease (Larsen & Christenfeld, 2009).

Some research supports a direct link between rumination and related repetitive thoughts (worry) and clinical disease-related outcomes (e.g., cancer, coronary heart disease). For example, worry—future-oriented repetitive thinking—is associated with coronary heart disease (Kubzansky et al., 1997). In a longitudinal study of over 2000 healthy men, participants reported at the beginning of the study the extent to which they worry. Over the subsequent 20 years, incidences of coronary heart disease and myocardial infarction were recorded. This study showed that men who tended to worry about social conditions were more likely to develop coronary heart disease and to experience a nonfatal myocardial infarction relative to those who reported little to no worry about social conditions. It is not clear from this finding if worry can lead to coronary heart disease or if risk factors for coronary heart disease lead one to report more worry, hence this avenue of research deserves further inquiry.

Rumination may also play an important role in cancer prognosis. For example, Thomsen et al. (2013) found that in a sample of individuals who recently received a colon cancer diagnosis, rumination predicted increased depressive, intrusive, and avoidance symptoms at baseline and 8-week follow-up. These results further support the notion that rumination may negatively affect disease prognosis.

Prevention and Intervention

As reviewed above, the potential impact of rumination on health is broad and consequential. Thus, some researchers have focused on identifying means to reduce the extent to which individuals ruminate or engage in other perseverative cognitions. A recent meta-analysis by Querstret and Cropley (2013) suggests that both cognitive behavioral and mindfulness-based interventions may be effective in reducing both rumination and worry. Cognitive behavioral interventions focus on changing one's thinking style so that it may be more concrete, constructive, and active. Mindfulness-based interventions aim to teach coping skills such as meditation while promoting the generalization these skills (e.g., acceptance, present moment awareness) to daily experiences. A recent experiment shows that relative to an inactive control, women with cancer who underwent an 8-week mindfulness-based stress reduction program showed a decrease in self-reported rumination (Campbell, Labelle, Bacon, Faris, & Carlson, 2011). In sum, mindfulness-based and cognitive behavioral interventions may effectively reduce ruminative thinking.

Summary and Conclusions

As discussed in relation to psychopathology, biological parameters, somatic health, and illness, rumination may exacerbate or perpetuate the inherent components of each of these areas so as to result in negative health-related processes and outcomes. In addition to extending physiological responses beyond their adaptive range of action, rumination may magnify one's perception of poor health and thus aggravate psychological distress resulting from normally occurring symptoms. Via these pathways, rumination can promote pathogenesis and impair well-being.

Nevertheless, each of the pathways linking rumination to health entails important moderators; not all populations or measures of rumination are equivalent in relation to health outcomes. Specifically, the multitude of moderators that contribute to empirical findings linking rumination to health should not be ignored. A promising yet relatively untouched venue of research lies in a systematic review of such moderators (e.g., definitions of rumination, state vs. trait, age, gender). Although some outcomes have been reviewed across moderators (e.g., cortisol recovery), others have not (e.g., utilization of healthcare facilities). We encourage such research.

Specific to rumination definitions, researchers would benefit from identifying "active ingredients" of rumination contributing to its potentially negative impact on physical health. For example, the content (e.g., stress, anger, and sadness), temporal focus, intentionality (e.g., voluntary vs. involuntary), level of construal (abstract vs. concrete), and other characteristics of ruminative thinking may not contribute equally to its impact on health. Examining the correlates and consequences of rumination across multiple kinds of ruminative thinking and multiple outcomes may be valuable for identifying common causes, mechanisms, and thus points of intervention that have wider leverage. For example, it is unclear if cognitive behavioral and mindfulness interventions are equally efficient in reducing stress-related, depressive, and angry rumination.

In sum, future rumination research should maximize generalizability while balancing the complex interplay of moderators that contribute to rumination's relationship to health. Rumination is worthwhile research subject due to its broad impact. As reviewed in the present entry, our everyday experiences, our physical health, and our well-being are at the mercy of our repetitive thoughts.

Author Biographies

Andrew W. Manigault is a doctoral student of experimental health psychology at Ohio University. Andrew Manigault studies the effects of mindfulness and other psychological factors on stress responses. His research focuses on the potential for mindfulness and meditation to affect the frequency of repetitive thoughts and ultimately physiological processes, with specific emphasis on the identifying underlying components of mindfulness, which may drive its positive health effects. He studies at Ohio University under the tutelage of Dr. Peggy Zoccola.

Peggy M. Zoccola is an assistant professor of psychology at Ohio University. Dr. Zoccola studies mechanisms contributing to persistent stress-related physiological activation and associated health consequences. Questions addressed by her research include the following: Do individuals who ruminate have increased cortisol and inflammation in response to psychosocial stressors? Are some individuals at increased risk for rumination? Are certain kinds of stressors or contexts more likely to elicit ruminative thinking and cortisol? How can we best measure or manipulate ruminative thought?

Screening Behavior

Leona S. Aiken

Department of Psychology, Arizona State University, Tempe, AZ, USA

Medical screening refers to the identification of undetected disease or risk for disease among asymptomatic, apparently healthy individuals. The driving force in medical screening from a public health perspective is the reduction of morbidity and mortality through early detection and treatment. More broadly, the identification of risk for disease may lead to health behavior change. Of the 10 great public health achievements of 2001–2010 in the United States (Centers for Disease Control and Prevention, 2011), two encompass screening across the lifespan: lifesaving treatment and intervention for newborns through "improvements in technology and endorsement of a uniform newborn-screening panel of diseases" (p. 620) and reduction in colorectal, female breast, and cervical cancer through improved cancer screening.

This entry targets the main social factors that relate to screening uptake, among them social norms, close interpersonal relationships, social networks, and racial/ethnic disparities. Genetic testing, with its impact on families, is considered. An overview of screening as a broad public phenomenon is provided to contextualize the review of social forces. The drive for universal and repeated screening emanating from health-related federal agencies and private medical organizations, operationalized through screening guidelines, is long standing. Yet recent writing in the medical community has raised questions about the risks versus benefits of screening, and ethical issues abound. These issues are included here as critical background for health psychology, as the field engages in both the study of screening behavior and in intervention research to increase screening. (A limitation was imposed on number of references per entry in this volume. A more complete reference list for this entry is available from the author.)

Varieties and Targets of Screening

Foci of screening are many and varied. *Genetic screening* has a long history. In newborns and infants, the earliest essentially universal genetic screening was and is for phenylketonuria (PKU), which results in severe mental retardation. Screening for PKU, begun in the 1960s, is now carried

General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

out throughout the United States. Since PKU is treatable if detected very early, it is an exemplar of human biochemical genetics applied to health. Newborn infants in the United States are genetically screened for 29 disorders recommended by the American College of Medical Genetics. The US federal Newborn Screening Saves Lives Reauthorization Act of 2014 extends appropriations for infant genetic screening through 2019. Genetic screening of the fetus targets incurable conditions like cystic fibrosis and Huntington's disease. Genetic screening and counseling of future parents inform decisions about whether to have children in the face of possible genetic disease transmission. Screening of children and adults is available for multitude of genetic disorders that place one at high risk of developing a disease. Given sequencing of the genome and new technologies that make genetic analysis accessible, private companies now offer direct-to-consumer genetic screening for multiple genes that might have some implication for disease risk.

Cancer screening has been a central focus since the 1980s, when mammography screening became increasingly available and the National Cancer Institute and American Cancer Society recommended universal screening. Now melanoma and colorectal screening are public health targets; controversial prostate cancer screening is now in the public focus. Screening for a host of other conditions and diseases is available, among them alcohol and substance abuse cardiovascular disorders, metabolic, nutritional, and endocrine conditions, sexually transmitted diseases, and musculoskeletal disorders.

The US Preventive Services Task Force (USPSTF), convened by the Agency for Healthcare Research and Quality (AHRQ), provides evidenced-based recommendations for clinical preventive services, including over 60 screening tests. The USPSTF employs a grading system for screening test utility: A and B (recommends, high certainty of substantial/moderate net benefit), C (recommends selective provision for individual patients), D (recommends against, no net benefit or harms outweigh benefits), and I (insufficient current evidence). Only a third of reviewed screening tests reviewed receive A or B grades. The C grade places a substantial shared decision burden on physicians and patients.

Health Psychology and Screening

Health psychology has long been active in research on individual, social, and system-wide factors associated with screening uptake, as well as interventions to encourage screening for multiple diseases among diverse populations. This involvement dovetails with advances in medical screening methodologies. The *American Psychologist* (February–March 2015) devoted a complete issue to cancer and psychology, considering both traditional screening for common cancers and newer screening approaches for genetic risk. Psychology has been active for over 40 years in cancer screening for common cancers, including breast, cervical, colorectal, and prostate cancer (Wardle, Robb, Vernon, & Waller, 2015), but only little involved in newer genetic screening (McBride, Birmingham, & Kinney, 2015). Genetic screening raises psychological issues ranging from the decision to undergo screening to the impact of positive screening outcomes for both the individual and their relatives.

Intraindividual Factors and Screening: Perceived Risk and Attitudes

As previously indicated, this overview focuses mainly on social factors that influence screening uptake and social impacts associated with screening outcomes. Much health psychology-based research on both the correlates of screening uptake and interventions to increase screening uptake has been driven by classic models of health behavior—the health belief model (HBM), the theories of reasoned action (TRA) and planned behavior (TPB), protection motivation theory (PMT), the health action process approach (HAPA), the transtheoretical model of change (TTM), and social cognitive theory (SCT). Overall, these models focus on intraindividual, mainly cognitive factors that relate to screening—perceived risk, attitudes (benefits, barriers), outcome expectancies, self-efficacy, and perceived behavioral control and planning.

Perceived Risk

Perceived risk for disease is a central driving force in screening uptake and a core component in interventions to increase screening. Health behavior models treat perceived risk for disease as a distal driving force in a chain of constructs that result in health protective behavior (Aiken, Gerend, Jackson, & Ranby, 2012). Aiken et al. (2012) provide an extensive treatment of the relationship of perceived risk to screening, both from the perspective of perceived risk as a correlate of screening and the role of perceived risk in interventions to increase screening.

Attitudes

Attitudes toward screening are represented by multiple constructs across health models, including perceived benefits versus barriers in the HBM and positive versus negative outcome expectations in the TRA/TPB. In general, attitudes constitute a more proximal factor than perceived risk in motivating health behavior. Many older women have been socialized into having regular cervical cancer screening as they became sexually active, into having regular mammograms beginning in their early 40s, and, along with men, into having colorectal screening by age 50. These individuals have already weathered winds of change in screening recommendations over the years—for example, the ongoing debate since the early 1990s as to whether women in their 40s should receive mammograms. For these individuals, ceasing screening requires an active decision, whereas continuing screening sustains their ongoing practice through adulthood (Torke, Schwartz, Holtz, Montz, & Sachs, 2013).

Many elderly individuals continue screening, valuing peace of mind and sensing a moral obligation to continue screening to care for their health. Physicians are more likely to discuss the pros than the cons of screening with older adults (Torke et al., 2013). In the United States, Medicare funding for senior healthcare includes regular mammograms and regular screening for cervical and vaginal, colorectal, and prostate cancer. In contrast, the USPSTF, which operates independent of US Department of Health and Human Services, recommends against PSA testing for prostate cancer, against routine colonoscopy above age 75, and against routine cervical screening over age 65 and reports insufficient evidence of benefits versus risks of mammography screening above age 75.

Barriers to Screening: An Overview

Myriad barriers to screening exist. In a review of barriers to mammography screening, Sarma (2015) provided a broadly applicable social ecological model to capture the interplay between the individual and the environment in relation to screening. The model employed a three-tier organization of barriers: healthcare system-level, social, and individual barriers. At the healthcare system level, nonadherence to screening recommendations was associated with lack of a healthcare provider (HCP) recommendation, lack of a usual HCP, and economic barriers, including lack of insurance coverage, lack of access to screening services in terms of both transportation and insufficient facilities, difficulty in getting a mammogram appointment, and language barriers. Social barriers included lack of social support for screening from others and nonadherence to guidelines in the social network; broader cultural impacts included fatalism with regard to contracting and dying from cancer. On the individual level, a lack of accurate knowledge about screening, negative expectations about screening, including the receipt of a cancer diagnosis, distrust of the medical system, and competing priorities all were negatively associated with screening.

Social Factors and Screening

Collectively across health behavior models, social factors are far less well represented than intraindividual factors. Social factors represented in current models include subjective norms in TRA and TPB and socio-structural factors in SCT.

Social Norms and Screening

Broadly conceived, two classes of social norms operate on behavior: descriptive norms that characterize predominant behavior by others in a given situation and injunctive norms that reflect behavior that is approved versus disapproved by society. Injunctive norms are most often represented in screening literature as subjective norms in TRA/TPB—specifically, what significant others believe that a target individual should do, weighted by the target individual's wish to comply. How accurately subjective norms predict screening intention and actual screening uptake varies widely across studies. In a meta-analysis of prediction of screening by the TRA/TPB (Cooke & French, 2008), attitudes toward screening exhibited a stronger relationship to screening intention than subjective norms. In contrast, Smith-McLallen and Fishbein (2008) found subjective norms to be the strongest predictor of screening intentions, above and beyond attitudes and perceived behavioral control. One complexity of research on subjective norms and screening is that multiple sources of norms may be folded into a single scale of subjective norms, including the physician, friends and family, and, specifically, an individual's spouse; these sources relate differentially to screening uptake. In addition, screening behaviors are performed in private, in contrast to observable health protective behaviors like exercise, which are subject to social evaluation. For further discussion of norm theory in relation to health behavior, see Reid, Cialdini, and Aiken (2010).

Given the extensive literature on breast and cervical screening, much of what is known about cancer screening uptake is based on women. PsycINFO contains over five times the number of peer-reviewed articles on breast and cervical screening (beginning in 1958) than on prostate screening (beginning in 1994). What this literature collectively illustrates is the complexity of the relationship of subjective norms (i.e., injunctive norms of what significant others believe one should do). Influence from significant others has been observed to support screening uptake on the one hand but to induce reactance and resistance to screening on the other hand. In a study of men's uptake of colorectal and prostate screening, subjective norms that aggregated partners, families, and people in general were positively related to whether men had never, intermittently, or regularly been screened (Sieverding, Matterne, & Ciccarello, 2010). However, subjective norms were negatively related to screening in the next year among those who had previously never or intermittently been screened. This result was interpreted in terms of reactance to pressure for screening from significant others, particularly wives. This finding highlights the complexity of the relationship of injunctive norms to behavior.

The descriptive norm of what others actually do contributes to the prediction of screening intentions above and beyond injunctive norms (Smith-McLallen & Fishbein, 2008). Yet descriptive norms have complex relationships to behavior. While the descriptive norm of high perceived prevalence of a particular behavior may encourage the behavior, low perceived prevalence may well discourage behavior. Hence, social norms-based marketing that bemoans the fact that few people are engaged in an important health protective behavior (a common theme in public health messaging) actually discourages the behavior. For example, communication addressing the low prevalence of cancer screening discouraged men's intention for screening (Sieverding, Decker, & Zimmerman, 2010).

Spousal Influence on Screening

Spouses exhibit high concordance in health behaviors, attributed in part to assortative mating but also to mutual influence on health behavior change (see review by Jackson, Steptoe, & Wardle, 2015). Manne, Kashy, Weinberg, Boscarino, and Bowen (2012) noted substantial concordance between spouses in screening practices. They employed an interdependence model that characterized spouses' mutual influence on colorectal screening based on each spouse's perceived risk of colorectal cancer (CRC), perceived benefits of versus barriers to colorectal screening (i.e., decisional balance), and marital relationship quality.

Apparent spousal impact on screening uptake varies across populations. Among elderly participants in the national Medical Expenditure Panel Survey, for example, residing with one's spouse was positively associated with screening uptake (Lau & Kirby, 2009). Yet the complexity of the spousal association is evident in considering diverse populations. Among immigrant Latinas, for example, being married has been associated with higher uptake of routine medical checkups, a factor positively related to screening. In contrast among Latinas from a range of countries including Puerto Rico and Mexico and countries in Central and South America, attending an educational intervention on mammography and cervical screening with their husbands was associated with lower screening uptake, attributable to patriarchal control of women's health decisions (Shelton, Jandorf, Thelemaque, King, & Erwin, 2012.

Social Network and Screening

Social networks play a role in adult health (Martire & Franks, 2014). Research on social networks and screening addresses diverse populations, among whom Mexican Americans and Asians residing in the United States are major foci. Early on, social networks were positively associated with screening among older Mexican American women. Yet more recent research indicates weaker association of social integration with screening uptake that varies across Latina groups in the United States (Suarez et al., 2000). Among Vietnamese American women, who are at high risk for cervical cancer and have low screening rates, recommendation from friends for cervical screening was associated with increased screening (Nguyen-Truong et al., 2012). Structural characteristics of communities, specifically community cohesion characterized by residential stability and available community ties, are positively related to peer referrals for mammography (Southwell et al., 2010).

Genetic Screening

As characterized by the National Institutes of Health, genetic screening associated with disease is organized into six broad classes related to health: (a) newborn testing for disorders that are treatable early in life, (b) diagnostic testing to confirm or disconfirm the presence of a genetic or chromosomal condition, (c) carrier testing to identify individuals who have a gene mutation that can be passed to offspring, (d) prenatal testing of the fetus in service of decision making about pregnancy continuation, (e) predictive and presymptomatic testing for diseases that may appear later in life, and (f) preimplantation testing of the embryo for procedures such as *in vitro* fertilization. There is a large expanding literature on factors associated with the decision to be screened (see review by Sweeny, Ghane, Legg, Huynh, & Andrews, 2014) and on the impact of test results on interpersonal relationships, particularly within the family.

The inheritance pattern of most cancer genetic mutations is autosomal dominant; there is a 50% risk of offspring inheriting the mutation if one parent is a carrier. Whether the disease itself is manifest in a carrier depends on gene penetrance. For BRCA1 and BRCA2 carriers, an oft-cited estimate of cumulative risk of breast cancer development is 57 and 49%, respectively, by age 70; for ovarian cancer, 40 and 18%, respectively (Chen & Parmigiani, 2007). Given high familial risk, family factors operate in both the decision to be screened for genetic mutations and in communication of screening results (see Katapodi, Northouse, Milliron, Liu, & Merajver (2013) for a summary). Discussion of genetic screening is positively associated with family cohesiveness and hardiness and negatively related to family conflict. Whether the decision to undergo screening is considered a personal or family matter differs across families.

Multiplex genetic susceptibility testing (MGST) is a form of genetic testing in which a single genetic sample is used to test for multiple gene variants that *may* alter the chances of developing particular diseases. A notion underlying such testing is that personalized medicine can be based on personal genetic profiles. "The future for the field is proffered as one in which individuals and health care providers might use genomic risk information to facilitate decision-making, personalize treatment approaches and motivate lifestyle improvements and adherence to screening recommendations" (Alford et al., 2011, p. 85). In 2007, the National Institutes of Health implemented the Multiplex Initiative to assess public response to genetic testing. Healthy young adults, all of whom had access to healthcare, were offered web-based information about genetic testing, free genetic multiplex testing for eight common diseases, and a personalized risk report. In all, 35% of those reached at baseline refused to participate; another 13% were ineligible. Only 6% of those initially reached at baseline actually received screening, having completed a complex multistep educational protocol required before screening. Consistent with previous findings concerning participation in genetic research, men had lower participation than women, and African Americans had lower participation than Whites (Alford et al., 2011).

A vision for health psychology is that advances in genomic technology, including understanding of epigenetic alterations of genetic material by environment and behavior, will lead to translational research that lowers the threat of genetically associated disease. McBride et al. (2015) identify three important research areas for health psychologists in the genetic testing sphere: (a) effective communication about gene–environment interactions, (b) provider–patient communication about the impact of genetic risk for disease development, and (c) design of behavioral risk-reduction interventions for those at genetic risk. The field of genetic counseling is already actively involved in these areas of research.

Social Stigma, Discrimination, and Screening

Social stigma may operate as a deterrent to screening or disclosure of screening—for example, screening for sexually transmitted diseases (Balfe & Brugha, 2010) and for blood diseases such as hepatitis B transmitted via bodily fluid from an infected person. Earnshaw, Bogart, Dovidio, and Williams (2013) provide a comprehensive model to account for racial/ethnic disparities in HIV. While HIV testing among Blacks and Hispanics exceeds that for Whites, minority individuals are tested at a later stage of disease progression. Avoidance of testing is attributed to anticipated discrimination as a result of a positive HIV diagnosis, as well as to the expectation that the fact of being tested itself will lead to stigmatization.

DiMillo et al. (2015) identified distinct spheres of discreditable stigma (that is, stigma that is not immediately perceivable by others) that are produced by genetic screening. Women carrying the BRCA1 or BRCA2 gene feared that they would be viewed by others as weak and unable to carry out work responsibilities and that their children might suffer stigmatization due to their potential for also carrying the genetic mutation. Discrimination in the workplace and discrimination in access to insurance are two spheres of serious concern with regard to genetic testing. In the United States, the federal Genetic Information Nondiscrimination Act of 2008 (GINA) contains both employment and health insurance provisions but leaves much uncovered. Employment provisions apply only to companies with 15 or more employees. Access to life insurance, disability insurance, and long-term care insurance and the use of genetic test results to determine health insurance payments are not covered.

Racial/Ethnic Disparities

Racial/ethnic disparities are evident in screening uptake in the United States. According to the 2010 National Health Interview Survey (NHIS), almost identical percentages of White and Black women received mammograms (73% each) and Pap tests (83, 85%, respectively) in accord with USPSTF recommendations. Hispanic women lagged behind both White and Black women for mammograms (70%) and Pap tests (79%). Overall, Asian women fell substantially behind White, Black, and Hispanic women for mammograms (64%) and Pap tests (75%). CRC screening uptake was higher among Whites than Blacks (60% versus 55%) and substantially lower among Hispanics and Asians (47% each). For all tests, having health insurance, higher education, a usual source of healthcare, and being US born were associated with higher screening rates. Among immigrants, being in the United States for fewer than 10 years was associated with lower screening (Centers for Disease Control and Prevention, 2012; see also Wardle et al., 2015).

Physician Recommendation

Physician recommendation is a gatekeeper for access to screening, among the most powerful correlates of screening uptake. Physician recommendation is also a marker variable for barriers to screening, including lack of health insurance and lack of access to regular healthcare. Physician recommendation has been scrutinized as a putative cause of lower screening rates among racial/ethnic minorities. Discrepancies in rate of physician recommendation across racial/ethnic groups vary across studies, and close attention to the databases and case selection on which outcomes are based is warranted. The NHIS has been employed over time to assess differences in physician referral for screening tests as a function of race/ethnicity. Based on the 2005 NHIS, Wallace, Baltrus, Wallace, Blumenthal, and Rust (2013) reported a lower rate of physician recommendation for colorectal screening among Black than among White study participants, all of whom had no family history of CRC. With age, gender, education, income, health insurance, and number of doctor visits in the past year controlled, the probability of recommendation was less than half for Blacks than for Whites.

Current Issues in Screening

Screening research in health psychology has for decades followed the medical community's endorsement of screening, associated with ever-refined technology for detection of disease before it is manifested in observable symptoms. Health psychology has researched putative determinants of and deterrents to screening uptake and has developed and evaluated interventions to increase screening rates. Yet now a new theme has emerged in the international medical community: that some screening procedures have health risks and screening yields false positives, over-diagnosis, and over-treatment for diseases that may never become life threatening.

The screening message to the public has been that early detection leads to better treatment outcomes and longer survival. Yet lead-time bias in screening refers to the detection of disease earlier than it would be diagnosed as a function of symptoms, while the course of disease remains the same. Thus, oft-cited 5-year survival rates after detection are not an accurate measure of the impact of screening on saving lives. In the current medical climate, joint decision making between physician and patient is the model. There are great emotional issues in screening decisions (Rosenbaum, 2014) coupled with a call for greater understanding of the interplay between affective science and cancer control (Ferrer, Green, & Barrett, 2015). Genetic screening brings a host of ethical issues—informed consent, ownership of genetic samples, disclosure of genetic findings, the impact of genetic screening on access to health insurance, and discrimination in the workplace. These issues are made more complex by direct-to-consumer marketing. The concern with over-screening is reflected in a recent funding initiative the National Cancer Institute to reduce over-screening older adults for breast, cervical, and colorectal cancers. In sum, as health psychology continues to participate in screening research, the complexity of screening from individual, public health, social, and economic perspectives appears to increase exponentially over time.

Author Biography

Leona S. Aiken is president's professor of psychology at Arizona State University (ASU); she chairs the PhD concentration in quantitative methods in psychology. She is coauthor of *Multiple Regression: Testing and Interpreting Interactions* and of *Applied Multiple Regression/Correlation Analysis for the Behavioral Sciences.* Her methodological work considers measured and latent continuous variable interactions. Her substantive research focuses on women's health protective behaviors across the lifespan. She is past president of the Society of Multivariate Experimental Psychology.

Selective Exposure in the Domain of Health

Zachary Fetterman and William Hart

Psychology Department, University of Alabama, Tuscaloosa, AL, USA

Consider the following scenario. Carl was diagnosed with severe sleep apnea. Carl's doctor suggested a treatment called continuous positive airway pressure (CPAP) to manage his condition. Carl had heard anecdotally that this treatment was uncomfortable and ineffective, and he had a preferred treatment in mind prior to receiving his doctor's recommendation. His doctor suggested he read more about his options and provided Carl with some reading material on the benefits of CPAP and the possible shortcomings of his preferred non-recommended treatment. Carl never read this information. Instead, Carl sought out Internet sources that validated his preexisting preference. Carl continued to stubbornly believe that he knew the best treatment despite his doctor's advice. From Carl's perspective, he had done extensive research on the issue, and the research clearly confirmed his views on treatment. In the end, the interaction between Carl and his doctor ended without a resolution. Unfortunately, untreated sleep apnea is associated with increased mortality risk (Young et al., 2008). It is possible that Carl could have experienced a healthier and longer life if he had been more open and willing to expose himself to alternative views about available treatment options.

Carl's actions reflect a common human behavior termed *selective exposure*. Selective exposure refers to the tendency to selectively seek out viewpoint supportive information and neglect viewpoint inconsistent information (Festinger, 1957; Fischer & Greitemeyer, 2010; Hart et al., 2009). It ensures that people will know more about why they might be right than why they might be wrong. Reviews of selective exposure suggest that this effect can be large (Fischer & Greitemeyer, 2010; Frey, 1986; Hart et al., 2009) and takes place in various domains including health, consumer decision making, politics, morality and values, and business decision making (Knobloch-Westerwick, Johnson, & Westerwick, 2013). Selective exposure is similar to but distinguishable from two related phenomena. First, selective exposure refers to the relative preference for supportive over conflicting information, which distinguishes it from mere information avoidance. Second, the selective exposure of interest here is

---

General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

driven by people's preferences for supportive over conflicting information, which distinguishes it from selective exposure driven by the availability of information in one's environment (a phenomenon called *de facto selective exposure*).

In this entry we will focus on selective exposure in the domain of health, but we will often refer to research without a clear health outcome that nonetheless sheds light on the mechanisms that guide selective exposure. Our assumption is that these mechanisms also operate in health-related selective exposure. Ultimately, understanding selective exposure and its manifestations in the context of health may allow scientists and practitioners to contribute to broad efforts to improve the health and well-being of both individuals and populations.

Selective Exposure and Health

Evidence suggests that people might selectively gather information that supports (vs. contradicts) their health choices. In one of the earliest studies relating selective exposure to health (Brock & Balloun, 1967), participants were asked to listen to recordings of health messages related to the smoking–cancer link; however, these messages were obscured by static. Participants were told that they could remove the static and more clearly hear the messages by repeatedly pressing a button. Smokers pressed the button more than nonsmokers to remove the static from a message discrediting the smoking–cancer link, and nonsmokers pressed the button more than smokers to remove static from a message validating the smoking–cancer link. Thus, people appear to have strategically clarified the message only when it would validate their own smoking-related behavior.

A more recent study assessed the relationship between participants' tendency to engage in various health behaviors (consumption of organic food, coffee, and vegetables as well as exercise habits) and the time they spent reading articles in support of or opposition to each of these various health behaviors (Knobloch-Westerwick et al., 2013). Across all studied health behaviors, the frequency of engaging in a behavior was positively associated with time spent reading information supporting (vs. challenging) that behavior. Other research in more naturalistic settings confirms the role of selective exposure in the health domain (e.g., Noguchi, Albarracin, Durantini, & Glasman, 2007). In one unfortunate example, individuals who are most at risk for contracting HIV appear to be the least willing to attend HIV intervention programs (Noguchi et al., 2007).

Although evidence suggests that selective exposure sometimes takes place in health decision making (Hart et al., 2009; Knobloch-Westerwick et al., 2013), the observed effects can be small. Presumably, health-related selective exposure effects might be dependent on the presence of personal and situational variables that bolster or weaken selective exposure. Next, we discuss the processes that seem to influence selective exposure and how these processes might be at work in health-related decision-making scenarios.

Mechanisms and Moderators

Feeling Good or Avoiding Feeling Bad

One long-standing assumption surrounding selective exposure is that it manifests, at least in part, as a means to make people feel good or avoid feeling bad. Indeed, early research conceptualized selective exposure as a way to cope with or avoid decisional remorse (i.e., dissonance;

e.g., Festinger 1957, 1964). By selectively seeking congenial information and avoiding uncongenial information, individuals can effectively reduce the unpleasantness of feeling foolish (e.g., "I made a stupid choice!") and promote the pleasantness of feeling wise (e.g., "I made a smart choice!"). Research reveals that selective exposure tends to be amplified when invalidation might particularly sting and validation might particularly satisfy (Fischer & Greitemeyer, 2010; Frey, 1986; Hart et al., 2009). As a few examples, selective exposure is amplified when individuals (a) are highly committed to an attitude or behavior (Jonas & Frey, 2003); (b) are dealing with information relevant to enduring, personally defining values (McFarland & Warren, 1992); (c) are reminded of their mortality (Jonas, Greenberg, & Frey, 2003); (d) are forced to choose information that is difficult to refute (Frey, 1986); (e) do not feel self-affirmed (Klein & Harris, 2009) or are placed in a negative mood (Jonas, Graupmann, & Frey, 2006); and (f) care a great deal about cognitive consistency (Hart, Adams, Burton, Shreves, & Hamilton, 2012).

These findings provide insight into the factors that might influence selective exposure in health-related decision-making scenarios. As a few examples, health-related decision-making scenarios that evoke negative moods (Penner et al., 2010), prompt concerns about one's own mortality (e.g., a health diagnosis that makes death salient; Bozo, Tunca, & Šimšek, 2009), or challenge a person's autonomy to make their own choices (e.g., a pushy healthcare provider; Fitzsimons & Lehmann, 2004) should be particularly likely to inspire defensive attempts to validate one's own health views. In these scenarios, addressing defensiveness is likely necessary to ensure evenhanded information gathering. Fortunately, research has found that defensiveness can be tempered, and selective exposure reduced, by validating a person's autonomy and sense of self-worth (Howell & Shepperd, 2012).

High Confidence

An additional mechanism proposed to underlie selective exposure is confidence. Various studies converge on the idea that increased decisional certainty, or confidence in one's attitudes, beliefs, and behaviors, is associated with an increased tendency to engage in selective exposure (Fischer, Fischer, Weisweiler, & Frey, 2010). For example, in one experiment (Fischer et al., 2010), some participants were led to feel reduced confidence in their decision because they made their decision under suboptimal, highly distracting conditions. Other participants were allowed to make an immediate decision before any distraction or were able to deliberate in a distraction-free environment. Participants in the distracted group, relative to participants in the other two non-distracted groups, showed less confidence in their decision and reduced selective exposure.

There are at least two reasons why high confidence might enhance selective exposure. First, it could be the case that highly confident individuals are more motivated to maintain their views than are less confident individuals (Frey, 1986). For highly confident individuals, confronting information that suggests the need for a change in attitudes, beliefs, or behaviors is likely to be perceived as counterproductive (e.g., "If it ain't broke, don't fix it!": Frey, 1986). Second, it could be the case that highly confident individuals are prone to misperceive supportive information as higher in quality than unsupportive information (Fischer & Greitemeyer, 2010). Imagine feeling extremely certain that refined sugar consumption is linked with obesity. You are likely to perceive any information that denies this link as invalid (e.g., ignorant, biased). Conversely, you are likely to perceive information that supports the link as reliable and possibly worth a read.

The confidence mechanism contributing to selective exposure seems particularly important to consider in the context of health-related information. Research suggests that people tend to be overconfident about their knowledge of various health topics (Weinstein & Lyon, 1999). In light of this overconfidence, it may be particularly important to address individuals' overconfidence and accordingly minimize selective exposure.

Cognitive Economy or Laziness

Selective exposure may also be motivated by efficiency. Information search is often conducted with a desire to conserve energy, and selecting supportive information is generally an effective way to preserve cognitive resources (Fischer, 2011). Disconfirming information is more difficult to process because it is harder to integrate into one's existing knowledge structures (Ditto & Lopez, 1992). Consistent with this idea, robbing people of energy increases their tendency to demonstrate selective exposure. In one study on this issue (Fischer, Greitemeyer, & Frey, 2008), participants either completed an easy task (watching a video of a politician speaking with words occasionally appearing on the bottom of the screen) or an energy-zapping version of the same task (watching the same video but with the instructions not to look at the words and to regularly redirect their attention from the words to the politician). All participants then indicated views on political and economic issues. As anticipated, participants who completed the energy-zapping task demonstrated increased selective exposure relative to those who did the easy task. Other research suggests that personal factors linked to "cognitive miserliness" predict enhanced selective exposure (Hart et al. 2009, Hart, Adams, Burton, Shreves, & Hamilton, 2012).

Selective exposure as a result of cognitive economy may be particularly prevalent in patient populations. Research shows that individuals with various health conditions report increased fatigue relative to controls (Stone, Richards, A'Hern, & Hardy, 2000). Consider this correlation in relation to our scenario involving Carl. Carl was suffering from sleep apnea and presumably often fatigued. This diminished energy should, in theory, make Carl even more motivated than a well-rested individual to preserve cognitive resources and thus engage in selective exposure.

A related barrier that potentially perpetuates selective exposure in the domain of health is the public's regular exposure to competing health information. Nutritional science, for example, often offers contradictory suggestions (e.g., high protein, low-carb diet vs. vegetarian diet vs. balanced diet based on moderation). In light of this lack of consensus, individuals may feel inclined to preserve their energy by avoiding exhaustive, potentially unproductive information search and instead indulge themselves in confirmatory messages.

Accuracy Motivation (Wanting to be Right)

Accuracy motivation refers to a desire to accurately appraise stimuli, reach correct conclusions, and discern truth independent of whether these appraisals and conclusions are consistent with existing thoughts, attitudes, and behaviors. Research shows that increases in accuracy motivation tend to reduce selective exposure because they can weaken the three mechanisms that promote this biased information gathering. For example, factors that enhance concerns for accuracy have been shown to encourage people to forsake immediate hedonic satisfaction (gained through selective exposure) for more long-term satisfaction that comes from making the most informed choice (Jonas & Frey, 2003), to question their preexisting confidence (Fischer, Greitemeyer, et al., 2008), and to inspire greater willingness to expend energy processing new information (Fischer, 2011).

Available research suggests strategies that may effectively induce accuracy concerns in health domains and reduce selective exposure. For example, encouraging people to confront the discrepancy between what they are doing and what they should be doing seems to inspire more evenhanded gathering of health information. In one study (Knobloch-Westerwick et al., 2013), participants who perceived a larger discrepancy between their stated health behaviors and their health goals showed a reduced tendency to selectively prefer information that supported (vs. challenged) their current behavior. Additionally, existing research suggests that accuracy motivation may be ignited by encouraging individuals to consider higher-order goals (Fischer, Jonas, Frey, & Schulz-Hardt, 2005; Fischer, Schulz-Hardt, & Frey, 2008). For example, encouraging individuals to consider their desirable health-related goals (e.g., achieve a state of health that allows for increased experience of family, fun, and leisure) prior to information gathering may promote more evenhanded information gathering.

Conclusion

Selective exposure can have deleterious consequences for health decision making (Noguchi et al., 2007). Failure to fully consider contradictory evidence about one's treatment options, diet alternatives, views on exercise, and ideas about sleep could result in poor health literacy as well as suboptimal health choices and outcomes. Evidence suggests that selective exposure may occur in health-related decision making, and it seems likely that the extent of this bias is influenced by at least four mechanisms: (a) wanting to feel good or avoid feeling bad, (b) being highly confident, (c) desiring cognitive economy, and (d) desiring accuracy.

Author Biographies

Zachary Fetterman is a doctoral candidate at the University of Alabama, currently completing clinical internship at Wilford Hall Ambulatory Surgical Center. His interests include bias at individual and system levels.

William Hart is an assistant professor in social psychology at the University of Alabama. Will received his PhD from the University of Florida in 2009. He is interested in judgment and decision making and goal pursuit.

Self-Affirmation and Health

Peter R. Harris, Donna C. Jessop, and Philine S. Harris

School of Psychology, University of Sussex, Brighton & Hove, UK

Self-affirmation theory (Steele, 1988) posits that people are typically highly motivated to protect their "self-integrity," which is their global sense of being morally and adaptively adequate. Steele described self-integrity as the "phenomenal experience" of such things as being "competent, good, coherent, unitary, stable, capable of free choice, [and] capable of controlling important outcomes …" (1988, p. 262). The motive to protect self-integrity renders people vigilant to threats to self-integrity. Such threats are subjective, many, and various and include both major life events (e.g., divorce, redundancy, illness) and more mundane, day-to-day experiences (e.g., petty insults, disappointing feedback). They have been labeled "psychological threats" and defined as "the perception of environmental challenge to one's self-integrity" (Cohen & Sherman, 2014, p. 335).

According to self-affirmation theory, experiencing or anticipating such psychological threats elicits the motivation to protect self-integrity. Protecting self-integrity can be achieved in different ways (Sherman & Cohen, 2006). People can reduce the threat by accommodation (i.e., changing their behavior or beliefs in appropriate ways), by assimilation (i.e., rendering the threat consistent with preexisting beliefs and knowledge, even if this involves distorting perceptions about the threat), or by self-affirmation. For example, from the perspective of self-affirmation theory, information about the health risks of smoking presents a self-integrity threat to smokers by challenging self-perceptions of adequacy; those who value being healthy are knowingly undermining their future health. A smoker might respond to such information by accommodation (e.g., quitting or at least trying to quit or cut down). However, behavior change is not always easy to achieve. Indeed, from the perspective of self-affirmation theory, change requires acknowledging that one's behavior has been unwise, which presents a self-integrity threat. Consequently, for these and other reasons, it may be easier to assimilate the threat. Thus, smokers may instead reject the information or its personal relevance (e.g., by denigrating the evidence or the source of the message) or generate cognitions that enable them to keep smoking while reducing the self-integrity threat (e.g., by forming the intention to quit but postponing the date on which

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

they will begin). However, self-affirmation theory posits a third possibility: they may self-affirm.

Self-affirmation is "an act that manifests one's adequacy and thus affirms one's sense of global self-integrity" (Cohen & Sherman, 2014, p. 337). For example, when faced with information about the health risks of smoking (e.g., exposure to a warning on a cigarette pack), smokers may cope by reminding themselves that they are talented musicians or reliable friends or by bringing to mind a recent act of generosity that typifies important personal values. By reminding themselves that they are morally or adaptively adequate, despite smoking, an effective self-affirmation will offset the self-integrity threat entailed in the warning. Thus, self-affirmation has the potential to preserve self-integrity.

In everyday life self-affirmation can be realized in many and diverse ways. In experimental work using self-affirmation theory, however, self-affirmation is often operationalized as a value affirmation, "an activity that provides the opportunity to assert the importance of core values, often through writing exercises" (Cohen & Sherman, 2014, p. 337). For example, participants may be asked to write a brief essay about their most important personal value and occasions on which they manifest it (e.g., Harris & Napper, 2005).

Steele's critical theoretical insight was that, in responding to psychological threats, people are concerned primarily with their general or global sense of adequacy, rather than with addressing the specific issue that triggered the threat (the focal threat). For instance, although smokers may indeed cope with the threat triggered by a health warning by quitting or by elaborating cognitions that reduce their dissonance without changing behavior, they may also do so by thoughts or deeds that are completely unrelated to smoking, such as through a value affirmation (e.g., by thinking about a recent act of generosity and the personal importance of that value). As a result, self-affirmation can ameliorate threats in a domain (e.g., health) that is different from the domain in which the self-affirmation occurs (e.g., generosity). That is, effective affirmations may involve thinking about the self or acting in a way that is unrelated to the focal threat.

Self-affirmations can be used prospectively, to ward off an expected psychological threat, or retrospectively, to ameliorate an experienced threat. To be effective, the self-affirmation must be at least as important to the self as is the focal threat.

It is important to note that self-affirmation does not eliminate the threat; instead, it serves to contain or contextualize it. That is, a threat that seemed potent seems less so once, through self-affirmation, individuals have reassured themselves that they are competent or morally worthy.

Most of the research on self-affirmation—especially in the context of health—has focused on a consequence of self-affirmation that Steele (1988) discussed only relatively briefly, namely, the possibility that self-affirmation may promote less defensive and more open-minded responding to threats. That is, the self-affirmed person should feel more secure and better able to confront a given threat because self-integrity has been bolstered by the self-affirmation. For example, smokers who have been reassured of their competence or moral worthiness through self-affirmation should experience less psychological threat when encountering a reminder of the foolhardiness of smoking and may be better able to face up to the need to quit. Thus, self-affirmation has the potential not only to preserve self-integrity but also to encourage adaptive change.

This element of the theory is of obvious interest to those working on problems such as defensive resistance to potentially useful but psychologically threatening information (e.g., critical feedback, uncongenial risk information), not least because the theory suggests how resistance may be reduced, by providing the opportunity to self-affirm.

Self-Affirmation and Health

Two broad strands of research have addressed self-affirmation and health. One strand applies self-affirmation theory to understanding and ameliorating defensive resistance to information about health risks and health status. The other strand, which has received less empirical attention, examines whether and how self-affirmation may ameliorate stress reactions or bolster well-being.

Self-Affirmation and Defensive Resistance to Health Information

Messages targeting unhealthy behavior and promoting healthier behavior are ubiquitous. They are an integral part of health promotion practice and come in many forms and through various media. However, it is not uncommon to find that members of the targeted audience engage in strategies to avoid, denigrate, or otherwise downplay the information and its implications for their behavior. As outlined above, the assumption underlying the extension of self-affirmation theory to research on message resistance is that such messages, at least in part, challenge self-integrity and therefore constitute a psychological threat. The benefits of this analysis in terms of self-affirmation theory are twofold. First, the analysis extends the account of the processes underlying message resistance to include psychological and physical threat. Second, it offers a practical solution, as self-affirming should reduce the psychological threat induced by the information and therefore lessen the need to engage in defensive resistance.

The research on self-affirmation and message resistance has been primarily experimental. The typical experiment involves the random assignment of participants to experimental condition (self-affirmation or a control activity), followed by the presentation of information targeting a specific health-promoting or health-damaging behavior and then the completion of an immediate set of outcome (dependent) measures assessing message uptake and readiness to change behavior. Additional elements may include some form of manipulation check, the assessment of potential moderators and mediators, and follow-up testing for effects on behavior subsequent to the experimental session. Space precludes exhaustive coverage of the many such studies here. Instead we attempt to illustrate the main findings, characteristics, and themes of this literature and to highlight some of the issues facing researchers (see Suggested Reading for more extensive coverage).

Overall, evidence suggests that self-affirmation can influence the cognitive, affective, and behavioral responses to health-related information, both immediately and at follow-up, and in the contexts of either health-damaging (alcohol consumption, cigarette smoking, unsafe sexual activity, consumption of mercury in oily fish, and doping in sport) or health-promoting (fruit and vegetable consumption, physical activity, dental flossing, sun protection, and screening for diseases) behaviors. Meta-analyses (see Suggested Reading) have reported small but reliable effects of self-affirmation manipulations on health-related outcomes comparable in magnitude to those obtained in meta-analyses of other health behavior change interventions. The health risk information used in these studies has been predominantly textual and has tended to emulate a typical health leaflet or brochure, but studies have also found positive effects of self-affirmation manipulations on other types of material (e.g., on-pack cigarette warning labels; Harris, Mayle, Mabbott, & Napper, 2007; Kessels, Harris, Ruiter, & Klein, 2016). Measures have been predominantly self-reported and have included measures of brain function (e.g. via fMRI; Falk et al., 2015); attention allocation (e.g. via eye tracking; Kessels et al., 2016); information avoidance (Howell & Shepperd, 2016); objective indices of behavior, such as weight loss (Logel & Cohen, 2012) and activity recorded on pedometers (Falk et al., 2015); and measures indicating improved treatment adherence in hemodialysis patients (e.g. Wileman et al., 2016).

Effects of self-affirmation manipulations or interventions have been detected at follow-up months later (Falk et al., 2015; Harris et al., 2014; Harris & Napper, 2005; Logel & Cohen, 2012). However, relatively little theoretical attention has been given to the role that self-affirmation may play at later stages in the behavior change process (see Suggested Reading), albeit theoretical attention has been paid to explaining how such a relatively brief intervention may have enduring effects in other contexts (see Cohen & Sherman, 2014).

Although researchers have proposed numerous potential moderators of self-affirmation effects, the published meta-analyses of self-affirmation and health found limited evidence for moderation by the variables they tested (see Suggested Reading). There is a need for more tests of potential moderators in order to advance understanding of the boundary conditions surrounding the positive effects of self-affirmation on health-related outcomes. Theoretically it makes sense for self-affirmation effects to be moderated by variables that affect the experience of psychological threat, such that those who experience more threat should benefit most. For example, there is evidence that the impact of self-affirmation on the response to health-related information can be moderated by risk level, with those at higher risk of some negative health outcome as a result of their behavior being more responsive to the message after self-affirming than those at lower risk (e.g., Harris & Napper, 2005). However, not all studies that have tested for moderation by risk level have found it (see Schüz, Cooke, Schüz, & van Koningsbruggen, 2017).

Support for mediating variables has also been mixed. In all likelihood, self-affirmation is multiply mediated (Cohen & Sherman, 2014). In relation to health, it may be important to differentiate the mediators (and moderators) of message acceptance processes from the mediators (and moderators) of the processes involved in subsequent health behavior change (Harris & Epton, 2010).

As the literature matures, negative findings are also being published, notably in the area of binge drinking among students (e.g. Norman & Wrona-Clarke, 2015). It is also not uncommon to find positive effects of self-affirmation manipulations on immediate outcomes but not on behavior at follow-up. It is not clear what is reasonable to expect in terms of the longer-term, and especially the behavioral, impact of such a relatively brief intervention. However, in the educational context there have been several findings of significant long-term effects of self-affirmation interventions, suggesting that the effects can endure (Cohen & Sherman, 2014).

Self-Affirmation, Stress, and Well-Being

Many stressors in the modern world can be construed as threats to self-worth or self-integrity (Sherman & Cohen, 2006). For example, losing one's job or failing a test may threaten one's view of the self as valued or capable. Self-affirmation manipulations may help to remind people of the bigger picture in such situations, reassuring them that they have integrity and broadening their focus beyond the threat (Cohen & Sherman, 2014). Self-affirmation is thought to boost perceptions of the psychological resources available for coping, thereby allowing individuals to better gain perspective, with the result that potential stressors may have less of an influence on their mental and physical well-being (Cohen & Sherman, 2014).

There is evidence that self-affirmation can reduce adverse psychological and physiological responses to stressors, both experimental and naturalistic (Cohen & Sherman, 2014). For example, participants who were self-affirmed before giving a speech and completing a mental arithmetic task in front of a hostile audience did not experience increases in cortisol (Creswell et al., 2005); similarly, self-affirmed university students taking midterm examinations displayed reduced epinephrine responses and reported less worry compared with their non-affirmed counterparts (Sherman, Bunyan, Creswell, & Jaremka, 2009).

Research attention has also been paid to whether self-affirmation might benefit well-being. Studies are few, but findings suggest that self-affirmation may have positive implications for both eudaimonic and hedonic well-being (see Howell, 2016). However, it should be noted that studies to date have tested for a direct impact of self-affirmation on well-being in the absence of an explicit threat. Although there are precedents for this in the broader literature on self-affirmation and health (e.g. Logel & Cohen, 2012, showed positive effects of self-affirmation on weight loss without explicitly introducing a threat), it is possible that the effects of self-affirmation on well-being may differ when an explicit threat is in place.

Practical Developments and Issues

Naturally, given the evidence that self-affirmation can reduce information resistance and avoidance, mitigate the response to stressors, and may even bolster well-being, researchers and practitioners have been keened to examine its role in interventions (see Schüz et al., 2017), including among various patient groups (e.g., Wileman et al., 2016), and its implications for public policy (Ehret & Sherman, 2014).

To date intervention research has produced some encouraging findings. However, caution should be exercised when employing self-affirmation as an intervention given that its mechanism of action is poorly understood, as are its limits and disadvantages. More generally, there is evidence that self-affirmation manipulations may produce distinctive and even detrimental effects on responses among those experiencing low or no threat (e.g., Briñol, Petty, Gallardo, & DeMarree, 2007). In mass communications, such individuals will inevitably form part of the audience.

Another potential problem for interventions is that being aware of the effects of self-affirmation can attenuate those effects; however, the effect of awareness seems to be eliminated when participants freely choose to self-affirm (Silverman, Logel, & Cohen, 2013).

Setting aside such concerns, the application of self-affirmation in many contexts outside the laboratory requires the development of reliable ways of self-affirming that are brief and easily implemented. Few such self-affirmation manipulations are currently available, and all require further testing.

One practical benefit of self-affirmation is that it can be used with existing health promotion materials. However, whether self-affirmation will boost persuasion is dependent on the materials themselves. Self-affirmation is hypothesized to work by promoting less defensiveness and therefore greater readiness to engage with information open-mindedly. It is not in itself a technique to promote persuasion. So, whether people are persuaded depends on the quality of the material, such as the strength of its arguments.

Individual Differences

Although the research to date has mainly used experimental manipulations of self-affirmation, there has been some research on health testing self-affirmation as an individual difference. Harris and colleagues (Harris et al., 2019) have developed a measure of individual differences in self-affirmation, items from which have been associated with beneficial outcomes among cancer survivors in a nationally representative US sample (Taber, Klein, Ferrer, Kent, & Harris, 2016) and with reduced information avoidance tendencies in a sample recruited to an NIH genome sequencing study (ClinSeq®) (Taber et al., 2015). A measure developed by Pietersma and Dijkstra (2011) was related positively to perceptions of the negative consequences of smoking in samples of smokers.

Theoretical Developments and Issues

Crocker and colleagues (e.g. Crocker, Niiya, & Mischkowski, 2008) have argued that value affirmation reduces defensiveness by inducing positive other-directed feelings, such as love and connectedness, and thus promotes self-transcendence rather than self-integrity. In contrast, Lindsay and Creswell (2014) have proposed that self-affirmation boosts self-directed compassion rather than self-transcendence. Both the self-transcendence and self-directed compassion accounts have some empirical support but require further testing. Critcher and Dunning (2015) have claimed (with supportive evidence) that self-affirmation expands the working self-concept, producing a broader perspective that reduces the impact of the threat. Other work points to the effects of self-affirmation on neural reward mechanisms (e.g., Falk et al., 2015), executive function (Harris, Harris, & Miles, 2017), and goal pursuit (e.g., Vohs, Park, & Schmeichel, 2013). Critcher, Dunning, and Armor (2010) have shown that self-affirmation reduces defensiveness as long as a defensive response to threat has not been initiated, suggesting that self-affirmation after experiencing a threat may not always be effective.

Sherman (2013) has drawn on elements of the above theorizing and findings to develop a three-component model of the effects of self-affirmation in which self-affirmation (a) boosts resources, (b) broadens the perspective with which people view information and events in their lives, and (c) uncouples the threat from the self, thereby reducing its impact and promoting more open-minded appraisal.

Harris and Epton (2010) argue that there are two broad foci for theoretical development in relation to health risk information, explaining the effects of self-affirmation on message acceptance and on behavior change processes. Although it remains possible that there are features peculiar to health, or even to specific health threats, the application of self-affirmation theory to message acceptance is potentially a straightforward extension of the theory to a domain in which participants are exposed to information that constitutes a psychological threat, and the mechanisms by which self-affirmation promotes more open-minded threat appraisal should be common across domains.

The application of self-affirmation theory to behavior change processes, however, is less straightforward. For example, should the effects of self-affirmation on motivation to change and subsequent behavior change be fully mediated by changes in known predictors of intentions and behavior—induced by persuasion following exposure to the message—or are there other effects that self-affirmation induces in parallel, including direct effects on outcomes? Purchase on this question is in part hindered by features of study designs to date, such as the tendency to not include a no-information control condition, which undermines the ability to differentiate direct from indirect effects of the manipulation. More broadly, it is important to note that most of the research involving self-affirmation has tested the reflective path to behavior change (e.g., mediated by intentions), and little research attention has been paid to its impact on automatic processes.

Directions for Future Research

Research on self-affirmation and health, especially as applied to responses to health risk information, is burgeoning. However, there are limitations to the current literature. For example, there is a need to broaden the range of manipulations employed and populations sampled and to increase the sample sizes routinely used. There is also inconsistency from study to study concerning what is measured, how it is measured, and which variables are affected by the manipulation, limiting the ability to integrate findings. More broadly, theoretical development, clarification, and integration with other related ideas would also be welcome. For example, greater attention could be paid to using relevant theories of attitude change, persuasion, and behavior change, when choosing measures and when constructing persuasive materials for self-affirmation studies. Work also needs to be done to better connect self-affirmation theory with other theories of self and identity and to clarify and operationalize the central theoretical processes.

Nevertheless, as the research reviewed here indicates, self-affirmation can reduce information resistance and avoidance, foster health behavior change, and mitigate the response to stressors. It may even bolster well-being. There are many promising avenues, both theoretical and practical, waiting to be explored.

Author Biographies

Peter R. Harris is a social and health psychologist and professor of psychology at the University of Sussex, UK. His principal research interests lie in the cognitive, emotional, and behavioral response to risk, especially health risks. A founder member of Sussex University's Self-Affirmation Research Group, to date he has published over 30 papers and articles on self-affirmation, particularly as applied to health.

Donna C. Jessop is a senior lecturer at the University of Sussex. Her research interests broadly lie in the fields of social and health psychology, with a particular focus on the design of interventions to promote health protective behaviors and well-being. She has conducted research applying self-affirmation theory to a range of health outcomes, including health-related behaviors, stress responses, and well-being. Donna is a founder member of Sussex University's Self-Affirmation Research Group.

Philine S. Harris is a research fellow at the University of Southampton, UK, where she develops health interventions aimed at supporting patients' self-care. Her PhD research (conducted at the University of Sussex with Peter Harris) investigated the immediate cognitive and emotional effects of self-affirmation, in particular its effects on the use of executive functioning resources and on mood.

Self-Awareness and Health

Melissa Spina and Jamie Arndt

Psychology Department, University of Missouri System, Columbia, MO, USA

Introduction

In the early 1970s, Shelley Duval and Robert Wicklund (1972; see Suggested Reading) formally introduced the modern psychological world to the concept of self-awareness. With their presentation of objective self-awareness theory, they explained how people can regard the self as the agent of experience or as the object of attention, and how the latter leads people to reduce or avoid discrepancies between their current state and their attitudes, standards, and goals. This process is now widely recognized as a pivotal aspect of self-regulation. Thus, although not always credited as such, the theory is the conceptual parent of many self-regulatory models. This and other contributions mark the concept of self-awareness as having a profound influence on understanding of human social behavior that notably extends into the field of health psychology. This entry offers a brief overview of conceptualizations of self-awareness and their impact on understanding health and health risk behavior.

Objective Self-Awareness Theory and Self-Regulation

According to objective self-awareness theory (Duval & Wicklund, 1972), an individual's conscious attention can be either focused outward on the environment where the self is the subjective agent of experience, or it can be focused inward with the self regarded as the object of attention. Holding the self as an object of attention initiates self-evaluative processes that help people navigate their social environments with desired behavior. The process of self-evaluation is such that when self-aware, people are motivated to match their behavior and attitudes with the standards they maintain for themselves. When an individual observes that she/he is meeting these standards, the individual experiences positive affect and a general tendency to continue this self-focused state. However, when a discrepancy is detected, this self-reflective process has the potential to arouse negative affect. These negative feelings then motivate

efforts to reduce the discrepancy between the individual's current state and the standard the individual holds for the self (e.g., changing the standard or changing behavior to meet said standard) or to avoid the self-focused state (Gibbons & Wicklund, 1976).

To illustrate how these ideas might work, consider a person who wants to maintain a healthy diet and is approaching the drive-through window at a fast-food restaurant. Will the person order the mega-burger or the grilled chicken? The theory suggests that people are more likely to act in accordance with their value of maintaining a healthy diet by ordering the chicken sandwich if they are self-aware. Further, if they do so, they will experience positive feelings as a result of matching their behavior of ordering grilled chicken with their goal of eating well. But if they order the mega-burger and are then made self-aware, the awareness of this discrepancy will increase negative affect. Faced with this situation, people may adjust their standard (e.g., "it is not that important to eat well"), their behavior (e.g., "I will exchange the burger for the chicken"), or try to avoid being self-aware and thus cognizant of the discrepancy.

Over the years, research has supported the core hypotheses of self-awareness induced discrepancy reduction and avoidance of self-focused attention in a variety of ways (see Silvia & Duval, 2001; see Suggested Reading). Research has also shed light on the conditions that motivate people to reduce discrepancies or avoid self-focused attention. For example, people will try to reduce a discrepancy to the extent that their rate of progress in reducing said discrepancy is sufficient relative to the degree of the problem (e.g., if our health conscious friend thinks eating well is important and feels like she/he is making progress toward maintaining a healthy diet); otherwise they will avoid self-focused attention. The original theory has also inspired a number of extensions, refinements, and alternatives. The most generative has been Carver and Scheier's (1981) self-regulatory theory. From this perspective, if people perceive their ability to reduce the discrepancy as high (e.g., our friend thinks she/he can buy, cook, and eat healthy food), they engage in discrepancy reduction behavior. However, if people perceive a low likelihood of reducing the discrepancy (e.g., our friend does not think she/he will be able to actually eat healthy food), they experience negative affect which then propels them to avoid self-focused attention.

Carver and Scheier's (1981) theory also distinguished between focusing on "private" or "public" aspects of the self and, importantly, more explicitly considered the self-evaluative process to exist within a hierarchy of goal-directed self-regulatory systems. For example, the goal of eating well may operate at an intermediate level, serving both the broader more abstract goal of being a healthy person and prescribing the more specific goal of eating more fruits and vegetables. This conceptualization led to further insights into the dynamics of self-regulation. This includes findings indicating that when people do not meet the standards of a certain representation (e.g., "I want to eat well"), they might either shift down to a lower level representation of the goal (e.g., "In the future I will eat more vegetables") on the "behavioral representation ladder" or might disengage and avoid self-focused attention (Carver & Scheier, 1981). While other models of self-awareness have been proposed over the years (see Silvia & Gendolla, 2001), the conceptualization of self-awareness as initiating a self-regulatory process by motivating either discrepancy reducing behavior or self-focused avoidance is the most well-supported and widely accepted view.

Across the literature, researchers have often used the terms self-awareness and self-focus interchangeably. The first experimental approach to inducing such a state was to present participants with a (unexpected) mirror in the research environment, thereby literally rendering the self the object of attention (see Duval & Wicklund, 1972). Over the years, a number of other methods have been used (e.g., listening to a tape -recording of one's voice; see Silvia & Duval, 2001). Research has also developed measures of self-consciousness, often used to describe a dispositional state of self-awareness to which certain individuals might be more or less disposed (Fenigstein, Scheier, & Buss, 1975). Fenigstein and colleagues also added the terms private and public self-consciousness to the lexicon. Private self-consciousness connotes an inclination to be highly aware of one's personal values and behavior, whereas public self-consciousness describes a tendency to be concerned with the opinions of others and thus to seek approval and avoid rejection from others. These concepts have implications for explaining *when* an individual might be more inclined to experience discrepancies between their own behavior and their self-standards and how concerned one might be about others' perceptions of the discrepancy.

Research on Self-Awareness and Health

Self-Awareness and Perceptions of Physical Symptoms

The original objective self-awareness theory makes no claims about the effect of self-focused attention on how accurately people perceive themselves. Yet such an effect has been implicated to varying degrees by different theories of self-focused attention (see Silvia & Gendolla, 2001). Of relevance to health, this idea inspired research on the effects of self-awareness on people's perceptions of their physical experiences and symptoms. For example, in a series of studies, Pennebaker and Lightner (1980) examined the impact of competing sources of attentional cues on physical performance and perceptions. This research discovered that individuals who engaged in physical exercise in environments containing little external distraction were more aware of their internal states (e.g., enhanced volume of breathing) than were individuals exercising in more stimulating environments (e.g., with distracting sounds). Lacking external distraction also led to a greater awareness of the physical symptoms of exercising (e.g., fatigue). Additional studies found that individuals who ran cross country as opposed to on a track typically ran faster. Presumably this occurred because less external stimuli were present on the track, and thus participants were more focused on the performance impairing awareness of their own physical experiences.

This work has implications for understanding psychological factors that can influence both the engagement in health-relevant behavior and for self-perceptions of health-relevant symptoms. With regard to the former, one possibility is that under certain conditions self-awareness might interfere with people's motivations to engage in a healthy activity (e.g., exercising). If the activity in question has the potential to bring about negative physical experiences (e.g., soreness and fatigue), especially when there is limited experiential stimulation and thus greater internal awareness, people may be less motivated to engage in the activity even if the activity is beneficial to physical well-being.

The effect of self-awareness on perceptions of physical states may also be helpful for understanding symptom reporting. Over the years research has suggested that interoception, or the perception of bodily cues, and the source to which these cues are attributed are important factors in hypochondriasis (e.g., Mechanic, 1972). The general idea is that heightened levels of interoception, as a facet of elevated self-awareness, lead people to amplify and misinterpret bodily sensations as reflecting symptoms of physical disease. This amplification and misinterpretation may be especially likely when heightened self-awareness is combined with negative feelings. In support of this joint impact hypothesis, Gendolla, Abele, Andrei, Spurk, and Richter (2005) found that elevated levels of negative affect coupled with high self-focused attention increased reporting of greater intensity somatic symptoms. Thus, overreporting of physical ailments as a result of enhanced self-awareness and negative mood could have implications for inaccurate symptomatic self-report, which in turn might contribute to inaccurate diagnoses and other health problems. For example, more recent research has focused on the role of interoceptive sensitivity in anxiety disorders (Domschke, Stevens, Pfleiderer, & Gerlach, 2010) and medication nonadherence (Alcántara et al., 2014).

Risky Health Behavior as Escape From Self-Awareness

Recall that different perspectives converge to posit that self-awareness initiates a self-regulatory process of comparing one's behavior with one's self-standards. When these standards are not being met, the individual is motivated to reduce this discrepancy between their behavior and self-standards or to avoid self-focused attention. But what happens when the need to avoid self-focused attention becomes chronic and is difficult to accomplish? This question has given rise to the general hypothesis that in these instances people might engage in maladaptive health behaviors that facilitate the avoidance of self-focused attention. This hypothesis was initially and perhaps most extensively examined in the context of alcohol consumption and binge eating, though conceptually similar analyses have also been directed to such domains as risky sex and drug use (McKirnan, Ostrow, & Hope, 1996) and self-harm (Chapman, Gratz, & Brown, 2006).

Alcohol Consumption

Excessive alcohol consumption as a mechanism to escape self-awareness has been proposed in several models. Hull (1981) suggested that alcohol use helps to disrupt the cognitive processes that contribute to stress when people are self-aware and confronted with an unfavorable self-evaluation. A number of studies support this hypothesis. For example, Hull, Levenson, Young, and Sher (1983) demonstrated in a series of experiments that alcohol reduced self-awareness and that this effect was especially strong in individuals high in private self-consciousness. Additional studies showed that individuals high in private self-consciousness consumed more alcohol when given failure feedback than individuals high in private self-consciousness who were given success feedback, whereas people low in private self-consciousness did not change their level of alcohol consumption as a function of the feedback given. Such studies suggest that for highly self-conscious individuals, alcohol use can be motivated by a desire to reduce self-focused attention in situations that reflect negatively on the self.

The attention-allocation model (an extension of alcohol myopia theory) offers a different perspective and argues that alcohol leads to a narrowing of attention to informational cues (e.g., "myopia") that enable the individual to avoid anxiety and depressive affect (Steele & Josephs, 1990). In accord with these hypotheses, individuals who are intoxicated and experience an anxiety-inducing situation are less likely to report anxiety when given a distracting cognitive task than intoxicated individuals who were not given the task (Steele & Josephs, 1988). This implies that for people who were performing a distracting task, alcohol facilitated a reduction in anxiety by narrowing the focus of their attention to the task at hand rather than on the potential for anxiety. However, individuals who were intoxicated but did not engage in a distracting task reported more anxiety than people who had consumed a placebo beverage, suggesting that without a distracting task, alcohol enhanced their focus on the anxiety experienced. Thus, the attention-allocation model suggests that using alcohol as a means to escape self-focused attention is primarily effective to the extent it enables one to narrow focus onto some other external cue unrelated to the self.

Eating Disorders and Appearance Concerns

A number of models have applied the general principle of escaping self-awareness to understanding eating disorders. Heatherton and Baumeister (1991) begin by noting that individuals who overeat seem to suffer from high expectations for the self as well as sensitivity to the approval of others (i.e., private and public self-consciousness). For individuals who maintain high standards for their physical appearance, failure to meet the standards they set for themselves can lead to the development of heightened levels of self-awareness and a chronic state of negative affect (i.e., depression and anxiety). The escape model proposes that to escape these negative emotions related to the discrepancy between self-standards and the reality of one's physical appearance, people might (ironically) overeat in an attempt to narrow their attentional focus on the immediate environment and avoid thoughts about their own self-values (Heatherton & Baumeister, 1991; see also Bardone-Cone, Abramson, Vohs, Heatherton, & Joiner, 2006).

Further, individuals with eating disorders are suggested to be plagued by concern for and preoccupation with others' evaluations of themselves. As a result, they construct a socially appealing "false self" (Striegel-Moore, Silberstein, & Rodin, 1993). Indeed, among individuals with bulimia nervosa, reported body dissatisfaction positively relates to their social anxiety, perceived fraudulence (or lack of true self), and public self-consciousness (but not private; Striegel-Moore et al., 1993). Thus, for those who are consumed by thoughts of others' perceptions of themselves, maintenance of a socially desirable "false self" to attain the approval of others could be an indication of a risk factor for an eating disorder (e.g., bulimia nervosa, anorexia).

The aforementioned research suggests that when individuals have difficulty with meeting self-standards (e.g., Heatherton & Baumeister, 1991) or are preoccupied with others' approval (e.g., Striegel-Moore et al., 1993), they can engage in a variety of risky eating behaviors. However, it is important to recognize that the self-regulatory processes instigated by self-awareness are not inherently harmful to health. Recall the example of the person interested in maintaining a healthy diet. The critical issue is whether the behavioral standard is appropriate and facilitates (or undermines) health enhancement or maintenance. Consider, for example, associations between self-consciousness, concern for oral hygiene, and oral well-being (Klages, Bruckner, & Zentner, 2004). If high self-consciousness motivates dental care habits that contribute to oral hygiene, then the self-awareness induced regulatory processes can be appreciated as having a productive effect on health.

Self-Regulation and Goal-Directed Health Behavior

Recognizing that people may seek to escape aversive self-awareness through health risk behavior is one way that understanding self-awareness processes can contribute to understanding health behavior. But more broadly, the maintenance and change of health behavior often, if not inevitably, requires self-regulatory steps of goal setting, goal striving, behavioral monitoring, and adjustment (Mann, de Ridder, & Fujita, 2013; see Suggested Reading). All of these steps either directly or indirectly depend on a capacity for self-focused attention. Thus, self-awareness can be noted as playing a key role in various aspects of health behavior maintenance and change.

One method of meeting one's goals, for example, is through effortful inhibition, a process of self-regulation whereby the individual attempts to elicit self-control to avoid temptation (e.g., avoiding unhealthy food when it is available). Being successful in this endeavor depends on one's capacity to consciously fight off temptation, to remain self-aware of one's current state relative to the goal one is trying to reach. Thus, when people experience a cognitive impairment (e.g., diminished cognitive resources), it is more likely they will act on impulsive processes that derail the pursuit of their goals. Indeed, research has shown that impairments in working memory and executive functioning relate to reduced self-regulation capacity. For instance, people are more likely to overeat when they are experiencing decrements in working memory capacity (e.g., Hofmann, Gschwendner, Friese, Wiers, & Schmitt, 2008) and a high cognitive burden (e.g., divided attention on multiple tasks; Ward & Mann, 2000). In sum, although classic self-awareness ideas are not always explicitly used in self-regulatory research on health goal maintenance, the basic concepts and processes are foundational to theoretical efforts to understand and predict health behavior.

Conclusion

Self-awareness processes arise in people's everyday involvement with their social environments, and these processes also are pervasively implicated within behavioral health domains. This entry has highlighted a few illustrative connections. These include the involvement of self-awareness processes in people's perceptions of physical symptoms, with implications for overreporting of negative bodily sensations. Self-regulation can also motivate an escape from self-focused attention through risky health behaviors (e.g., binge drinking, overeating) when people fail to meet self-relevant standards or are overly vigilant about the evaluations others hold for them. Lastly, self-awareness plays a general role in the self-regulatory maintenance of health goals.

Author Biographies

Melissa Spina received her BA in psychology from California State University, Fresno, in 2013 and began pursuing her PhD at the University of Missouri, Columbia, in 2013. Her research examines motivational theories generally, with an emphasis in terror management theory, and applies these theories to such areas as health decision making, prosociality, and environmentally friendly behaviors.

Jamie Arndt received his BA from Skidmore College and his PhD from the University of Arizona in 1999. He is currently a professor in the Department of Psychological Sciences at the University of Missouri. His work focuses on the self, existential motivation, psychological defense, and health decision making, among other topics, with an increasing interest is moving basic social psychological ideas to translational health domains.

Self-Efficacy and Health

Lisa Marie Warner[1] and Ralf Schwarzer[1,2]

[1]*Health Psychology, Freie Universität Berlin, Berlin, Germany*
[2]*Health Psychology, Australian Catholic University, Melbourne, Victoria, Australia*

Perceived self-efficacy has been described as “the conviction that one can successfully execute the behavior required to produce the outcomes” (Bandura, 1977, p. 193) or the “can-do cognition” (Schwarzer & Warner, 2013, p. 139). This optimistic belief in being capable of succeeding at novel or difficult tasks reflects a sense of control over unforeseen situations as well as challenging environmental demands by means of one’s own behavior (Bandura, 1997). Engaging in a healthy lifestyle is a challenging task for most people. Therefore, self-efficacy is a construct of great importance to health psychology.

Individuals with high self-efficacy tend to see challenges and opportunities instead of problems and obstacles, choose more ambitious goals, and motivate themselves to attain these goals. They think in a more positive manner and are less stressed prior to challenging situations. If they are confronted with obstacles, people with high self-efficacy show more perseverance and maintain their efforts over longer periods of time. In contrast, individuals low in self-efficacy doubt their capabilities to reach their goals. They experience more self-doubts and anxiety when confronted with situations they perceive as challenging and avoid such situations. Therefore, they cope less effectively and are more vulnerable to stress and depression. Self-efficacy beliefs hence affect how people feel, think, and act (Bandura, 1997).

Concepts Distinct From Self-Efficacy Beliefs

Self-efficacy beliefs do not necessarily reflect *ability*—they are an individual’s subjective impression of being able to succeed. Actual abilities do not need to be high to build self-efficacy, as self-efficacy can also generalize if related tasks have been mastered successfully (Bandura, 1977).

Self-efficacy beliefs are distinct from *optimism*. Optimism is the belief that one’s future will be prosperous and favorable. The causes for this positive outlook into the future need not lie within the person. They can lie, for example, in favorable circumstances, help by others, or

pure chance. Self-efficacious persons, however, believe that they can shape their own future and attain desired outcomes by means of their own actions and decisions. Although the correlation between self-efficacy and optimism is moderate to high (about.60), optimism can be considered a superordinate construct under which optimistic self-beliefs, such as self-efficacy, can be subsumed (Alarcon, Bowling, & Khazon, 2013).

Whereas *outcome expectancies* refer to the perception of consequences of a behavior (e.g., better health, lower weight), self-efficacy refers to personal *control* over the execution of a behavior. Both outcome expectancies and self-efficacy, however, predict health behaviors well and play a major role in Bandura's (1997) social cognitive theory as clearly distinct constructs.

The *self-concept* is regarded as being multidimensional, and it subsumes hierarchically organized cognitions people hold about themselves at different levels of concreteness. The self-concept is also associated with affective components such as self-regard or self-esteem. It is rather normative (developed in comparison to others) and stable, whereas self-efficacy has been conceptualized as situation and task specific and malleable to new experiences. Therefore, self-efficacy is a cognition that is more proximal to behavior.

Whereas *autonomy* refers to the experience of choice and the ability to pursue activities that are intrinsically motivated, self-efficacy refers to the belief in being able to pursue those actions that are necessary to successfully accomplish the chosen goals. Some studies find a strong association between autonomy and self-efficacy in specific domains (Vieira & Grantham, 2011), whereas others show that they discriminate well (Warner, Ziegelmann, et al., 2011).

Locus of control incorporates external causes for an outcome, such as luck or task difficulty, as well as internal causes, such as ability or effort. Despite the close connection (about.56) between having an internal locus of control and self-efficacy, the two constructs are clearly distinct (Judge, Erez, Bono, & Thoresen, 2002). Individuals who think that the cause for an outcome is inherent within themselves do not necessarily believe that they can easily change this internal factor. The difference hence lies in the amenability of the internal cause. Self-efficacy is operative, which means that it pertains to one's future behavior, whereas internal control may refer to one's personal characteristics in the past (e.g., I caused the accident because I am a poor driver).

Whereas some researchers use the terms *perceived behavioral control* and self-efficacy interchangeably, others prefer to distinguish them. To understand their conceptual difference, a closer look into typical scale items helps. Perceived behavioral control items usually include a statement about the ease or difficulty of a task, such as "It is easy/difficult for me to…" Self-efficacy items mostly incorporate the "can-do" component, like "I am sure that I can do…"

In contrast to related constructs, self-efficacy hence always implies an internal attribution (one's own capability is the cause), refers to future actions (prospective), and is proximal to the behavior to be executed (operative).

Self-Manifesting Mechanism of Self-Efficacy

Through the processes of setting more ambitious goals, acting more determined to attain those goals, and putting more effort into overcoming obstacles, individuals with high levels of self-efficacy create more opportunities for themselves to experience mastery (Bandura, 1997). Mastery experiences, in turn, increase self-efficacy beliefs, maintaining a self-manifesting mechanism of both. As individuals with low self-efficacy believe less in being able to achieve what they want, they give up more easily and invest less effort—or as Bandura (1995, p. 4) describes it, "Disbelief in one's capabilities creates its own behavioral validation." Also, less self-efficacious people tend to take more responsibility for their failure than for their success. The issue of attribution—the perceived reasons for success or failure—is very important to consider. Failure only decreases self-efficacy if attributed to internal causes such as low capabilities. If failure is attributed externally, for instance, to low effort or overwhelming obstacles, it does not affect self-efficacy. Likewise, success only increases self-efficacy if attributed internally. If attributed to chance or help from others, successes do not increase self-efficacy.

Measurement of Self-Efficacy

Dimensionality of Self-Efficacy Measures

Items to assess self-efficacy can differ on three dimensions: level, strength, and generality. The *level* dimension describes the difficulty of a task. For tasks that can easily be performed, most people will have similarly high self-efficacy beliefs, for example, "I am certain that I can eat five portions of vegetables." To assess variation in levels of self-efficacy, items need to include tasks with varying difficulty, such as "I am certain that I can eat five portions of vegetables every day," or additional contextual challenges, such as "I am certain that I can eat five portions of vegetables every day, even on holidays." For most health behaviors it is the self-regulatory challenge that determines the level of self-efficacy that is needed on a regularly basis and in the face of difficulties and temptations. These difficulties or barriers should previously be identified for each target group.

The *strength* dimension refers to how robust the self-efficacy belief is against failures. If failures can easily diminish a self-efficacy belief, the belief was low on the strength dimension. Thus, the strength dimension is of special importance for the maintenance of effort and recovery after setbacks.

The g*enerality* dimension of self-efficacy spans the narrowness or broadness of a capability belief. If individuals have efficacy beliefs for very specific actions in specific situations but not for similar tasks in comparable situations, their generality dimension is low. Self-efficacy was originally developed as a task- or domain-specific construct (Bandura, 1997). Badura assumed that individuals hold very different self-efficacy beliefs for different domains and situations on a more or less general level, like being good at math or at academic tasks in general. This view implies that items to assess self-efficacy should be formulated at a level of specificity that corresponds with the specificity of the outcome behavior. Specifically assessed self-efficacy beliefs were also found to predict specific outcomes best (Bandura, 1997). Some researchers, however, argue that experiencing failure and success can generalize to a global perception of one's ability to deal with various challenges. Hence, the concept of *general self-efficacy* was developed (Schwarzer & Jerusalem, 1995a; Sherer et al., 1982). It represents a global confidence in one's abilities to cope with a wide range of demanding or novel situations.

Self-efficacy should preferably be measured with a psychometric scale consisting of several items. To construct self-efficacy items, one can apply this scheme: "I am confident that I can perform action XYZ, even if the XYZ barrier occurs." Sometimes the barrier does not have to be mentioned explicitly, for example, in domains where the execution of a task is quite challenging for an individual without additional barriers, like "I am confident that I can finish a marathon." Detailed guidelines on the construction of self-efficacy measures can be found in a comprehensive book chapter by Bandura (2006).

Measurement of General Self-Efficacy

Examples of items to measure general self-efficacy would be "I am confident that I could deal efficiently with unexpected events," and "If I am in trouble, I can usually think of a solution" (Schwarzer & Jerusalem, 1995a). Assessing a global measure of self-efficacy can be useful in some research contexts, for example, if multiple health behaviors, multiple chronic diseases, or adjustment to traumatizing experiences are being studied.

Measurement of Domain-Specific Self-Efficacy

There are measures for more or less specific self-efficacy beliefs depending on the focus of research. To investigate a healthy diet, self-efficacy items can, for example, include particular foods or refer to the self-regulatory effort to resist temptations. For safer sexual behavior, different barriers are named within self-efficacy items, such as the ability to use condoms correctly or suggest condoms to a new partner. Other examples of specific self-efficacy scales are diabetes self-care self-efficacy, breast feeding self-efficacy, or work self-efficacy.

Self-efficacy scales, however, are not without criticism. Williams and Rhodes (2014) recently reactivated a debate about the confoundedness of self-efficacy measures with outcome expectancies and motivation and suggest including "if I wanted to" at the end of each self-efficacy items to control for some of the shared variance.

Measurement of Phase-Specific Self-Efficacy

As the challenge for most health behavior is not the performance of the specific behavior but the initiation and maintenance of that behavior over longer periods of time, Scholz, Sniehotta, and Schwarzer (2005) have developed phase-specific self-efficacy beliefs. *Motivational self-efficacy* (task or pre-action self-efficacy) refers to the goal-setting phase and can, for example, be assessed with the stem "I am certain…" followed by items such as "…that I can be physically active on a regular basis, even if it is difficult" (Lippke, Fleig, Pomp, & Schwarzer, 2010). *Volitional self-efficacy* refers to the goal-pursuit phase. It can be subdivided into *maintenance self-efficacy* (e.g., "I am capable of strenuous physical exercise on a regular basis even if I need several attempts until I will be successful") (Lippke et al., 2010) and *recovery self-efficacy* (e.g., "I am confident that I can resume a physically active lifestyle, even if I have relapsed several times").

Measurement of Sources of Self-Efficacy

There has not been much research on the systematic assessment of the sources of self-efficacy for specific health behaviors. According to Bandura (1997), mastery experience is the best source, followed by vicarious experience (role modeling), verbal persuasion, and physiological feedback. To assess the sources of self-efficacy for physical activity, Warner et al. (2014) validated six scales with items such as "Even if it turned out challenging at times, I have managed to remain active" for mastery experiences; "I feel motivated to be active if I see people my age being active" for vicarious experiences; "Others encourage me to be physically active" for verbal persuasion by others; "I motivate myself to be physically active on a regular basis" for self-persuasion; "Just before I start physical activities, I feel tired" for negative affective states; and "Just before I start physical activities, I feel energetic" for positive affective states.

Self-Efficacy in Health Psychology: Some Research Findings

Self-Efficacy in Health Behavior Change Theories

The concept of self-efficacy was originally developed by Bandura as the key construct within his social cognitive theory (Bandura, 1977, 1997). Because of the predictive power of self-efficacy beliefs for various health behaviors, other health behavior change theories like the protection motivation theory, the revised health belief model, and the transtheoretical model included self-efficacy beliefs as well. The related construct of perceived behavioral control was added to the theory of reasoned action, which was then renamed the theory of planned behavior. In the meantime, specific self-efficacy beliefs were found to be highly predictive of a wide range of health behaviors.

There are also several hypotheses addressing how self-efficacy beliefs interact with other resources such as social support. Luszczynska and Cieslak (2009), for example, found support for the *enabling hypothesis* (assuming that social support elicits self-efficacy), as self-efficacy mediated the association between social support from families and fruit and vegetable consumption in patients after a myocardial infarction. Evidence for the *cultivation hypothesis* (more self-efficacious individuals mobilize more support) was found among patients after prostatectomy, who received more social support to perform pelvic floor exercises if they showed more self-efficacy previously (Hohl et al., 2015). For the adaptation of survivors of an earthquake, higher levels of family support were found to compensate for lower levels of self-efficacy (*compensation hypothesis*; Warner, Gutiérrez-Doña, Angulo, & Schwarzer, 2015). However, for individuals with high self-efficacy beliefs, additional support sometimes also shows an *interference effect*, for example, for autonomy beliefs of older adults (*interference hypothesis*; Warner, Ziegelmann, et al., 2011).

General Self-Efficacy

A good example of the use of general self-efficacy is a study on East Germans who migrated to the West after the Berlin Wall had come down. Over a 2-year period, general self-efficacy turned out to be the best single predictor of overall adjustment, as assessed by a number of outcomes such as employment status, social integration, physical health, and subjective well-being (Schwarzer & Jerusalem, 1995b). A measure of general self-efficacy proved to be valuable in this study because an assessment of all corresponding domain-specific self-efficacy measures for every coping outcome would not have been possible under the circumstances of this particular study. Measures of general self-efficacy have also been found to relate to a number of mental and physical health outcomes (e.g., depression, stress, physical activity).

Phase-Specific Self-Efficacy

In an intervention to increase breast self-examination, task self-efficacy was associated with intention, whereas maintenance self-efficacy related to planning and behavior (Luszczynska, 2004). There is also evidence that interventions to increase physical activity affect different phase-specific self-efficacy beliefs depending on whether they focus on the adoption or maintenance of physical activity (Higgins, Middleton, Winner, & Janelle, 2014).

Sources of Self-Efficacy

A study on the sources of self-efficacy for physical activity in older adults concluded that mastery experiences, vicarious experiences, and subjective perceptions of health were associated with self-efficacy and physical activity over time (Warner, Schüz, Knittle, Ziegelmann, & Wurm, 2011). A longitudinal study with validated scales showed that mastery experience, self-persuasion, and negative affective states were the most prominent predictors of self-efficacy for physical activity in community-dwelling older adults (Warner et al., 2014).

How Can Self-Efficacy Be Increased?

From a theoretical perspective, self-efficacy is built upon four sources: mastery experiences, vicarious experiences, verbal persuasion, and somatic and affective states (Bandura, 1997). Bandura states that *mastery experiences* are “the most effective source of efficacy information because they provide the most authentic evidence of whether one can master whatever it takes to succeed” (1997, p. 80). Intervention techniques have proven successful for enhancing mastery experiences. However, meta-analyses have come to the conclusion that graded mastery could also lower self-efficacy (e.g., Ashford, Edmunds, & French, 2010).

To make the most of newly gained mastery experiences, it is also essential to target a positive attributional style. Interventions can prepare for temporal setbacks and lapses to help individuals avoid what Marlatt and Gordon (1985) called the abstinence violation effect. This effect describes that people tend to see lapses as proof for incapability, which makes them drop all effort so they experience a full relapse. When people learn to attribute lapses to external causes, such as the end of a stressful day or highly tempting situations, self-efficacy can be maintained and trained for future risk situations.

Although not always named among the sources of self-efficacy, Bandura also identifies *mental imagery* as another possible origin of self-efficacy beliefs (Bandura, 1977) and proves its use to treat phobias. Health psychological research shows that imagining the outcomes of a behavior (*approach imagery*) as well as the steps that need to be fulfilled to attain a goal (*process imagery*) can also be effective to increase physical activity among sedentary adults (Chan & Cameron, 2012).

Vicarious experience, like observing others perform a specific behavior with a specific outcome—be it live or symbolic such as in a video or testimonial—increases the belief in being able to master similar tasks and produce comparable results (Bandura, 1977). Vicarious experiences provide the observer with strategies and techniques needed to attain desired goals or to overcome certain stressors. Usually, it is assumed that role models that resemble the observer in attributes such as background, age, gender, or level of expertise show better effects on self-efficacy than dissimilar models (Bandura, 1997).

Verbal or social persuasion happens if someone expresses faith in the capabilities of another (Bandura, 1997). Verbal persuasion from credible sources such as health professionals is most effective (Perloff, 1993). If, however, someone already has a strong belief in *not* being capable to achieve their goal, for example, derived from negative experience in the past, it is easier to lower their self-efficacy than to increase it by attempts of persuasion. Therefore, this source of self-efficacy needs to be addressed with care and experience to avoid reactance.

Previous to challenging tasks, most people perceive *somatic* and *affective states* such as a fast beating heart or sweaty hands. As the natural tendency is to interpret such physiological symptoms as signs of unpreparedness or anticipation of poor performance, people are more likely to feel competent if they do not experience highly aversive arousal (Bandura, 1997). The optimal level of arousal should, however, lay somewhere in the middle, as too high and too low arousal may impede performance. A meta-analysis by Prestwich et al. (2014) shows how stress management strategies can be used to prompt self-efficacy for a healthier diet.

Several meta-analyses have summarized the behavior change techniques that are most effective to increase self-efficacy in physical activity interventions (e.g., Ashford et al., 2010; Olander et al., 2013). However, interventionists in this field should keep in mind that there can be "too much of a good thing." First, evidence shows that very high levels of self-efficacy can be detrimental to intervention success, especially in the smoking context (e.g., Staring & Breteler, 2004). Self-efficacy beliefs should hence be realistic to generate motivation and health behavior, as overconfidence could elicit frustration and disappointment along the health behavior change process. To conclude in Bandura's (2004, p. 162) words, "As you venture forth to promote your own health and that of others, may the efficacy force be with you."

Author Biographies

Lisa Marie Warner is a guest professor at the Division of Health Psychology at the Freie Universität Berlin, Germany. Her research at the interface between health psychology and gerontology focuses on personal and social resources for older adults' physical activity and social participation, such as their social support and self-efficacy.

Ralf Schwarzer is a professor at the SWPS University of Social Sciences and Humanities in Wroclaw, Poland, and emeritus professor at Freie Universität Berlin, Germany. His research focuses on various aspects of psychology, including stress and anxiety, coping, social support, health behavior change, and self-efficacy. He is the editor of the journal *Applied Psychology: Health and Well-being*. Visit http://my.psyc.de for more information.

Self-Esteem and Health

Danu Anthony Stinson and Alexandra N. Fisher

Psychology Department, University of Victoria, Victoria, BC, Canada

Self-esteem has been the subject of intense empirical and theoretical study by psychological scientists for over 50 years, and in the latter decades of the twentieth century, this psychological phenomenon also succeeded in capturing the imagination of popular culture. The notion that one's feelings of worth as a person matter and have important consequences for emotion, cognition, behavior, and experiences resonated with the general public. People embraced insights from psychological science concerning the origins and nature of self-esteem, and individuals and governmental organizations alike sought methods for improving self-esteem and reaping the many benefits associated with positive self-regard, including career and academic success, and increased life satisfaction. As a result of this academic and public attention, if a student of psychology tells her friends or family that she is studying self-esteem, her disclosure will often be met with a nod of understanding or a personal anecdote concerning the listener's own experiences.

Yet despite the widespread popularity of self-esteem and the general acknowledgment of its importance, most students of psychology and the general public remain unaware that self-esteem also plays an important role in shaping people's health. Many people who hear of this connection may wonder, "How can *feelings* influence something tangible and *physical* like health?" This question arises from the lingering assumption that the mind and body are distinct entities, an assumption that arose during the dawn of modern Western medicine and continues to dominate Western conceptions of health. But this assumption is erroneous. In fact, the mind and the body are intimately connected, and this connection is abundantly evident in the pervasive links between self-esteem and the various dimensions of well-being that characterize human health.

What Is Self-Esteem?

Before it is possible to understand how and why self-esteem predicts such a seemingly unrelated experience as health, it is essential to first understand how this psychological

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

characteristic develops and how it relates to other aspects of *the self*: the collection of traits, qualities, schema, roles, beliefs, and attitudes that form the core of one's identity.

The self resides at the very center of one's psychological universe, allowing people to make sense of their past experiences, guide their present behavior, and predict their future experiences. Indeed, when the philosopher René Descartes famously opined, "I think, therefore I am," he was relying on his sense of self to prove his very existence.

As one might expect, a psychological system so important takes time to develop. The first sense of self that coheres during infancy is the sense of being an entity distinct from others, who persists over time and across places. Around the age of 3, as children mature and interact with their social and physical worlds, they gradually develop beliefs about their specific traits and abilities ("I am athletic"), learn the social roles that they are expected to fulfill ("I am a girl"), and develop theories, or scripts, to explain and predict their actions ("If I ask Marjan to play with me, she will say yes"). As children approach puberty, they begin to evaluate their worth and value, and it is this global evaluative component of the self that psychologists call *self-esteem*.

Self-esteem develops in part through a reflected appraisal process, whereby children observe how other people treat them, and from that treatment infer their worth. Being treated with responsive kindness, warmth, and positivity by social partners, especially family, communicates that the self is worthy and valuable. In contrast, being ignored, invalidated, overlooked, or abused by unresponsive or unavailable social partners, especially family, communicates that the self is not worthy of care or deserving of loving kindness. Over time and through repeated exposure, children internalize these social messages, and thus self-esteem is born.

Of course, people are not passive *tabula rasa* onto which their social experiences write. Babies are born with a genetic heritage that shapes the ways in which they interact with the world, and these same forces influence the development of self-esteem. Of particular relevance to the discussion at hand, some people are temperamentally inclined to focus their attention and energy toward seeking rewarding experiences and to experience high levels of positive affect, whereas others are temperamentally inclined to focus their attention and energy toward avoiding punishing experiences and to experience high levels of negative affect. In turn, these higher-order temperamental factors are also related to self-esteem. Reward-focused people who are relatively insensitive to stressors and recover quickly from negative moods will tend to develop higher self-esteem. In contrast, people who are temperamentally attuned to punishments like criticism, who react strongly to stress and take a long time to recover, and who experience frequent negative moods tend to develop lower self-esteem.

This association between temperament and self-esteem probably exists because temperament influences the ways in which people experience the world, which in turn informs self-evaluations. For example, if someone is very sensitive to rewards, she will be more likely to notice and internalize praise and thus develop higher self-esteem. Conversely, if someone is very sensitive to criticism, he will feel the sting of social rebuff more deeply and thus will be more likely to develop lower self-esteem. Thus, temperament is a lens through which self-esteem-relevant experiences and messages must first pass before they are internalized, resulting in self-esteem that is highly subjective in nature. Two people with different temperaments can have the same experiences and from those experiences infer different conclusions about their social worth and thus develop different levels of self-esteem. As this example illustrates, self-esteem develops from a true symbiotic interaction between nature and nurture.

Once self-esteem crystallizes around the age of 12, it remains remarkably stable across the lifespan. Perhaps due to its high degree of stability, people often rely on their self-esteem to regulate their interactions with their material and social worlds. The lens of self-esteem helps people to make sense of their past experiences, to determine a present course of action, and to predict future outcomes. In each of these domains, lower self-esteem individuals tend to adopt a more pessimistic and cautious outlook than higher self-esteem individuals, who can be quite optimistic and blithe in many circumstances. For example, a lower self-esteem person may attribute past failures to personal shortcomings and thus avoid situations that call on the skills he believes he does not possess because he anticipates failure. In contrast, a higher self-esteem person is more likely to dismiss past failures as resulting from external factors and thus pursue opportunities that offer rewards he feels equipped to effectively claim. These differing orientations are evident in school and workplace settings and in social contexts ranging from interactions with strangers to interactions with lovers, and they result in differing outcomes for people with lower and higher self-esteem. In many life domains, higher self-esteem individuals tend to experience more positive outcomes than their lower self-esteem counterparts, and this difference extends to the domain of health.

How Is Self-Esteem Related to Health?

Following the World Health Organization, we consider health to be a multifaceted construct comprising psychological, physical, and social well-being. Self-esteem predicts outcomes in each of these varied domains.

Psychological Well-Being

Self-esteem is negatively associated with a range of mental health concerns, including depression, anxiety, stress, disordered eating, negative body image, and suicidal ideation. Although it is difficult to determine whether self-esteem is a cause or consequence of these mental health conditions, longitudinal studies that control for third variables and rule out reverse causation can help to tease apart these possibilities. For example, one such study observed that adolescents with low self-esteem and individuals whose self-esteem declined during adolescence were more likely to experience depression fully two decades later (Steiger, Allemand, Robins, & Fend, 2014). Another study that examined self-esteem and mental health outcomes at multiple points in time found that lower self-esteem predicts depression, which, in turn, predicts heightened rates of stressful life events (Orth, Robins, & Meier, 2009). The consensus among psychological scientists is that lower self-esteem is an independent risk factor for the development of numerous mental health conditions.

Physical Well-Being

Self-esteem is also related to a broad range of physical health conditions. For example, lower self-esteem university students report that they experience worse physical health, visit the doctor more often, and miss more days of school due to illness than their higher self-esteem counterparts (Stinson et al., 2008). Moreover, self-esteem is positively associated with people's ability to recover from physical illness and cope with chronic health conditions, including heart disease, HIV/AIDS, cystic fibrosis, and autoimmune disorders. For example, compared with higher self-esteem individuals, lower self-esteem individuals with asthma or rheumatoid arthritis experience more negative affect, less positive affect, greater stress and symptom severity, and more symptom interference and activity restrictions in daily life (Juth, Smyth, & Santuzzi, 2008). Lower self-esteem is also a risk factor for mortality among the elderly. These and other links between self-esteem and physical health offer a stark reminder of the extensive mind–body connections that characterize the human experience.

Social Well-Being

Self-esteem is also strongly tied to social well-being. Lower self-esteem individuals report that they receive less social support, experience more interpersonal stress, and suffer from loneliness and social isolation to a greater extent than their higher self-esteem counterparts. Such perceptions may accurately reflect important developmental experiences of acceptance and rejection from family and peers. But with the changing social context of adulthood, appraisals of social well-being can diverge from objective reality. Lower self-esteem individuals often underestimate their social partners' actual regard, whereas higher self-esteem individuals' perceptions are often more accurate, or perhaps even overly optimistic. Such individual differences are thought to be motivated by concerns about rejection. Lower self-esteem people are extremely risk averse and would rather err on the side of caution and overlook some acceptance cues than risk rejection by perceiving acceptance that is not actually present. In contrast, higher self-esteem people are blithe in the face of rejection and will boldly perceive acceptance from even the most neutral social companions. These differing social orientations can have self-fulfilling consequences. Lower self-esteem individuals' social insecurities and resultant cool, inhibited social behavior can be off-putting to social partners, whereas higher self-esteem individuals' confident and warm social behavior is attractive to others. Thus, self-esteem and social well-being are linked throughout the lifespan by a recursive process whereby early social experiences help to forge self-esteem, which later guides social experiences that further reinforce self-esteem.

Why Is Self-Esteem Related to Health?

Two dominant models have emerged to explain why self-esteem and health are so intricately woven together.

A Resource Model of Self-Esteem and Health

Self-esteem and health may be linked because higher self-esteem is a psychological resource on which people can rely in times of adversity. In this model, the same temperamental factors and developmental experiences that give rise to higher or lower self-esteem also give rise to characteristic psychological orientations that benefit, or undermine, health. Specifically, the affective, cognitive, and motivational styles that characterize higher self-esteem may allow such individuals to cope with and recover from stressors more effortlessly and quickly than their lower self-esteem counterparts. For example, higher self-esteem individuals effectively employ strategies to improve negative moods and prolong positive moods, whereas lower self-esteem individuals tend to allow negative moods to linger and will actively dampen positive moods (Wood, Heimpel, & Michela, 2003). Higher self-esteem individuals are also motivationally inclined to overlook criticism, failure, and other negative outcomes in favor of rewarding goal pursuit, whereas lower self-esteem individuals are decidedly attentive and sensitive to negative stimuli.

In turn, these characteristic psychological orientations are thought to influence health. Thus, people with lower self-esteem exhibit a stronger stress–illness association than higher self-esteem individuals, such that they are more likely to experience psychological and somatic problems both on and following stressful days (DeLongis, Folkman, & Lazarus, 1988). Lower self-esteem individuals are also more susceptible to illness and mood disturbance when stress levels increase, even if overall stress is low. In light of these and other findings, many psychological scientists consider lower self-esteem to be a causal risk factor for poor health outcomes.

A Self-and-Social-Bonds Model of Health

A second explanatory model posits that self-esteem predicts health outcomes because self-esteem regulates responses to the threat of rejection in a manner that can undermine lower self-esteem individuals' health (Stinson et al., 2008).

A growing body of evidence suggests that self-esteem plays an important role in a broader psychobiological regulatory system that services the fundamental human *need to belong*, which is a drive to connect with and maintain relationships with benevolent social partners, and conversely, avoid the social pain of rejection. In particular, people rely on their self-esteem to make sense of their past social experiences, to regulate their responses to in-the-moment social cues concerning acceptance and rejection, and to predict their future social experiences. As we have already discussed, lower self-esteem individuals readily perceive rejection from others and react strongly to avoid the rejection they often anticipate, whereas higher self-esteem individuals eagerly anticipate acceptance from others and pursue rewarding opportunities for social connection with little concern about rejection. In turn, these differing psychological orientations influence physiological responses to the threat of rejection.

For everyone, the threat of rejection activates a neuroendocrine system called the hypothalamic–pituitary–adrenal axis (HPA), which triggers a cascade of hormones that characterize the physiological stress response. However, because lower self-esteem individuals are more sensitive to rejection threats than higher self-esteem individuals, they are more likely to exhibit this stress response in their daily lives. For example, lower self-esteem individuals experience a heightened physiological stress response to the threat of rejection, as indicated by increased salivary cortisol levels immediately following rejection and during the early recovery phase (Ford & Collins, 2010). Unfortunately, chronic activation of the HPA is physiologically costly and can undermine health, which may explain why lower self-esteem individuals experience worse health outcomes than their higher self-esteem counterparts. Consistent with this account, on the day following an experience of interpersonal rejection, lower self-esteem individuals report heightened stress, poorer general health, increased physical symptoms of illness, and worse sleep quality relative to both higher self-esteem individuals' experiences on similar days and their own experiences following days when they did not experience rejection (Ford & Collins, 2013). Thus, poor outcomes in the domain of social well-being may be an important mechanism to explain why individuals with lower self-esteem also experience poor outcomes in psychological and physical health domains.

Conclusions

It is tempting to conclude from the preceding discussion that improving self-esteem could result in a miracle panacea. Unfortunately, attempting to improve self-esteem is more easily said than done. The stability of important self-views like self-esteem is so essential to people's daily functioning that people will vociferously defend their existing self-views against the forces of change, even when such defense means maintaining negative evaluations about the self. As a result, attempts to directly improve self-esteem through positive self-statements or other forms of positive feedback often backfire for lower self-esteem individuals, resulting in undesirable decrements to well-being.

Thus, we suggest that rather than targeting self-esteem directly, health interventions should instead attempt to improve the quality of people's social bonds. Such interventions could directly improve health by improving people's social well-being. In turn, because social well-being has been causally implicated in both physical and psychological well-being, such interventions may have spillover benefits for other health domains. Moreover, social well-being interventions could result in persistent benefits if repeated positive social experiences are internalized over time, resulting in increased self-esteem. Psychological scientists have already identified a number of effective social well-being interventions, including belongingness interventions for stigmatized or marginalized groups. Close relationships researchers have also identified simple interventions that specifically target the social doubts that are characteristic of lower self-esteem. Currently, psychological scientists are working to determine whether this and other promising social well-being interventions can serve as "psychological immunizations," yielding long-term increments in self-esteem that also benefit well-being and health.

Author Biographies

Danu Anthony Stinson is an associate professor in the Psychology Department at the University of Victoria, Canada. Most of her research to date has examined how and why self-esteem influences health and well-being. More recently, she has begun to investigate and seek ways to alleviate social psychological barriers to health and well-being that affect negatively stereotyped groups, including higher body-weight people and women in high-status social positions.

Alexandra N. Fisher is completing her master of science degree in social psychology at the University of Victoria, Canada, under the supervision of Danu Anthony Stinson. She studies the social and interpersonal experiences of female breadwinners and other successful women. Specifically, her research examines the stereotypes and impressions that are often formed and applied to female breadwinners and how these impressions may influence close relationship initiation and maintenance processes.

Self-Regulation

Richie L. Lenne and Traci Mann

Psychology Department, University of Minnesota Twin Cities, Minneapolis, MN, USA

Self-regulation is the set of processes through which individuals make efforts to alter or exert control over their behaviors, cognitions, and emotions, or, more simply, the processes used for setting and pursuing goals.

Self-regulation plays an important role in health promotion and illness prevention because many of the most common causes of death in the United States have a behavioral component that requires ongoing management. Poor health may result from failing to regulate smoking, drug and alcohol use, eating, exercise, and sexual activity, and many treatments require individuals to adhere to medical regimens or do exercises to manage pain. Other health problems may result from failing to regulate anger, anxiety, or stress.

Self-regulation can be conceptualized as a feedback or cybernetic system. In this kind of system, there are three main processes. First, individuals have a standard or goal, imposed by themselves or by others, that they wish to obtain. Second, they monitor their current state and compare it to the standard. Third, if their current state does not match the desired standard, they make changes to their behaviors, cognitions, or emotions aimed at moving closer to the standard. A person may have a goal of weighing a certain weight, for example. They may compare their current weight with that goal weight, find that they weigh too much, and therefore change their eating or exercise behavior in an effort to get closer to the goal weight.

This conceptualization implies that self-regulation is conscious and deliberate, but that is not always the case. Self-regulation can also be automatic, operating through nonconscious processes, for example, when individuals engage in habitual behaviors, or when goals are primed by situational cues.

In addition, the real-life context of self-regulation is considerably more complicated than implied by a simple feedback system. At any given moment, individuals may have multiple competing goals that they are aiming to fulfill simultaneously. Each goal must not only be attended to but also be protected and shielded from distractions, disturbances, and temptations, many of which come from other goals. For example, the goal of avoiding sugar may conflict with the goal of being a doting parent and baking a cake for one's child's birthday.

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

Regardless of the overall conceptualization, most concepts that pertain to the topic can be incorporated in one of two components of the self-regulation process: goal setting and goal striving.

Goal Setting

Goal setting is the process of deciding what goals to pursue and by what criteria to judge successful goal attainment. These goals can be as small as deciding to take the stairs instead of the elevator or as large as living a more healthy lifestyle. Individuals adopt health goals for different reasons, and the goals themselves have different characteristics that can affect whether goal pursuit is successful. In addition, people abandon goals for different reasons.

Adopting Health Goals

Most people want to live a long and happy life and do not need to be convinced that it is a good idea to take care of their health. However, some form of information is usually the first component to the adoption of a health goal. Accurate health information is not always easy to find in a landscape saturated with often-conflicting accounts and competing incentives. It can be challenging to know what to believe, which can prevent people from forming health goals. According to theories of health behavior change, once people come to believe that certain behaviors carry health consequences, they are more likely to set goals, particularly if they believe they have the ability to control these behaviors and the behaviors align with what society and significant others deems appropriate (Ajzen, 1991).

Another influence on the goal setting process is an individual's attempts to maintain a consistent self-concept (Fishbein et al., 2001) and to move toward aspirational selves and away from feared selves (Markus & Nurius, 1986). Whether a person adopts a new health goal will also be determined by the fit of this goal into the person's larger system of goals (health related or otherwise). Goal systems theory makes predictions about the adoption and successful completion of a goal by accounting for how other goals compete with or support each other (Kruglanski et al., 2002). According to this perspective, goals can be interrelated such that many goals are associated with a common means (multifinal), or a single goal can be achieved through many means (equifinal). The theory postulates that the more goals are interconnected, the stronger motivational value they carry and the more likely people are to adopt and accomplish them.

Goal Characteristics

Despite the desire to live a healthy life, people struggle to set goals that will last long enough to make a difference in their health and well-being. Certain characteristics of goals have been shown to have meaningful implications for successful goal setting and pursuit. These features include motivational aspects of goals, the level of difficulty of the goal, and the type of goal.

Goals may differ based on their motivational focus. People can have goals that are approach oriented, which are focused on moving toward a positive end state, as well as goals that are avoidance oriented, which are focused on preventing a negative end state. Goal orientations are not merely linguistic differences, but they have consequences in terms of whether the goal is likely to be met and for whom. Overall, approach-oriented goals tend to lead to more positive outcomes than avoidance-oriented goals (Elliott & Dweck, 1988). Approach goals may be more effective because it is harder to define success criteria for avoidance goals (i.e., not getting a disease), and to maintain motivation when faced with an obstacle, it is beneficial to have a clear idea of what steps are required for success. There are also individual differences in motivational orientations, with people tending to be oriented toward either approach or avoidance goals, and these differences may have implications for goal pursuit. For example, there is some evidence that it may be beneficial to match health messages to an individual's motivational orientation (Mann, Sherman, & Updegraff, 2004).

An important predictor of successful goal setting and pursuit, according to self-determination theory (Deci, Koestner, & Ryan, 1999), is whether a person perceives that they have autonomous control over the decision to change their behavior. In fact, social psychologists as early as Lewin (1935) have proposed that self-imposed goals are more motivating than goals imposed by others. Evidence for the importance of self-set goals in the health domain is mixed, however. Interventions in which healthcare providers discuss patient values and support the patient's goal choice instead of recommending a course of action support this hypothesis (Silva et al., 2011). But other research has found similar outcomes for patient and provider set goals (Alexy, 1985), as well as employee and employer set goals (Locke & Latham, 1990).

Goals imposed by others may be less motivating because this undermines the intrinsic value of the goal (Deci et al., 1999). Meta-analytic evidence indicates that extrinsic rewards reduce intrinsic motivation (Deci et al., 1999). In situations where people lack internal motivation, however, extrinsic motivation may be an effective motivator, such as when external reinforcements are added to employee health promotion programs. Having recognized the cost savings that come from investing in the long-term health of the workforce, many employers have adopted material incentive programs designed to encourage their employees to engage in healthy behaviors, such as exercise and smoking cessation. There is little empirical research on the effectiveness of such programs and what, if any, payment structures are the most effective.

Goals also differ in their level of difficulty. Some research suggests that successful goal pursuit requires that the goal is feasible, but other work has found that unrealistic goals may actually inspire goal pursuit (Linde, Jeffery, Finch, Ng, & Rothman, 2004). Research in vocational settings also suggests that high demands (i.e., the goal is challenging) lead to better performance than easier goals as long as self-efficacy is sufficient (Latham & Locke, 2007). In support of this view, when the goal is highly desirable but unrealistic, there is evidence that people will take actions to better achieve the goal, instead of changing the goal itself.

A single goal, such as a weight-loss goal, can be cast in multiple ways. A person may set a goal to develop the knowledge and cooking skills required to eat a healthy diet (i.e., a "mastery goal"), or they may aim to demonstrate their success by achieving a certain weight (i.e., "performance goal"). There is evidence that mastery goals lead to better outcomes than performance goals (Elliott & Dweck, 1988). For example, mastery goals lead to deeper processing, whereas performance goals trigger superficial processing (for a review, see Covington, 2000). Mastery goals have also been shown to bolster self-efficacy, increase amount of time spent on task, augment the belief that effort leads to success, and help lead to persistence in the face of obstacles, whereas performance goals have been found to undermine intrinsic motivation and increase avoidance of difficult tasks. While it is reasonable to believe that this distinction applies to health behavior, it has not often been applied.

Goal Abandonment

Goal abandonment is common and often happens soon after goal setting. People frequently abandon their goals when other goals compete for time and energy or when there are no facilitating goals that share a common means of pursuit. Research tends to focus on ways to bolster goal persistence, but this is not always the most advantageous response. Abandoning a goal that is not attainable is an adaptive strategy that can free up time and energy (Latham & Locke, 2007), reduce negative feelings that come from repeated failure to achieve goals, and minimize stress from setting goals without the proper resources to attain them (Schönpflug, 1986). Goal abandonment is also advantageous when goals are beyond personal control, such as the case of those who strive toward the goal of having a "perfect" thin body.

Goal Striving

Goal striving encompasses all actions, either deliberate or automatic, to achieve goals. This involves not only carrying out actions that directly promote goal attainment but also protecting those goals from being disrupted by competing goals or temptations. Individuals use many strategies in goal striving, which can be loosely categorized into planning strategies, automatic strategies, cognitive strategies, and effortful inhibition.

Planning Strategies

Planning strategies involve making arrangements before one is in a situation in which goal-directed behavior will be needed, so that either (a) temptation to engage in behavior counter to the goal can be avoided or (b) the individual is ready to meet the challenge when it occurs. By thinking ahead of time about potential obstacles that may arise, individuals can plan ways to overcome those obstacles. A simple example would be changing one's route to work so that they do not pass the fast-food restaurant with a drive-through window, which they know would dangerously tempt them from their weight-loss goal. Choosing to keep tempting foods out of one's home or at a distance are other examples.

Mentally rehearsing or simulating a strategy ahead of time is also a form of planning. People may envision themselves engaging in each of the steps necessary to achieve their goal so that they know what to expect and are ready with the appropriate response when the time comes. This strategy has been found effective among students mentally simulating the process of studying and preparing for exams, compared with students imagining the outcome of successful studying (Pham & Taylor, 1999). Focusing on the process rather than the outcome is an important aspect of the strategy, as only a process focus will reveal potential obstacles and challenges that may be encountered.

Automatic Strategies

Automatic strategies operate without an individual's conscious awareness, or with less than full awareness. Automatic strategies are advantageous in many circumstances. They can operate when individuals are not motivated to comply with their goals and when individuals do not have sufficient attentional resources to dedicate to carefully monitoring and altering their behavior. When goal striving is automated, individuals are less likely to consciously talk themselves out of engaging in the relevant goal-directed behavior and are less susceptible to interference from competing goals.

Habits, once formed, operate automatically and can be an effective strategy for reaching a goal. Habits are formed when a behavior is paired with a particular environmental cue many times. After sufficient pairing, the behavior operates automatically whenever that environmental cue is present. An individual may put on their seat belt when they get into their car so often that this becomes a habit, and they eventually do it without giving it any conscious thought.

Behaviors that only happen infrequently are less likely to become habits, as they do not have enough opportunities to be paired with a particular contextual cue. However, they may still be made automatic with the use of implementation intentions. Implementation intentions are if-then plans that specify a particular action to perform in a particular situation, such as "If I am in the produce section of the store, then I will buy apples." Forming an implementation intention and repeating it several times has been shown to lead to improved regulation of many health-related behaviors (for further reading, see Gollwitzer & Sheeran, 2006).

Another way in which goal pursuit may become automatic is if alterations are made to one's environment (planning) so that the goal-consistent behavior is the more likely response (or the only possible response). This may be possible by changing which behavioral options are available or possible, or by changing how the options are presented. Using "nudge"-type interventions, for example, keeps all options available but makes certain options more likely to be chosen, by, for example, making certain options more salient, closer, easier, more convenient, or cheaper. The fact that people have behaved based on responding to such changes is generally outside of their conscious awareness.

Cognitive Strategies

The category of cognitive strategies includes efforts to change the way one thinks about one's goals and the obstacles to those goals. There are many ways one might think about the same goal or obstacle, and these different construals affect whether an individual is likely to be successful at attaining the goal. For example, temporal construal theory (Trope & Liberman, 2003) postulates that distant-future events are evaluated primarily in terms of their desirability, whereas near-future events are evaluated primarily in terms of their feasibility. When people set a goal, they tend to focus on desirable outcomes in the distant future, but during goal pursuit, these outcomes lose focus, challenges become more apparent, and persistence becomes more difficult, frequently leading to failure to achieve the goal. Individual differences in the extent to which people focus on proximal or distal goals influence goal attainment, with a more distal focus leading to better outcomes.

Individuals can be induced to focus on the future by having them think about possible events that could occur, and this serves as an effective self-regulatory strategy. It should be noted, however, that there is also evidence for the reverse position and that focusing on the means to success rather than on the ends of success leads to more successful goal pursuit and attainment, particularly if the task is difficult. Differences in these perspectives may be explained by the reward value of goal-directed behavior. A process focus may increase the intrinsic value of a rewarding behavior (e.g., engaging in a desired sport for exercise) but may simply highlight the drudgery of a less rewarding one (e.g., resisting desired foods).

Individuals also think about temptations and obstacles differently when those challenges are abstract than when they are specific. Challenges that are more vague and abstract seem less daunting than challenges that are concrete and detailed. For example, when children were trained to think about a tempting marshmallow in an abstract way (as "fluffy clouds") instead of as a specific yummy treat, they were able to resist eating it for longer (Mischel, Shoda, & Rodriguez, 1989). Merely taking on an overall abstract mindset can work as well. Thinking about general categories of animals instead of specific animals led individuals in one study to think more abstractly, and they were more likely to successfully resist a tempting snack (Fujita & Han, 2009).

Effortful Inhibition of Impulses

The final category of goal striving strategies is effortfully inhibiting an impulse that would interfere with goal pursuit, by fighting off or suppressing the counterproductive thoughts, feelings, or behaviors. This subset of self-regulation processes is sometimes specifically referred to as self-control (although in many other cases, the terms self-control and self-regulation are used interchangeably), willpower, or delaying gratification. Effortfully inhibiting an impulse is, by definition, not automatic, as it requires conscious effort, and therefore it is subject to derailment or interference when these resources—whether they are cognitive or motivational—are scarce (for further reading, see Inzlicht & Schmeichel, 2012).

Dual-process models suggest that impulsive behaviors may be automatically enacted when there are not sufficient cognitive resources to challenge them. For example, when cognitive resources are scarce, individuals may not notice that they are violating their standards or may not have the ability to consider another option for how to behave. Individuals with impairments to their cognitive functioning, such as impaired working memory or executive function, have less success in regulating their behaviors. In addition, other factors that temporarily occupy these cognitive resources, including divided attention, alcohol intoxication, or fatigue, also reduce self-regulatory success.

Effortful inhibition may also be undermined by a lack of motivation. In particular, an extensive literature on the phenomenon of ego depletion shows that inhibiting one behavior makes it difficult to inhibit another behavior, due to the temporary depletion of a motivational resource. For example, in one study, after resisting eating a tempting cookie, participants performed worse on an unrelated self-regulation task, persisting in their efforts to solve a difficult puzzle (Baumeister, Bratslavsky, Muraven, & Tice, 1998). Even behaviors that seem to only require a small amount of effort to regulate (such as making a choice between two pens or suppressing one's facial expression) can still make it difficult to regulate another behavior soon after. Because of the ease and frequency with which both motivational and cognitive resources can become depleted, effortful inhibition is a strategy that is prone to failure.

While there is very little evidence that individuals can be taught to increase their effortful inhibition ability, there is some evidence that the depletion effect may be prevented with interventions that provide cash incentives, induce a positive mood, or reduce fatigue. In addition, depletion may be prevented by having participants form an implementation intention beforehand, by reminding them of their core values or even by teaching them that willpower is not limited.

Relying solely on effortful inhibition is not likely to be an effective strategy for goal attainment, but making use of multiple strategies may be more successful. For example, cognitive strategies might be used in an effort to help resist temptation, or planning strategies might be used so that individuals are less likely to encounter temptation. Similarly, if automatic strategies have been used to form habits or implementation intentions, effortful inhibition may not be necessary.

Future research on self-regulation might aim to focus on delineating the types of situations in which particular strategies may be effective, as well as the role of partners and family members in aiding an individual's self-control. This work may ultimately lead to effective interventions to help people successfully control their health behaviors.

Author Biographies

Richie L. Lenne is a PhD student in psychology at the University of Minnesota. He received his BA from Lewis & Clark College in 2011. He spent 3 years conducting research at the

Oregon Health & Science University before starting his doctorate. His research applies social psychological theory to public health and behavior change interventions with the dual purpose of informing theory and developing effective and efficient health programs.

Traci Mann is a professor of psychology at the University of Minnesota. She received her PhD in 1995 from Stanford University and spent ten years on the faculty at UCLA. She is interested in basic science questions about cognitive mechanisms of self-control and in applying social psychology research to promoting healthy behavior—particularly eating—in individuals' daily lives. Her research has been funded by NIH, NASA, and the USDA.

Sex Differences and Health

Vicki S. Helgeson and Katilyn Mascatelli

Department of Psychology, Carnegie Mellon University, Pittsburgh, PA, USA

One of the seemingly contradictory findings in health psychology is the paradox that women are sicker than men, yet women outlive men. Women report feeling more pain and physical symptoms than men, perceive their health to be worse than men, and are more likely to be depressed than men. Yet men are more likely than women to die from 9 of the 10 leading causes of death in the United States. There are robust sex differences in psychological and physical health. The goal of this encyclopedia entry is first to orient the reader to the nature of these differences and then to offer explanations rooted in both culture and biology for the disparities. We use the phrase "sex differences" rather than "gender differences" when describing these statistics because we are comparing the biological categories rather than the social categories of male and female.

Mortality

There are long-standing sex differences in mortality in the United States. More males than females die at every age, with the ratio of male-to-female deaths peaking in adolescence and young adulthood. For example, for every 121 males who die between the ages of 20 and 24, 44 females die, which results in a male-to-female ratio of 2.75 (Centers for Disease Control and Prevention, 2015). This phenomenon makes the finding that women have longer life expectancies than men unsurprising. In 2013, the life expectancy was 81.2 years for females and 76.4 years for males (Centers for Disease Control and Prevention, 2015). This sex difference remains even when examining individual races and ethnicities. Life expectancy for Black women is 78.4 and for Black men is 72.3, whereas White women can expect to live to 81.4 and White men to 76.7 years. Latina women have a life expectancy of 83.8, and Latino men have a life expectancy of 79.1.

This sex difference in mortality favoring women has been documented for over a century, although the size of the difference has varied over the decades. In 1900, the life expectancy for

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

men was 46 years and for women was 48 years. As lifespans increased for both men and women over the twentieth century due to improvements in medicine and technology, the sex difference in mortality steadily increased, peaking in 1979 when women outlived men by nearly 8 years. This increased sex difference can be attributed to the reduction in women's mortality during childbirth and the increase in men's mortality from heart disease and lung cancer, which can be directly linked to smoking behavior. In recent decades, the sex difference in mortality has narrowed. This change has been credited to the relatively greater decrease in mortality from heart disease and cancer among men compared with women, in part due to men's higher quit rates of smoking compared with women.

Females outlive males in countries outside of the United States, but the magnitude of this difference is not consistent. Developing countries have shorter life expectancies than Westernized countries, and the sex difference in mortality is more variable and oftentimes smaller than that in more developed nations. The smaller sex difference in developing countries might be explained in part by the greater status difference between women and men, which contributes to female infanticide, higher maternal mortality, and poverty-linked mortality.

Morbidity

While lifespans have increased over the past century, rates of illness have increased. This trend reflects the fact that people who once would have died from acute illness live longer lives and acquire chronic diseases with which they can often live. In the early part of the twentieth century, it was much more common for people to die from acute illnesses such as influenza, but now they are able to survive these diseases and live long enough to contract illnesses that are more chronic in nature. Although men have higher death rates from the two major chronic diseases and the two leading causes of death (heart disease and cancer), women suffer from more acute and nonfatal chronic illnesses than men. Women suffer more than men from immune-related disorders, such as lupus, rheumatoid arthritis, and multiple sclerosis, as well as painful disorders, such as migraines, back pain, and carpal tunnel syndrome, and women report more overall disability than men and poorer self-ratings of health.

A primary contributor to the higher rate of morbidity among women compared with men is depression and depressive symptoms. Women experience more depressive symptoms than men in the general population and are also more likely than men to be diagnosed with clinical depression. This finding holds across many different countries, although the size of the difference varies. Interestingly, this difference emerges at the start of adolescence. That is, before age 13, boys and girls are equally likely to be depressed. Thus, any explanation of gender differences in depression must therefore account for this age-linked phenomenon.

Biology

There are a variety of biological explanations for sex differences in health. First, there are clearly some disorders that are linked to chromosomes that may place women or men at a disadvantage. Females are resistant to some X-linked chromosomal abnormalities because they have a second X chromosome. This may partly explain why women are less likely than men to suffer from hemophilia, meningitis, and muscular dystrophy. There are also disorders that are linked to the XX genotype, such as breast cancer, osteoarthritis, and glaucoma.

Hormones play a role in health, and men and women have varying levels of different hormones. Estrogen is a hormone that is thought to protect women from heart disease until menopause, after which estrogen levels decrease and women's levels of heart disease dramatically increase (Fetters, Peterson, Shaw, Newby, & Califf, 1996). The relation between estrogen and heart disease specifically and health more generally is not that simple, however. For example, oral contraceptives can increase the risk for heart disease (especially if combined with smoking), and hormone replacement therapy after menopause has not been linked to a reduction in heart disease (Lowe, 2004). Estrogen is thought to play a role in the development of some cancers, such as breast cancer. Thus, although hormones clearly play a role in health, they are likely to interact with genetic and environmental factors to influence health.

A third biological explanation for sex differences in health involves the immune system. It has been suggested that the nature of women's and men's immune systems differs, but the nature of these differences is not clear. Women are clearly more vulnerable than men to a host of immune-related disorders, such as lupus and rheumatoid arthritis. Immune factors also are likely to interact with hormones to influence health.

Health Behaviors

Smoking

There are a variety of health behaviors for which women and men differ that are directly linked to sex differences in morbidity and mortality. One is smoking. Smoking tobacco is one of the leading causes of heart disease and stroke and contributes to over a dozen kinds of cancer. While its ill effects are well known, the link between sex and smoking, as well as its long-term implications, is best understood within an historical perspective. In the early twentieth century, smoking was socially unacceptable for women. The smoking rate was twice as high among men than women, until the middle of the twentieth century. At that time, social norms relaxed, and advertising agencies focused their sights on selling cigarettes to women as part of a "liberated" lifestyle, a technique that allowed them to sell their product to a previously untapped other half of the population. Thus, smoking among women increased in the 1960s and 1970s as it became associated with women's fight for equality. In 1970, 31% of women and 44% of men were smokers. Overall smoking rates for both men and women have decreased dramatically as the health hazards of smoking became more widely known, and in 2013 about 15% of women and 20% of men smoked (Jamal et al., 2014).

Paralleling the changes in the rates of smoking for women and men, the sex difference in lung cancer has correspondingly shifted. The incidence of lung cancer has decreased for men but increased for women since the 1980s. In 1960, the male–female ratio of lung cancer was 6.7; in 1990, it was 2.3; and in 2015, it was projected to be 1.1 (American Cancer Society, 2015). Because lung cancer develops over the two to three decades following smoking, the changes in men's and women's rates of lung cancer can be directly tied to the changes in their rates of smoking.

Although both women and men have been quitting smoking, smoking cessation attempts are less successful for women than for men (Piper et al., 2010). Both nicotine replacement therapy and interventions that combine prescription smoking cessation medication with antidepressants are more effective in helping men than women quit smoking. One reason that women have more trouble quitting smoking than men is that women are more likely to be depressed than men, and smoking is more strongly associated with mood enhancement among women than men.

Other potential explanations are that smoking is more of a social experience for women than men and that women place higher value on the perceived weight-loss benefits of smoking than men.

Alcohol

Men drink more than women and have more alcohol-related problems than women. Women tend to have an older age of onset of regular drinking, to drink alcohol less frequently and to be more likely to abstain compared with men.

Regardless of the level of alcohol intake, the consequences of alcohol are different for women and men. It takes proportionately less alcohol to have the same effect on a woman as a man. For a woman and a man of the same weight who consume the same amount of alcohol, the woman will have a higher blood-alcohol level than the man due to the greater ratio of fat to water in a woman's compared with a man's body. This means that men have more water available in their systems to dilute consumed alcohol. The greater impact of alcohol on women compared with men may be why alcohol is more strongly associated with cirrhosis of the liver in women than in men. The progression from the first drink to an alcohol-related problem is faster among women than men. Thus, women are more vulnerable than men to both acute and chronic ailments of alcohol.

Despite women being more vulnerable to the health consequences of alcohol compared with men, men suffer more alcohol-related problems than women. The percentage of all deaths attributable to alcohol consumption is greater for males and females of all races: among Whites, 12.4% for males compared with 3.9% for females; among Blacks, 9.9% for males compared with 4.8% for females; among Native Americans, 25.8% for males compared with 11.6% for females; and among Asian/Pacific Islanders, 6.0% for males compared with 2.2% for females (Shield et al., 2013).

Obesity and Exercise

The United States has seen a dramatic rise in obesity rates over the past four decades. Men are more likely than women to be overweight, but women are more likely than men to be obese. Overweight is defined as a body mass index that exceeds 25, whereas obesity is defined as a body mass index that exceeds 30. In the majority of countries in the world, women are more likely than men to be obese. In the United States, the rate of obesity is the same for White women and men (33% women, 32% men), whereas the rate of obesity is much higher for females compared with males among Blacks (50 vs. 37%) and Hispanics (45 vs. 36%; Flegal, Carroll, Ogden, & Curtin, 2010). Aside from the fact that obesity is a risk factor for all causes of mortality for both women and men, the social and economic implications of obesity impact women more than men.

Women are more likely than men to be obese for two reasons. First, there are life events that are associated with obesity in women, such as having children and menopause. Women are also more likely to gain weight after marriage than men. Second, women are less likely than men to engage in physical activity, which is associated with a reduced risk of obesity. In addition, physical activity is associated with a lower risk of heart disease, hypertension, type 2 diabetes, and depression for both sexes. One reason that women have lower rates of exercise than men is that men tend to be motivated to be active by competition, whereas women are motivated by concerns about appearance and weight control. Unfortunately, body-shape motives are associated with lower levels of physical activity compared with other motives for exercise (Segar, Spruijt-Metz, & Nolen-Hoeksema, 2006).

Sexuality and Reproductive Health

The importance of understanding the impact of sexuality on health was brought to the forefront in recent decades, mostly due to the emergence of the AIDS epidemic. In particular, the idea that people belonging to sexual and gender minorities (i.e., lesbian, gay, bisexual, and transgender individuals, hereafter referred to as LGBT) might have unique healthcare needs gained validation only after the American Psychiatric Association acknowledged that homosexuality was not a psychiatric illness in 2000. LGBT youth are at greater risk for suicide attempts than non-LGBT youth (Silenzio, Pena, Duberstein, Cerel, & Knox, 2007). Lesbians are more likely than non-lesbian women to be overweight and obese (Boehmer, Bowen, & Bauer, 2007), putting them at risk for cardiovascular disease, glucose intolerance, and other obesity-related morbidities. These health problems are exacerbated by unique barriers LGBT persons encounter when attempting to access healthcare, such as reluctance to disclose sexual orientation to healthcare providers and structural barriers that impede access to health insurance for LGBT persons and their partners.

Although men tend to have more permissive attitudes about sex than women, this difference has decreased in magnitude over the past several decades, possibly due to an increase in women becoming more permissive. One potential reason for women's change in attitudes toward sex is the increased safety, efficacy, and availability of birth control. Virtually all women who have ever engaged in sexual intercourse in 2006–2010 have used some form of contraception, compared with about a third of women in the 1970s (Daniels, Mosher, & Jones, 2013). Today, the majority of women who use birth control are on oral contraceptives (the pill), although the proportion of women using other hormonal methods (the patch or shot) has increased from 4.5% in 1995 to 23% in 2006–2010 (Daniels et al., 2013). The proportion of women using long-acting reversible contraceptives (e.g., the intrauterine device) has also increased. Another tool women in the United States use to control their reproductive health is abortion, rates of which have been steadily declining over the past two decades. The abortion rate in 2010 for women aged 15–44 (14.6 per 1,000) was 32% lower than the rate in 1990 (27.4 per 1,000; Curtin, Abma, Ventura, & Henshaw, 2013). This decrease in the abortion rate has coincided with a national decline in the birth rate (16.7 per 1,000 women in 1990 compared with 13.0 per 1,000 women in 2010), and the most probable cause for these trends is improved or increased contraceptive use. By using birth control, women are able to delay, plan, and space their pregnancies.

Unintended pregnancy is not the only potential consequence of sexual activity—the risk of contracting a sexually transmitted infection (STI) is notably present for both males and females. In 2012, nearly 50,000 individuals were newly diagnosed; new cases occurred disproportionately among men who have sex with men, African Americans and people in their 20s (Centers for Disease Control and Prevention, 2014). The rate of HIV infections in the United States has remained stable since the late 1990s due to widespread prevention and testing efforts.

Sociocultural Factors

There are also a set of sociocultural factors that are implicated in the relation of gender to health. Here we consider three such factors: gender-related traits that are socialized in men and women, risky behavior that is socialized in men, and nurturant roles that are socialized in women.

Gender-Related Traits

As indicated in Janet Hyde's (2005) summary of 46 meta-analyses that compare women and men on a host of cognitive and social abilities, there are far more similarities than differences between men and women. Some of these differences may be attributed to the social roles that men and women possess in our society. Men are socialized to be agentic, and women are socialized to be communal. There is a strong body of research that shows the gender-related traits of agency and communion are more predictive of health than simply the categorical variable of sex (Helgeson, 2012).

In fact, there is strong evidence that agency is associated with good mental health outcomes and can account for sex differences in those outcomes (Helgeson, 2012). Agency is also related to good health practices, such as exercise, healthy eating, and good dental hygiene. However, communion is typically unrelated to health and health behaviors. Instead, communion is related to more supportive relationships and can account for sex differences in support. However, as discussed later, relationships are a double-edged sword for women. Thus, agency but not communion may account for some of men's lower rates of morbidity compared with that of women.

Aside from agency and communion, two more specific gender-related traits have been examined in their connection with health—unmitigated agency and unmitigated communion (Helgeson, 2012). Unmitigated agency is characterized by an excessive focus on the self and a negative view of others. Unmitigated agency has been linked to reckless driving, substance abuse, poor health behavior, risky behavior, and poor adjustment to disease (Helgeson, 2012). Unmitigated communion reflects a focus on others to the exclusion of the self and is defined by overinvolvement with others and self-neglect. Unmitigated communion has been linked to depressive symptoms, poor healthcare, and poor adjustment to disease (Helgeson, 2012). Even though some of the relations to health are the same, the reasons differ. For example, unmitigated agency is related to poor health behaviors due to feelings of superiority, beliefs in invulnerability, and possibly psychological reactance—that one does not need to engage in specific behaviors in order to be healthy. By contrast, unmitigated communion is related to poor health behavior due to an involvement with others that detracts from tending to one's own needs.

Risky Behavior

Men are socialized to take risks, whereas women are not. Parents are more encouraging of risk taking in boys than girls. For example, one study had parents watch a video of children on a playground and asked what they would say (Morrongiello & Dawber, 2000). Parents were more likely to intervene and warn of injury when they thought the child was a girl than a boy. Not surprisingly, men report engaging in more risky behaviors than women (Byrnes, Miller, & Schafer, 1999). As evidence of risk-taking behavior, men work in more hazardous jobs compared with women and have much higher rates of fatal work injuries compared with women; men handle more risky chores around the house compared with women, such as climbing on the roof; men are more aggressive drivers than women; and men engage in riskier leisure activities compared with women, such as skiing, mountain biking, and skydiving. Men are also more likely than women to own guns, and a greater use of guns contributes to a greater number of fatal gun accidents. Thus, risk-taking behavior may account partly for men's greater mortality from accidents and injuries compared with women. The male-to-female ratio of death from injuries—intentional and unintentional—persists across ethnic groups in the United States but is largest for Hispanic Whites and lowest for Asian/Pacific Islanders.

Nurturant Roles

Women report more supportive relationships than men, but these relationships have been cast as a double-edged sword. Relationships are not only sources of support for women but also sources of strain. That is, women not only receive but also provide support. Women are socialized to be caretakers, and caregiving has costs to health. According to the "nurturant role hypothesis," women's caretaking leads to increased exposure to communicable diseases, fatigue and vulnerability to illness from taking care of others, and self-neglect because caring for others takes precedence over caring for the self (Gove, 1984). In the United States, women are more likely than men to engage in volunteer work, women are more likely than men to be the primary caregivers of children, and women are more likely than men to take care of sick family members—spouses, parents, or children. In addition, caregiving is associated with greater burden and greater distress among women than men (Pinquart & Sörensen, 2006).

Conclusion and Future Directions

Health—psychological and physical—is one domain for which sex differences persist, although the size of these differences has shifted substantially over the last century. We reviewed several different classes of explanations for these differences—those involving biology, health behaviors, reproduction, and sociocultural variables – but note that these explanations have largely been examined in isolation of one another. It is increasingly recognized that biological, behavioral, and social factors are likely to interact to influence health. Future research aimed to increase our understanding of sex differences in health would benefit from a multidisciplinary approach. Research in this area also is expanding in terms of the methods used to study sex differences in health. Correlational research is being replaced with longitudinal studies, research on middle-class White persons is increasingly cross-cultural, and experimental approaches have been used to understand how we react to men and women as well as how hormones influence behavior. Finally, it is increasingly recognized that the category of being male versus female intersects with multiple other categories, such as race, ethnicity, and social class. Future research on sex differences in health would benefit from incorporating greater intersectionality in its approach.

Author Biographies

Vicki S. Helgeson is professor of psychology at Carnegie Mellon University where she studies the intersections of gender, relationships, and health. She studies how people adjust to chronic illness with a focus on the implications of gender-role socialization and social environmental factors for health. Her most recent work involves couples in which one person has diabetes, with a focus on communal coping. She recently completed the 5th revision of her textbook titled *Psychology of Gender*.

Katilyn Mascatelli is a graduate student in the social/health psychology program at Carnegie Mellon University in Pittsburgh, Pennsylvania. Her research interests include gender, stereotyping, and discrimination based on violations of gender stereotypes.

Social-Evaluative Threat

Sally S. Dickerson

Department of Psychology, Pace University, New York, NY, USA

Have you ever thought that others were negatively judging you while you were giving an important talk or presentation? Have you felt criticized by a relationship partner, friend, or acquaintance or felt that you were judged or rejected by others on the basis of a stigma, devalued characteristic, or an aspect of your identity? These types of situations can be inherently difficult, painful, and threatening—and they all share an underlying core element of social evaluation. Social-evaluative threat (SET) occurs when an important aspect of the self could be judged by others (Dickerson & Kemeny, 2004). Theoretical and empirical work has documented how these social-evaluative situations may be associated with patterns of emotional and physiological reactivity.

Why are social-evaluative situations threatening? Humans have a fundamental need to belong, and maintaining the social acceptance of others is critical to well-being and survival (Baumeister & Leary, 1995; Holt-Lunstad, Smith, & Layton, 2010). Situations with the potential for evaluation or rejection therefore jeopardize this fundamental goal. We have proposed that social-evaluative situations may elicit a coordinated psychobiological response, characterized by emotional and physiological changes (e.g., Dickerson, Gruenewald, & Kemeny, 2004). Our theoretical and empirical work has documented that SET can lead to increases in self-conscious cognitions and emotions (e.g., shame, embarrassment) and other negative cognitive and affective states. Physiologically, SET can elicit increases in cortisol, an important hormone that is involved in energy mobilization, and can help organize the body's response to stressors; SET can also lead to changes in the cardiovascular and immune systems. If the physiological activation elicited by SET is experienced chronically or persistently, there could be implications for health.

Social-Evaluative Threat and Cortisol Reactivity

A great deal of research has tested whether SET can elicit the hormone cortisol. In a meta-analytic review of 208 acute laboratory stressor studies that assessed cortisol as an outcome

(Dickerson & Kemeny, 2004), we found that stressors characterized by SET (e.g., evaluative audience present) were associated with substantially larger cortisol responses than those without this element (e.g., completing difficult math problems alone). The effect size for social-evaluative stressors was nearly three times the magnitude of the non-SET tasks ($d = 0.67$ vs. $d = 0.15$). The increase in cortisol was particularly pronounced when stressors were both *social-evaluative* and *uncontrollable*. Social-evaluative, uncontrollable stressors were associated with large increases in cortisol ($d = 0.92$); however, those without either element did not on average lead to increases in this parameter. Taken together, this meta-analysis demonstrates that social-evaluative stressors—particularly when uncontrollable—can elicit strong, substantial cortisol reactivity.

Subsequent studies have manipulated the social-evaluative context of the stressor to experimentally test the conditions in which cortisol reactivity is observed. Gruenewald, Kemeny, Aziz, and Fahey (2004) randomly assigned participants to deliver a speech and complete a computerized math task either in front of an evaluative audience (SET) or alone in a room (non-SET). Participants in both conditions reported that the task was challenging and difficult and required effort (e.g., "stressful"); however, only the SET condition elicited increases in cortisol. Performing the identical task in the absence of social evaluation did not lead to cortisol changes, demonstrating that the social-evaluative nature of the stressor can shape the physiological response.

This SET manipulation has now been used in a number of studies and the primary findings replicated using laboratory performance stressors (e.g., Bosch et al., 2009; Dickerson, Mycek, & Zaldivar, 2008; Het, Rohleder, Schoofs, Kirschbaum, & Wolf, 2009; Taylor et al., 2010) and physical stressors (e.g., cold pressor task; Schwabe, Haddad, & Schachinger, 2008). Other studies have examined whether naturally occurring instances of SET (e.g., real-life competitions) can also elicit cortisol reactivity. Rohleder, Beulen, Chen, Wolf, and Kirschbaum (2007) collected cortisol from ballroom dancers during both rehearsal and competition days. They found that cortisol levels were much higher on the competition days, when their performances were being judged by an evaluative panel, compared with days in which they were rehearsing (and not evaluated). Further, the dancers who reported feeling more stressed by the judges also showed greater increases in cortisol. Another study examined cortisol responses during a competitive audition for a musical theater production (Boyle, Lawton, Arkbage, Thorell, & Dye 2013). Audition exposure led to increases in cortisol, and cortisol reactivity correlated with subjective ratings of SET. Taken together, these studies demonstrate that naturally occurring performance contexts characterized by social evaluation can also trigger increases in cortisol and that cortisol can be linked to perceptions of social evaluation.

Components of Social-Evaluative Threat Linked with Cortisol Reactivity

We have been interested in unpacking the critical components of the social-evaluative context that elicit increases in cortisol. For example, is the mere social presence of others enough to trigger cortisol reactivity, or does the social evaluation need to be explicit to lead to increases in this parameter? To test this question, we conducted a study with three experimental groups (Dickerson et al., 2008). Similar to Gruenewald et al. (2004), participants delivered a speech in front of an evaluative audience (SET) or alone in a room (non-SET). We also included a third experimental condition, in which a research assistant was inattentive (working on a laptop in the room) (PRES). We found that the SET condition elicited a robust increase in cortisol;

however, the non-SET and PRES conditions did not lead to increases in this parameter. This suggests that simply having others present during a performance stressor may not be enough to elicit increases in cortisol; instead, the perceived evaluation of others may be critical for activating this physiological system.

Others have examined whether SET that occurs remotely can trigger cortisol reactivity; do the evaluative others need to be physically present to elicit a response? Several studies have found that remote evaluation (e.g., participants believe they are being evaluated through a one-way mirror) is sufficient to increase cortisol levels (e.g., Kelly, Matheson, Martinez, Merali, & Anisman, 2007); evaluation by avatars in an immersive virtual reality environment has also been shown to elicit cortisol reactivity (Fallon, Careaga, Sbarra, & O'Connor, 2016). One study that experimentally manipulated whether the evaluators were physically present or remote (virtual audience or one-way mirror; Kelly et al., 2007) found having an audience that was physically present elicited about cortisol increases of about three times the magnitude of more remote forms of social evaluation. While future research should test key moderators (e.g., immersive nature or believability of the remote evaluation), it is clear that when perceptions of evaluation are evoked (whether the evaluation is in person or virtual), the cortisol system can be activated.

The threat inherent in a social-evaluative context is multidimensional and could lead to concerns of loss of social standing or loss of acceptance. Smith and Jordan (2015) conducted a study to delineate whether status or acceptance concerns are driving cortisol responses to SET. They randomly assigned participants to complete a public speaking task in one of four conditions: a low-threat condition, in which they were told they would not be evaluated; a high-acceptance threat condition, in which they would be judged in terms of how likeable, friendly, and interesting they were; a high-status threat condition, in which they were judged on how competent, skilled, and intelligent they appeared; and a high-acceptance/high-status condition, where the instructions were combined. They found that both status and acceptance threats elicited greater increases in cortisol compared with the low-threat condition and the largest increases were observed for the high-status/high-acceptance threat group. This suggests that both status concerns and acceptance concerns can lead to increases in cortisol and contexts that trigger both are potent elicitors of this physiological parameter.

The behavior of the evaluators could also be an element that influences cortisol reactivity to SET. Cundiff, Smith, Baron, and Uchino (2016) found that an evaluative interaction with a highly dominant individual (e.g., assertive voice) led to greater cortisol responses compared with interactions with someone low on dominance (e.g., spoke deferentially). This suggests that qualities and behaviors of the evaluative others can also shape responses to SET.

Taken together, these experimental studies demonstrate that contexts that heighten the evaluative potential (e.g., explicit evaluation, dominant interaction partner, threaten salient goals) lead to pronounced increases in cortisol. Future research should continue to unpack the critical elements of the social-evaluative situation that trigger this system and identify important moderators of reactivity.

Emotional and Cognitive Effects of Social-Evaluative Threat

SET can elicit robust increases in cortisol, but what are the emotional experiences of individuals in these situations? We have been interested in the affective changes that occur under social-evaluative contexts. Consistent with theoretical and empirical literature that self-conscious emotions and affective self-evaluative states are sensitive to assessments of declining status or acceptance (e.g., Gilbert, 2000; Leary, 2007), we have found that the SET conditions are associated with greater increases in self-conscious cognitions and emotions compared with the non-SET conditions (Dickerson et al., 2008; Gruenewald et al., 2004). Further, there were no differences between conditions in other emotional states, such as fear or sadness, demonstrating that the self-conscious states were most sensitive to the social-evaluative context of the stressor. In both of these studies, we also found correlations between the self-conscious emotions and cortisol; those who showed the greatest increases in self-conscious emotions also showed the greatest increases in cortisol. There was not a relationship between cortisol reactivity and other negative emotions assessed. Taken together, this suggests that social-evaluative conditions can elicit both self-conscious emotions and cortisol reactivity and these systems could be activated in parallel under SET. However, this self-conscious emotion/cortisol association could vary depending on the type of SET experienced (e.g., status vs. acceptance threats; Smith & Jordan, 2015) or individual difference factors (e.g., subjective social status; Gruenewald, Kemeny & Aziz, 2006); additional research on the emotional correlates of SET, and accompanying physiological changes, is warranted.

For some, the social-evaluative experience may not end when the interaction is over. SET can lead to rumination, or repetitive, unwanted, past-oriented thoughts. In our experimental studies that manipulate SET, we have assessed post-task negative thoughts to test if social-evaluative contexts are more likely to trigger rumination and if rumination is linked to persistent cortisol activation. Consistent with this premise, we have found that explicit social-evaluative conditions elicit more negative thoughts (e.g., "I looked stupid") in the 10 min post-task compared with other conditions (Zoccola, Dickerson, & Zaldivar, 2008). Additionally, those who reported higher levels of post-task rumination also had greater cortisol reactivity, and levels remained elevated longer compared with those who reported lower levels of rumination following the stressor.

We conducted another study to test whether the SET-rumination link persists beyond the immediate post-task period (Zoccola, Dickerson, & Lam, 2012). Replicating our previous finding, post-task rumination was higher in the SET condition compared with a non-SET condition 10 min post-stressor. In this study, we also assessed rumination 40 min post-task, later that evening and 3–5 days later. At all time points, participants in the social-evaluative condition reported higher levels of rumination compared with those in the non-SET condition. Further, we found this effect was mediated by self-conscious cognitions and emotions; the SET condition led to greater increases in self-conscious cognitions and emotions, which in turn was associated with greater rumination. This demonstrates that SET contexts can elicit ruminative thought even days beyond the initial stressor, potentially through the ability to elicit self-conscious cognitions and emotions.

Social-Evaluative Threat Activates Other Physiological Systems

While much of the research on SET has examined activation of the cortisol system, these situations can elicit changes in a wide range of physiological parameters. SET can lead to increases in cardiovascular (e.g., systolic blood pressure, diastolic blood pressure, heart rate) and sympathetic (e.g., epinephrine, norepinephrine, alpha-amylase) activity in both laboratory (Kirschbaum, Pirke, & Hellhammer, 1993; Nater & Rohleder, 2009) and naturally occurring contexts (Lehman & Conley, 2010). Studies that have manipulated the social context of the stressor often observe greater cardiovascular reactivity under conditions that were social evaluative or where the evaluative potential was emphasized (e.g., Bosch et al., 2009).

SET can also lead to changes in immunologic parameters. For example, we conducted a study in which we randomly assigned participants to a SET or non-SET laboratory stressor (Dickerson, Gable, Irwin, Aziz, & Kemeny, 2009). We found that the SET condition elicited increases in the production of the pro-inflammatory cytokine TNF-α compared with a non-SET condition. Further, we found that those who felt the most evaluated during the task showed the greatest increases in TNF-α production, suggesting a link between perceptions of social evaluation and markers of inflammation. Future research should examine the different systems that can be activated under SET and their interactions.

Implications for Health

While acute instances of SET can elicit short-term increases in cortisol and changes in other systems, experiencing chronic forms of SET could take a physiological toll. For example, a meta-analysis found that chronic social stressors were associated with higher morning and evening cortisol levels compared with nonsocial stressors (Miller, Chen, & Zhou, 2007). Over-activation and/or dysregulation in cortisol and other physiological systems is thought to impact health over time and put individuals at greater risk of disease (e.g., McEwen, 1998). Future research should pair acute laboratory reactivity methodologies with longitudinal assessments, to further clarify how patterns of physiological reactivity to SET may be associated with long-term negative health outcomes.

Author Biography

Sally S. Dickerson is the associate provost for research and a professor of psychology at Pace University. Her research integrates psychological and biological levels of analysis by applying theories of social and emotional processes to the context of stress and disease. She examines how social-evaluative threat and accompanying self-conscious emotional responses affect neuroendocrine and immune outcomes and how individual differences may heighten vulnerability to these psychological and physiological changes.

Social Factors in Diet and Obesity

Gbolahan O. Olanubi and A. Janet Tomiyama

Psychology Department, University of California Los Angeles, Los Angeles, CA, USA

Introduction

When attempting to understand factors that influence diet, or food choice, people are quick to assume that people eat when they are hungry and stop when they are full. Hunger, however, turns out to be one of the least important factors in eating. This is because there are a multitude of other social, economic, and psychological factors at play that shape our eating choices, which can over time affect weight and body mass index (BMI).

The purpose of this encyclopedia entry is to describe the social factors that are involved in eating, dietary choices, and obesity. We organize our discussion of social factors roughly from the macro- to microlevel. The literatures we cover are enormous, but space and reference constraints allow only for highlights of each topic. Throughout the entry, we note when there are seminal review papers in each area. Ultimately, our goal is to highlight the role of social factors in diet and obesity and to position psychology in its rightful place as a key player in diet and obesity research.

Culture

Culture has been shaping food choice for millennia. Rozin and Vollmecke (1986) noted that if you want to know as much as possible about a person's food preference, simply ask, "What is your culture or ethnic group?" Culture, a way of life of a society or an amalgam of shared practices and meanings among a group that guides interactions and is shaped by experience, plays a major role in diet and food choice. Culture influences attitudes toward food, our preferences, and perceptions of what is healthy compared with what is unhealthy.

Everyone needs to eat, but not everyone needs to be happy about eating. Among Americans there is an attitude not only that food is "nutrient," a source of nourishment, but also that it may be dangerous—almost as dangerous as abstaining from food (Rozin, 1996). Americans

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

also endorse attitudes that even trace amounts of salt and fat may be harmful (Rozin, 1996). In contrast to American attitudes, the French have a more positive attitude toward food, viewing it as both nutrient and a source of pleasure. Considering these cultural differences in attitudes, there are also cultural differences in consumption. The French, compared with Americans, eat more high-fat foods (yet tend to be healthier—a phenomenon known as the French paradox; Ferrières, 2004). Although Americans have more negative attitudes than the French about food, Americans eat larger servings of food.

Expanding on this research Rozin, Fischler, Imada, Sarubin, and Wrzesniewski (1999) examined cultural differences in food attitudes and behavior in the United States, France, Belgium, and Japan. Congruent with previous research, they found that Americans had the highest concern about healthiness of food choice, worried about the fattening effects of food as opposed to the savoring of food, and were more likely to make nutritional, as opposed to culinary, associations with food. Americans also had the lowest food-positive attitudes, considering food less important and drawing little pleasure from food. Finally, despite the worry, concern, and attitudes toward food, Americans also reported viewing themselves as the least healthy eaters compared with the other countries.

Socioeconomic Status

Food choice is predicated upon access to foods. Socioeconomic status, comprising income, education, and occupation, plays a focal role in determining purchasing power and food choice. Cost has been one of the most important factors in food choice for low-income individuals. Ironically, the cost of food is actually more expensive in low-income neighborhoods compared with high-income neighborhoods because of a dearth of low-cost supermarkets and presence of higher-priced convenience stores (see Morland, Wing, Roux, & Poole, 2002).

If low-income families have a restricted budget but more expensive foods, what are they eating? Low-income families may be cornered into low-cost energy dense diets (Darmon, Ferguson, & Briend, 2003). Energy density refers to calories per edible weight of a food item. Energy dense diets consist of eating foods high in energy density (cereals, meats, sweets) more so than foods low in energy density (fruits, vegetables, whole grains). A low-cost energy dense diet would essentially attempt to maximize calories per dollar while still maintaining sufficient nutrients.

Supporting this perspective, Darmon et al. (2003) used a computer simulation to model the food choices of individuals under economic constraint. Under increasing economic constraint the model selected for less fruits and vegetables (FV), meats, fish, and cheese and higher contents of milk, sweets, and starchy foods compared with a normal diet.

Fortunately, this barrier appears surmountable. Researchers have intervened to remove financial barriers to increase selection and consumption of FV for low-income individuals and found that subsidizing FV costs increases consumption for low-income individuals (Anderson et al., 2001).

Social Norms

Norms surrounding food consumption are powerful drivers of eating behavior (see Herman, Roth, & Polivy, 2003). In general, an inhibitory social norm surrounding eating exists in Western countries, based on widespread weight stigma and negative stereotypes of those who overeat (Vartanian, Herman, & Polivy, 2007). This inhibitory norm appears to be most pronounced in eating among strangers, due to impression management concerns, and true particularly for women, who are seen as more feminine and socially appealing when they eat less (Vartanian et al., 2007). Inhibitory norms are highest with a non-eating observer, according to a meta-analysis of studies that experimentally manipulated awareness of one's eating being observed (Robinson, Hardman, Halford, & Jones, 2015).

In contrast, eating in the presence of close others appears to trigger social facilitation of eating (de Castro, 2002). In one illuminating study, Howland, Hunger, and Mann (2012) experimentally manipulated eating norms in existing friend groups. Two members of a friend trio were enlisted to set an eating norm, and the third member's eating was examined. Participants followed whatever eating norm was set, and these eating norms carried over into situations where participants were then eating alone.

A subtype of norms are informational norms, wherein information about eating behavior is communicated (e.g., through visual cues of leftover food). In a meta-analysis of 15 studies examining experimental manipulations, Robinson, Thomas, Aveyard, and Higgs (2014) found that both high and low informational intake norms had moderate effects on eating behavior. Thus, there appear to be general social norms that affect eating behavior, but these processes are amenable to manipulation, pointing to potential intervention targets.

An interesting offshoot related to norms is research that investigates the weight of others in determining an individual's food intake. Some studies have found that non-dieters consume more calories when their food server is overweight compared with when she is normal weight (e.g., McFerran, Dahl, Fitzsimons, & Morales, 2010).

Social Support

Social support, characterized as instrumental, emotional, or informational, is related to eating behavior and diet quality (for a review, see Vesnaver & Keller, 2011). Social support may be particularly relevant in the context of healthy, as opposed to unhealthy, eating behavior. For example, the national representative National Health and Nutrition Examination Survey found that greater frequency of contact with family, friends, neighbors, coworkers, and others was related to eating at least five servings of FV per day (Ford, Ahluwalia, & Galuska, 2000). A systematic review of environmental determinants of FV intake (Kamphuis et al., 2006) identified social support as a contributor to more intake of FV. One rigorous study included in this review was a brief intervention in low-income participants, where FV consumption was confirmed via plasma/urine biomarkers (Steptoe, Perkins-Porras, Rink, Hilton, & Cappuccio, 2004). Baseline social support specifically for dietary change was related to 12-month increases in FV intake, independent of experimental group or other controls, suggesting the effects of social support are robust to a variety of settings and populations (Kamphuis et al., 2006).

Social support is a component of Bandura's social cognitive theory (SCT; Bandura, 1997), and in a study testing multiple components of SCT, social support was an important correlate of FV intake (Anderson, Winett, & Wojcik, 2007). In the context of an online SCT-based lifestyle intervention (Anderson-Bill, Winett, & Wojcik, 2011), perceived social support (from friends and family) was a predictor of better nutrition.

The relationship between social support and obesity is best tested in longitudinal studies, and such studies find mixed results. Moreover, positive and negative qualities of social relationships may affect BMI differently. In 4,724 Dutch adults, low positive social support was related concurrently to FV intake, and high negative social support was related concurrently to overweight status, but neither was related to future weight change (Croezen et al., 2012). Negative relationships, however, were related to future risk of gains in BMI and waist circumference in another longitudinal study (Kouvonen et al., 2011). To inform this conflicted literature, Kershaw et al. (2014) examined a time frame when obesity tends to develop using 10-year longitudinal data in 3,074 participants. They found that those with continuously high levels of social support had lower likelihood of gaining (by more than 10%) in BMI or waist circumference than those with continuously low levels of social support. Those who increased in frequency of negative social contacts had higher likelihood of increasing waist circumference, but there was no relationship with BMI, and increasing frequency of positive social contacts showed no effect.

Social Networks

One of the most famous findings in the area of modern social network analysis is that obesity spreads across networks. Christakis and Fowler (2007) demonstrated this in the 12,067 participants of the longitudinal Framingham Heart Study (FHS; 1971–2003). Individuals' risk of becoming obese was higher if their spouses, siblings, and friends previously became obese, with stronger concordance among same-sex social ties. This phenomenon was not driven merely by similar BMI individuals forming relationships, nor was it driven by neighborhood/ geographic distance effects.

Although much of the work examining social network effects on diet have been cross-sectional, Pachucki, Jacques, and Christakis (2011) used 10-year longitudinal data from the FHS to examine social influences (spouses, siblings, and friends) on dietary patterns. Using data classification procedures, they extracted dietary patterns based on food frequency questionnaires and found longitudinal social influence was exerted on those such as "alcohol and snacks" and "meat and soda" as well as those such as "healthier" and "caffeine avoidant." This indicates that both healthy and unhealthy eating patterns are subject to social influence. A study in adolescents in Australia across three waves of data in 1 year found that friends appear to influence low-nutrient, energy dense food consumption (de la Haye, Robins, Mohr, & Wilson, 2013). This effect, however, was not mediated by beliefs about unhealthy food, indicating that social network influences may be operating implicitly.

Family Relationships and Parenting

Parents, caregivers, and families exert enormous influence on eating and diet in children. Food preferences of parents affect children's eating (Patrick, Nicklas, Hughes, & Morales, 2005), due to simple availability of those foods. Attachment style is also related to eating behavior.

In their review, Ventura and Birch (2008) distinguish between parenting styles (attitudes and interaction styles) and parenting practices (behavioral patterns). Moreover, there is likely a bidirectional relationship with children shaping parent's behavior (e.g., a child rejecting broccoli, causing the parent to avoid serving it again). Authoritative feeding styles are linked to better quality eating (Patrick et al., 2005), whereas authoritarian ("clean your plate!"), permissive, and neglectful parenting styles are associated with greater likelihood of having an overweight child (see Ventura & Birch, 2008). Using longitudinal design, steeper BMI trajectories and less leveling off of BMI were observed in authoritarian and disengaged parenting styles as opposed to balanced parenting (Fuemmeler et al., 2012).

Examples of parenting practices are using food as reward, restricting access to food, or modeling eating (Ventura & Birch, 2008; see Modeling section below). Using food as a reward was shown in experimental studies to increase consumption of the target food but decrease liking. Restricting food can backfire, where children work harder to obtain restricted snacks and eat and prefer them more.

Families create a social context around mealtimes (for a review, see Patrick et al., 2005). Families eating together is related to better diet quality. When TV watching is part of mealtime, however, diet quality is poorer, likely due to exposure to advertising.

Given the importance of parenting for child weight and diet, interventions such as the "Lifestyle Triple P" have targeted parenting. In a randomized controlled trial, this intervention positively affected intermediate outcomes such as soda consumption, but saw no differences at 12 months between intervention and control in terms of weight or body composition (Gerards et al., 2015).

Romantic Relationships

Romantic relationships have effects on healthy and unhealthy eating. Women appear to play a larger role than men in terms of controlling eating behaviors of the couple (note: the literature has focused on heterosexual relationships; we know nearly nothing about eating behavior in same-sex romantic relationships). This is likely due to cultural norms surrounding the idea that women should be the ones who cook, and marriage appears to have differential effects on the eating of men versus women. For example, when wives report poorer marital quality, they also report more unhealthy dieting behaviors, particularly if they have low self-esteem (Markey, Markey, & Birch, 2001). In this same study, however, no marital quality variables were significantly related to healthy dieting behaviors. However, the literature on marital status and diet/nutritional quality is very mixed (reviewed in Vesnaver & Keller, 2011), indicating that it may not be marital status per se, but living alone that imparts risk for poor eating.

Marriage is associated with greater BMI, and spouses tend to have similar BMI (Jeffery & Rick, 2002). Longitudinal studies indicate that marriage is related to BMI gain, with effects most pronounced for African American women. Spouses' BMIs also predict one another's longitudinal BMI change (Jeffery & Rick, 2002). Divorce, in this study, was related to 2-year weight loss, although other studies have found divorce and other indices of marital dissatisfaction are related to increased BMI trajectories.

Modeling

Many food choices are derived from modeling—a behavioral mechanism related to social norms. Nisbett and Storms (1974) were among the first to test the effects of social influence on eating. Initially, they hypothesized that normal weight and overweight participants' eating behavior would be differentially affected by social suppression or social facilitation cues of eating compared with a no-cue control condition. Participants completed a task with a confederate where there happened to be crackers on the table. In the suppression condition, the confederate ate one cracker; in the facilitation condition, the confederate ate 20 crackers, and there was no confederate in the control condition. Rather than a differential effect, they found that regardless of participant weight, participants typically mimicked the consumption behavior of the confederate.

This finding launched a line of research into the modeling effect and underlying mechanisms of modeling behavior in food consumption (reviewed in Herman et al., 2003). Researchers have tested if these effects were moderated by participant dieting status, participant satiation, and personality characteristics such as extraversion and self-monitoring and found that the expected main effect of modeling occurs regardless of these moderators. Researchers have even found that participants model behavior when left alone but are given information on others' behavior (e.g., with a bogus "data sheet" left behind with information on how much the prior participant had ostensibly eaten; see also informational norms section above).

Conclusion

People often think of diet and obesity as matters of individual will—individuals exert control over their food choice, and the choices they make directly impact their weight. However, in this entry we covered a wide array of evidence that suggests this is not entirely the case. Culture forms our attitudes around food, socioeconomic status impacts our access to foods, norms guide behavior around food, and social connections with friends, family, and even strangers modify our behavior around food. In addition we showed that weight and obesity are also tied to social factors. Changes in BMI travel through social networks and are affected by social support and the status of our marriages.

In considering future directions, it is important to note that these factors we have discussed in isolation are deeply connected and build on one another to create our attitudes and subsequent eating behavior. Future directions should integrate these factors to build better interventions with potentially cascading impacts. For example, a future intervention aiming to change eating norms or attitudes toward food within a community should first examine the community's social network to identify particular individuals or groups who will have the strongest impact. On a larger scale, another future direction could aim to change eating norms in parents and also to explicitly test whether this also changes norms in children through modeling, with implications for the norms within both parent and child social networks. And, after some time, since culture is shaped by the people within it, these changes in norms in parents could even lead to lasting cultural changes in attitudes toward food and healthier diets.

Author Biographies

Gbolahan O. Olanubi, C. Phil, is a doctoral student in the Department of Psychology at the University of California, Los Angeles. His research investigates concealable identities and stereotype threat, and of particular relevance to this entry, he is interested in how race affects perceptions of the healthiness and quality of food and the downstream health implications of these perceptions.

A. Janet Tomiyama, PhD, is an associate professor in the Department of Psychology at the University of California, Los Angeles. Her research investigates stress, eating, dieting, and weight stigma.

Social Factors in Neuroendocrine Function

Theodore F. Robles and Ben W. Shulman

Psychology Department, University of California, Los Angeles, CA, USA

Social Neuroendocrinology

Social neuroendocrinology is an interdisciplinary field that examines bidirectional links between neuroendocrine function and social behavior. This entry reviews key theory and evidence, focusing on neuroendocrine systems that are key players in responses to stressful events, because such systems are biologically plausible mechanisms through which social relationships can "get under our skin" and impact physical health (Miller, Chen, & Cole, 2009). Specifically, we focus on two main neuroendocrine axes: the autonomic nervous system (ANS) (subdivided into the sympathetic and parasympathetic nervous system [SNS and PSNS], respectively) and the hypothalamic–pituitary–adrenal (HPA) axis.

The ANS is critical for mounting rapid bodily responses to help individuals adapt to environmental challenges. For example, the SNS can speed heart rate and increase sweating through norepinephrine and epinephrine signaling, and the PSNS can promote bodily growth and restoration at rest through acetylcholine signaling from parasympathetic nerves to their target organs. The HPA axis is a multi-hormone cascade that culminates in the adrenal cortex releasing cortisol, which is capable of signaling to virtually all cells in the body. Because of their critical roles in mobilizing stored energy, and the multiple effects their signaling hormones have throughout the body, both axes have received the most attention in research linking social factors to health.

We note however that other neuroendocrine axes and hormones are also relevant for social neuroendocrinology, in part by interacting with the ANS and the HPA axis. These include estrogen and the hypothalamic–pituitary–gonadal axis (where prolactin and testosterone are the major signaling hormones), posterior pituitary hormones (including oxytocin and vasopressin), and hormones involved in regulating growth and energy metabolism (including growth hormone, insulin, leptin, and glucagon). We direct interested readers to several reviews and empirical papers (Carter, 2014; Robles & Carroll, 2011).

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

Social influences on neuroendocrine function begin in our earliest days of life (Repetti, Robles, & Reynolds, 2011). However, this entry primarily focuses on adulthood, which has received the most empirical attention. In addition, we restrict our discussion to hormone *signals* that are released by nerves and glands to the rest of the body, as opposed to the *effects* of those signals on target tissues and cells. For example, we discuss social factors and SNS responses, such as norepinephrine production, but do not discuss the effect of these responses on targets like the heart (in terms of increasing heart rate or blood pressure) or immune cells. That said, this entry will discuss the association between social factors and cardiovascular measures that are considered "pure" indices of sympathetic or parasympathetic activity. For instance, SNS activity is indexed by pre-ejection period (a time-based indicator of how quickly the heart contracts, assessed by impedance cardiography), and PSNS activity is indexed by high-frequency heart rate variability (assessed using electrocardiography and referred to in this entry simply as HRV).

This entry is divided into four sections. First, we describe key conceptualizations and measures and examine links between stress-related neuroendocrine function and structural aspects of social networks, such as the number or frequency of social contacts. We then review links with functional aspects of social networks, both positive (social support) and negative (social strain and conflict). Finally, we conclude by reviewing the neural and psychological mechanisms that link social relationships to stress-related neuroendocrine activity.

Key Concepts and Research Approaches

A key distinction must be made between two different aspects of neuroendocrine function: basal activity and physiological responses to environmental challenges (Robles & Carroll, 2011). Basal activity refers to the steady-state activity of biological systems, when the organism is not facing environmental challenges, in contrast to physiological responses to such challenges. Each aspect is measured differently. For example, a researcher could examine basal activity by measuring hormone levels at known low points, such as bedtime or at "rest" prior to a laboratory challenge, or measuring hormone levels at consistent times during the day over several days. To measure reactivity to environmental challenges, researchers frequently examine changing hormone levels in response to a laboratory stressor.

Models linking social functioning to physical health also distinguish between two types of associations, which stem from broader models linking social functioning to physical health (Cohen, Underwood, & Gottlieb, 2000). Specifically, social functioning may be associated with neuroendocrine function regardless of whether the individual is facing an environmental challenge, which would be consistent with a "main-effect" model. Alternatively, social functioning may be related only to neuroendocrine responses to an environmental challenge or stressor, which would be consistent with a "buffering" (protective) or "reactivity" (exacerbating) model.

Finally, the association between social functioning and neuroendocrine activity can be interrogated in a number of research designs. Correlational methods examine concurrent or prospective associations between neuroendocrine measures and social functioning (self- or other-reported), such as perceived social support or loneliness. Nonexperimental laboratory methods involve assessing social functioning in the laboratory, such as through observational coding of a social interaction paradigm, and correlating measures obtained during the interaction (self-reported, objectively observed) with neuroendocrine measures. Experimental methods involve manipulating social functioning, such as having an individual go through a laboratory stressor either with or without the presence of a friend, and testing whether the manipulation changes neuroendocrine activity.

Structural Aspects of Social Networks

Structural features of social networks, also described as social integration, refer to the number of social relationships in which a person is involved and the degree of connection between the people they know (Taylor, 2011). For instance, some individuals have more interconnected social networks (in which most people know each other), while others have less interconnected social networks. Most social neuroendocrinology research has focused on number and frequency of social contacts, with few studies of social interconnections.

ANS functioning is linked to social integration in prairie voles (a social mammal). When subjected to social isolation, these animals show reduced HRV, which may be due to both increased SNS and reduced PSNS influence on the heart. In humans, the evidence suggests a similar picture. In several large studies, high social integration was related to greater resting HRV and lower basal levels of SNS hormones. In particular, weekly religious attendance was specifically related to less likelihood of having high urinary epinephrine, and being married was related to lower urinary epinephrine. Finally, in a small prospective study, international students were followed from arrival in their host country to 2 and 5 months later. Individuals with low social integration, particularly low social contact with people from other cultures, showed lower HRV over time, an association that grew stronger over the course of the study. Notably, baseline HRV did not predict changes in social integration over time, suggesting the causal direction may be from social structure to parasympathetic function, rather than the reverse.

In terms of HPA axis functioning, living alone and reporting less social contact were related to higher cortisol levels at bedtime, when cortisol is expected to be at its lowest levels, and greater cortisol production throughout the day. These findings were observed in middle-aged and older adults, and work in younger samples shows a similar pattern. In a social network analysis of nursing students, those who were less likely to nominate their classmates as friends had higher daily cortisol levels.

The overall pattern of findings across the ANS and HPA axis suggests that lower social connection is related to elevated basal SNS and HPA activity, as well as lower basal PSNS activity. This pattern indicates that neuroendocrine systems designed to respond during stress are upregulated, even when the individual is not facing a challenge. Considerably less is known about links between social structure and neuroendocrine responses during stress, but the literature reviewed suggests plausible neuroendocrine pathways through which low social integration may negatively impact health over time (Holt-Lunstad, Smith, & Layton, 2010).

Positive Aspects of Social Relationships: Social Support

A central benefit of social relationships is the experience of being cared for by others and being valued in a network of mutual dependence and assistance (Taylor, 2011). Social support can be informational (advice), instrumental (tangible assistance), or emotional (validation, comforting). Moreover, the way support is measured varies, and this entry focuses on two broad distinctions: perceived available support (often described as perceived support), which is the expectation of being able to call on others for support when needed, and received support, which refers an individuals' self-report of being the beneficiary of helpful behavior. Perceived and received support are only moderately correlated, and greater perceived support is more consistently related to psychological and physical well-being compared with greater received support (Uchino, 2009).

Perceived Support

Research on perceptions of support availability is mostly correlational and focused on basal functioning. Perceived support is generally associated with lower SNS and higher PSNS activation. For instance, among people living with chronic stress, those with higher perceived support have lower catecholamine levels. For HPA axis function, the results are mixed. Some studies have found no association between 24-hr cortisol output and perceived support, both at work and at home (although greater perceived work support was related to higher cortisol output on weekends). Other studies have found that perceived support at work is linked to lower daily cortisol.

Received Support

While observational studies assess received support by self-report, experimental studies manipulate the social conditions of individuals facing laboratory stressors. In such experiments, received support consistently reduces blood pressure and heart rate responses to stress (Thorsteinsson & James, 1999). However, these outcomes are not pure indices of SNS or PSNS function. Received support is related to increased activity in pure markers of PSNS function. For instance, received support was related to elevated HRV when facing a laboratory stress task (particularly for individuals high in dispositional compassion). Similarly, received support is related to decreased activity in pure markers of SNS function. For example, receiving support from a member of one's self-identified social group was related to lower galvanic skin response. However, the benefits of received support may be offset by the added evaluative threat of another person's presence. Even in the presence of a supportive companion, people performing a speech task in an evaluative context had increased SNS activity compared with performing the speech alone, as indicated by larger decreases in cardiovascular pre-ejection period.

One of the earliest and most cited examples of received support and HPA reactivity to stress involved participants either receiving support from an opposite-sex confederate, receiving support from an opposite-sex romantic partner, or being alone (no support) prior to going through a speech and arithmetic task. Interestingly, men who received support from their female partners showed a smaller cortisol response during the stressor compared with when alone or receiving support from a stranger. In contrast, women receiving support from their male romantic partners did not show smaller cortisol responses compared with the other conditions. In other studies, men, but not women, receiving verbal support from their best friends showed reduced cortisol responses to a laboratory stress task. Women, in contrast, showed an increase in cortisol responses when receiving verbal support from their male partners but showed buffered responses after a partner's massage. Finally, men receiving support from a stranger, with whom they had a brief closeness manipulation, showed higher cortisol responses, but women showed no difference. Similar to the literature on autonomic responses, evaluative threat influences HPA axis responses and may explain the mixed pattern of results. Indeed, one study found that performing speech and mental arithmetic tasks in front of a supportive audience showed higher cortisol responses than those performing the task alone. Moreover, the benefits of social support in attenuating cortisol responses to stress may depend on oxytocin. A specific polymorphism (rs53576) in the oxytocin receptor gene moderates the benefits of social support on cortisol response to stress, and oxytocin administration can improve the stress-buffering cortisol reduction of social support.

Summary

Research on perceived support and stress-related neuroendocrine function is largely correlational, with a focus on basal activity. In contrast, research on received support is largely experimental, focusing on reactivity to stress. Interestingly, while findings linking perceived support and health are more consistent than those linking received support and health (Uchino, 2009), the opposite seems to be the case for stress-related neuroendocrine activity. Received support is robustly related to ANS and HPA responses to stress. However, factors like gender of the support provider, the degree of evaluation potential, and other neuroendocrine systems (i.e., oxytocin) can modify those links. A smaller literature suggests that greater perceived support is related to lower basal SNS and higher PSNS activity, while research on basal HPA axis activity is mixed.

Negative Aspects of Social Relationships: Social Negativity and Loneliness

Social Negativity

Relationships can be sources of negativity when people face aversive or unwanted behavior from another person (Brooks & Dunkel Schetter, 2011). Such negativity can involve provoking conflict, being insensitive to an individual's needs, and disrupting an individual's ability to pursue goals. Most research to date has focused on conflict, and even research examining insensitivity to an individual's needs has done so in the context of conflict.

Most research on social conflict has focused on cardiovascular reactivity in close, romantic relationships. However, a few studies have measured pure indicators of autonomic activity (Robles, Slatcher, Trombello, & McGinn, 2014). In newlywed couples, greater hostile and negative behavior during problem discussions was related to elevated epinephrine and norepinephrine responses during the discussion. Older couples showed similar effects, with negative behavior related to increased epinephrine levels. In terms of PSNS activity, among young married couples, marital conflict was associated with lower HRV, but only for women.

Conflict in many different kinds of relationships has been linked to HPA activity (reviewed in Robles et al., 2014). People reporting higher levels of negativity from friends, family, and romantic partners had lower morning cortisol levels and flatter cortisol slopes across the day. In newlywed couples, greater hostile behavior while discussing problems in the relationship was related to elevated adrenocorticotropic hormone levels (ACTH, which stimulates cortisol release by the adrenal cortex) during and after the discussion. Similarly, for these newlyweds, the combination of low supportive behavior and high hostile behavior was related to elevated cortisol levels. Older couples showed similar effects, but only among women, whose levels of cortisol and ACTH increased following more conflictual discussions. Moreover, conflicts in which one spouse withdraws from the other's demands (e.g., avoids the topic, a notable example of social insensitivity) are viewed as particularly destructive for relationships. Accordingly, in newlywed couples, greater probability of husbands withdrawing from their wives' demands was related to elevated wives' cortisol over a 24-hr period.

Loneliness

Loneliness is distinct from low social integration. People may live contently in solitude or have active social lives and still feel lonely (Hawkley & Cacioppo, 2010). Few studies have examined links between loneliness and pure indicators of autonomic function, although thus far research suggests that loneliness is not related to SNS or PSNS influences on the heart. However, loneliness was associated with elevated epinephrine in overnight urine samples in middle-aged and older adults. Thus, the vasculature (arteries), but not the heart, may be targets for loneliness-related elevations in SNS activity. This pattern could explain the consistent elevations in blood pressure related to loneliness. Regarding HPA functioning, loneliness is related to elevated basal cortisol levels in a number of studies. No studies have examined HPA reactivity to stress, but several studies have found that greater loneliness is related to larger cortisol responses to awakening.

Neural and Psychological Mechanisms

We conclude this entry by discussing the mechanisms that may explain how social functioning can impact stress-related neuroendocrine function and linking those mechanisms to models of how social relationships influence health. To directly influence neuroendocrine functioning, the neural circuits involved in social information processing must interface with circuits that regulate the HPA axis and the ANS. Over the past decade, neuroimaging research in humans has identified the circuitry involved in regulating neuroendocrine function, which had been previously outlined in animal models. Specifically, a "medial prefrontal–brain stem axis" involves evolutionarily newer brain structures processing information about the social environment (e.g., prefrontal cortex, anterior cingulate; Eisenberger, 2013) and then sending signals to evolutionarily older structures that modulate HPA and ANS activity (e.g., amygdala, hypothalamus). More recent work is now identifying links between social relationships and neural structure and function.

In terms of neural structure, most work has focused on social integration (Platt, Seyfarth, & Cheney, 2016). Early studies found that greater social integration was specifically associated with greater amygdala volume. This pattern parallels work in macaques, where living in larger social groups (2–7 per group) vs. alone was related to increased gray matter in the amygdala. Living in larger social groups was also related to more gray matter in regions that track attention and process social information and face and body movement. Similarly, in humans, larger social networks were related to greater orbitofrontal cortex volume, a region specifically implicated in social cognition and affective processing, but were not related to dorsal prefrontal cortex volume, a region involved in planning and executive function. In terms of neural connectivity, greater social integration was related to stronger connections between the amygdala and brain regions involved in social perception and affiliation. In addition, greater social integration was related to stronger interconnections (greater white matter integrity) in a frontal region involved in interconnecting other regions involved in social information processing and reward processing (Molesworth, Sheu, Cohen, Gianaros, & Verstynen, 2015).

Studies linking the quality of social interactions to neural mechanisms implicate the same medial prefrontal axis structures. For example, Eisenberger, Taylor, Gable, Hilmert, and Lieberman (2007) had participants complete a brief laboratory stressor, 10 days of repeated measures on the degree of supportiveness in their daily social interactions, and finally a neuroimaging task assessing neural responses to social rejection. Greater daily reports of feeling supported during social interactions were related to lower neural activity in several regions of the medial prefrontal axis during social rejection. Moreover, activity in several medial prefrontal axis regions explained associations between daily social support and cortisol reactivity during the laboratory stressor.

Main effects models suggest that a network of high-quality relationships provides more opportunities for social influence from others, support provision, and benefits for mood that then influence neuroendocrine responses (Cohen et al., 2000). However, some researchers have argued that social relationships are so intrinsic to human experience that the presence of other people should be regarded as a default or baseline state (Coan & Sbarra, 2015). Because people adapted to living in close proximity and connection to other people, the brain expects to assess social resources and functions best under such conditions. Deviations from this social baseline (perceiving fewer social resources) are perceived as threats to well-being, and the individual must be prepared to respond. In the context of social neuroendocrinology, mounting ANS and HPA responses, even at rest, prepares the organism to deal with what it perceives as a threatening environment (mainly by increasing energy available for use by the brain and body).

Stress-buffering models suggest that perceiving greater availability of social resources, or actual receipt of social resources, should affect neuroendocrine mechanisms through mitigating negative cognitive (e.g., reducing threat appraisals) and emotional responses (e.g., reducing negative mood) (Cohen et al., 2000). However, to date, the literature is mixed as to whether positive aspects of social functioning are linked to neuroendocrine function via psychological mechanisms (Uchino, Bowen, Carlisle, & Birmingham, 2012). Fortunately, a number of potential ways forward have been suggested, including improving research designs, rethinking how social relationships are conceptualized and measured, and including a focus on automatic social cognitive processes (Uchino et al., 2012). Increased attention to these issues will hopefully yield advances in research on social neuroendocrinology.

Author Biographies

Theodore F. Robles is an associate professor in the Department of Psychology at the University of California, Los Angeles. His research examines the biological mechanisms that explain how close relationships impact health. His empirical work includes both allostatic and restorative processes, such as HPA responses, inflammation, and skin barrier recovery, and covers the life course, including childhood, young adulthood, parenting age, and older ages.

Ben W. Shulman is a graduate student in health psychology at the University of California, Los Angeles, where he studies how challenging self-regulation affects conflict in romantic relationships. He was a research assistant in the Culture Cognition and Coevolution Lab at the University of British Columbia and at the Center for Health Coping Studies. There, he studied the development of human culture and the ways spouses support each other through the stress of chronic disease.

Social Factors in Sleep

Zlatan Krizan and Garrett Hisler

Department of Psychology, Iowa State University, Armes, IA, USA

Humans spend about a third of their life sleeping, typically once every night for 8 hr. Sleep is behaviorally defined as a reversible state of perceptual disengagement from—and unresponsiveness to—the environment. In an adult, sleep proceeds in alternating cycles of slow-wave sleep (non-rapid eye movement, NREM) and more active rapid eye movement (REM) sleep associated with emotional dreams (Carskadon & Dement, 2011). Modern neuropsychology reveals that circadian (daily) rhythms in wakefulness and sleep are controlled by an internal biological clock located in the suprachiasmatic nuclei of the hypothalamus. This mechanism controls most physiological activity, including daily (i.e., circadian) rhythms in body temperature, hormone levels, psychomotor vigilance, and affect (Van Dongen & Dinges, 2003). Although these rhythms are internally generated, they are synchronized with external time cues, the most important of which is the light-dark cycle. Critically, sleep plays a vital role in health given its many key functions such as toxin disposal from the brain, physical rest and physiological regeneration, and encoding and integration of newly learned information and emotional experiences (Walker, 2010).

Any significant deviation in sleep quantity or timing relative to the optimal sleep needed by a given individual (typically between 7 and 9 hr of uninterrupted sleep during the night) is deemed sleep disruption. Critically, various forms of sleep disruption (i.e., total deprivation, partial restriction, or fragmentation) can produce similarly deleterious neurobehavioral effects. These include reduced attention, lowered energy and enthusiasm, compromised executive functioning, and poor self-control (Reynolds & Banks, 2010; Van Dongen & Dinges, 2003). In this vein, sleep problems often present themselves alongside anxiety, mood, impulse control, and substance abuse disorders. Conversely, improving sleep problems can alleviate emotional problems such as depression. Sleep problems are also a major risk factor for physical conditions such as obesity, diabetes, and cardiovascular diseases. Sleep problems are even associated with increased all-cause mortality (Hublin, Partinen, Koskenvuo, & Kaprio, 2007). Although the exact causal mechanisms between sleep and health problems are yet to be elucidated, sleep plays an essential role in maintaining good health, earning its status as the third "pillar of health" alongside diet and exercise.

Social Behavior and the Sleep–Wake Cycle Are Mutually Dependent

Although sleep is a biological phenomenon, it is intrinsically connected to social behavior. The organization of human social and cultural activities has always been constrained by the rhythm of the biologically mandated sleep–wake cycle. Humans need to be awake and alert in order to meaningfully interact with others, so most social interaction is confined to daylight hours (although the need to protect the community from threats also meant some individuals needed to be awake at night). Throughout the day, social behavior such as work and recreation tends to be further concentrated around times of circadian peaks in alertness (i.e., late morning and early evening). Indeed, both the drive to engage socially and the ability to successfully interact with others reflect the endogenous circadian rhythm (Hasler, Mehl, Bootzin, & Vazire, 2008). Social behavior is thus heavily dependent on daily rhythms in biological capacities for psychological and motor engagement. However, any individual's level of alertness or sleep timing is also highly flexible, showing sensitivity to a variety of internal (e.g., motivation, drug effects) and external modifiers (e.g., threats, social incentives). As illustrated in the next section, many of the most important modifiers of human sleep behavior are social in nature.

The Impact of Social Behavior on Sleep

Social Behavior as a Time Cue

The general propensity toward social behavior is constrained by the daily rhythm of alertness, yet this rhythm can also be entrained to the regular timing of social interactions. Although light exposure plays the most important role (Czeisler et al., 1999), socially influenced behaviors such as collectively determined sleep–wake schedules, exercise, or eating food can shift the internal clock (Mistlberger & Skene, 2004). Moreover, regularity of social activities may be an important support to a regular sleep–wake cycle and optimal sleep quality (Monk, Petrie, Hayes, & Kupfer, 1994). The social zeitgeber theory goes so far as to suggest that stressful life events lead to depression because they disrupt social rhythms needed for a stable cycle in mood and motivation (Ehlers, Frank, & Kupfer, 1988). Fatigue, negative affect, and impaired processing resulting from sleep disruption may then further perpetuate depressive symptoms. Given the extensive confounding of social activity with light exposure and food intake (e.g., most interactions occur under light, and most eating involves socializing), social factors exert considerable impact on our biological rhythms by affecting when we engage in arousing activities (e.g., going for a run when it fits others' schedules), go outside into natural light (e.g., leaving the house to go to work), or eat (e.g., having dinner when the family is available). In short, socializing modulates human biological rhythms through other variables, even if not in itself an essential time cue.

Social Interactions as Disruptors of the Sleep–Wake Cycle

Although not the chief entrainment signal for our biological rhythms, social factors play a major role in how and when individuals sleep. First, social experiences are often the source of stressors that create insomnia (problems with initiating or maintaining sleep) by undermining onset, subjective quality, or consolidation of sleep. The most stressful events in life are social in nature; losing one's parent or spouse, being fired, being romantically rejected, and failing to be selected for a promotion are all essentially social experiences that draw their power from impact on social identity and connections (Almeida, 2005). Such stressful experiences carry with them physiological arousal, anxiety, and ruminative thinking, which disrupt sleep as individuals aim to cope with the stressors.

Critically, these markers of stress play a key role in the formation and development of insomnia, with negative social events often being a precipitating or perpetuating factor (e.g., work and home conflict; Riemann et al., 2010). For example, embroilment in aggression and interpersonal conflict can fuel worry and rumination about one's safety or guilt about one's own behavior and its consequences on others; all these can undermine sleep over time, especially among romantic partners (Krizan & Herlache, 2016). Conversely, having trust and intimate relationships with others who can provide social support during a time of crisis may reduce the impact of stressful events on one's sleep. For people who live and sleep with romantic partners, there seems to be an especially close tie between social interactions and sleep—one study found that when women reported less negatively toned social interactions with their male partner, *both* individuals slept more efficiently the next night (Hasler & Troxel, 2010). As a result, social experiences not only play a major role in development and perpetuation of sleep problems such as insomnia but also can provide a buffer against them in the form of social support (Maume, 2013). Such processes also contribute to why sociocultural factors such as personal socioeconomic status or neighborhood quality negatively impact sleep and health among disadvantaged populations.

Second, conformity to social norms (going out late) and pursuit of personal social goals (getting up early to help an ill partner) exert a large impact on behavioral choices that impact sleep. Correspondingly, perceived norms have been found to predict intentions toward behaviors that promote optimal sleep, referred to as *sleep hygiene*. Standard recommendations to aid proper sleep include avoiding psychoactive substances that interfere with sleep (e.g., caffeine, alcohol), exercising regularly (although not before bed), maintaining a regular sleep–wake schedule, reducing stimulation in the sleeping environment (e.g., bedroom noise) that is only used for sleeping, and avoiding excessive daytime napping. All of these factors have been linked to optimal sleep in some way, although their potential as public health interventions is still being evaluated (Irish, Kline, Gunn, Buysse, & Hall, 2015).

Despite the fact that sleep hygiene recommendations are made to individuals, whether any given individual actually follows good sleep practices often comes down to the social influence of others, be it because of concerns about what others will think or because of others' pleas and persuasive attempts. For example, the pressure to be constantly available on social media and respond quickly has pushed teenagers to stay up late, use electronic devices in bed, and resultantly displace or harm their sleep (Woods & Scott, 2016). Even more disconcerting is the rise of "sleep texting," wherein individuals wake up to respond to text massages with little or no memory of the interaction the next morning. Unfortunately, sleep practices can spread through social networks such that one's friend adopt similarly bad sleep habits.

In a similar vein, the use of psychoactive drugs that interfere with sleep typically occurs within social milieus. The impact of social ties on sleep-relevant behavior is especially strong in adolescence given increased concerns about acceptance (Maume, 2013). In fact, teenagers are more likely to use substances such as tobacco and alcohol (both disruptive to sleep) as a result of both active influence by others (e.g., being offered a cigarette) and more passive modeling of others' behavior or alignment with social norms (e.g., drinking because others are drinking). In short, understanding individuals' social ties is critical for understanding why people engage in poor sleep hygiene such as substance use and bedtime delays.

Third and finally, whether people lie down in bed regularly and keep the bedroom free of distractions strongly depends on people with whom they live, be they family members, roommates, or romantic partners. Romantic partners are likely to play the most significant role given the sharing of both evening activities and the bedroom; for example, couples are more concordant in their behaviorally measured sleep than are random pairs of individuals (Gunn, Buysse, Hasler, Begley, & Troxel, 2014). Moreover, bed times and rise times are typically a function of preferences and responsibilities of both partners, requiring frequent compromise. How people balance work and family demands is constantly shaped by interactions with one's partner, so understanding the nature of intimate relationships is critical for understanding sleep.

The Impact of Sleep on Social Behavior

Social processes undoubtedly play an important role in shaping human sleep, and this role represents one pathway by which social behavior affects health. At the same time, sleep itself molds social and health behavior. Although scientific evidence on this score is only emerging, accumulating evidence converges on the conclusion that when and how humans sleep carries considerable consequences for what people do, how they think and feel about others, and how they interact with them.

How Optimal Sleep Timing (Chronotype) Shapes Social Experience

A typical person usually sleeps during the night, but individuals' ideal times for going to sleep and waking up vary considerably. A key reason for this variability stems from individual differences in timing of biological rhythms, namely, circadian phase or *chronotype*. Although behavior of every individual follows his or her internal biological clock, this clock is often slightly ahead or slightly behind the earth's 24-hr light-dark cycle. As a result, some individuals' internal cycle starts and ends earlier than the 24-hr day; these "larks" are said to have a morning chronotype as they rise earlier, feel more energetic in the morning, and have difficulties extending wakefulness late into the night. Conversely, others' internal cycle starts and ends later than the 24-hr day; these "owls" have an evening chronotype as they rise later, feel most energetic in the evening, and find it easy to stay up late (Roenneberg, Wirz-Justice, & Merrow, 2003). Most individuals ("hummingbirds") fall somewhere in between these extremes along a continuum. As we outline next, individuals' chronotype exerts a powerful impact on the social environments people inhabit, their psychophysiological state during social interactions at a particular time of day, and weekly patterns of rising and falling asleep that impact socializing.

First, because people's chronotypes bias sleep propensity toward the most optimal time for the individuals' biological clock, they partially determine when people are awake and participating in social activities. Critically, the nature of social environments accessible to a person throughout the day varies, as early morning affords chatting over a cup of coffee (but not grabbing a beer), while later evening or night affords socializing in entertainment establishments that serve alcohol or provide adult entertainment such as bars and clubs. Because chronotypes partially determine the time of day people have the energy and interest to participate in (social) activities, they also constrain available social opportunities and resultantly the likelihood of participating in them. As a result, evening-oriented individuals should be more likely to come in contact with vices such as drugs, alcohol, or sex (more available at night) than are more morning-oriented individuals. Consistent with this premise, evening-oriented individuals are more likely to smoke, drink, and behave promiscuously (Wittmann, Dinich, Merrow, & Roenneberg, 2006). This pattern may partially result from individuals' self-selection into these nighttime environments, but persistent exposure to them may promote the development of substance use problems, impulsive behavior, and social conflicts associated with nighttime environments and intoxication.

Second, chronotype also strongly impacts individuals' psychophysiological state during a given time of day. This resultantly affects both the momentary ability and motivation of an individual to cope with situational and social demands occurring at a particular time of day. Specifically, "larks" are more likely to feel alert and interested, be vigilant, perform better physically, and think carefully earlier rather than later in the day, whereas the opposite is true for "owls." These interactive patterns between the time of day and chronotype have significant consequences for numerous social variables such as engagement with others, group performance, perspective taking, and impression formation. For example, morning-oriented individuals maintain exercise more effectively when such activity occurs during morning hours than evening hours (Hisler, Phillips, & Krizan, 2017).

Third and finally, because the "social" clock (i.e., timing of socially formalized activities such as work) is more aligned with the "biological" clock of morning-oriented – rather than evening-oriented – individuals, the latter experience "social jet lag," that is, a misalignment of biological and social time. As normal work schedules are best suited for morning chronotypes, evening individuals who fall asleep later accrue a sleep debt during the week, for which they compensate by sleeping in on the weekends (Wittmann et al., 2006). This dilemma also leads to greater daytime tiredness, more psychosomatic disturbances, and more emotion dysregulation for evening-oriented individuals during a typical weekday. Given that many social behaviors (e.g., drinking, smoking, exercising) have important implications for health, these findings point to the essential role that chronotypes play in social behavior and especially to the importance of match between people's biological clocks and the social opportunities and demands that fluctuate with time of day.

The Effects of Sleep Disruption on Social Behavior

Losing sleep has far-reaching consequences on people's health and well-being, yet chronic sleep restriction seems to be prevalent in the US population, with 30% of American adults reporting less than 6 hr of sleep a night (the National Sleep Foundation recommends 7–9 hr of sleep a night). Furthermore, this population has increased over the past two decades. Because sleep impacts virtually all aspects of cognitive and emotional functioning, existing evidence suggests that it creates downstream consequences for how we perceive and interact with the social world.

First, sleep disruption leads to feelings of fatigue, loss of energy, and lack of motivation. Specifically, sleep loss leads students to prefer easier tasks, to spend less time on activities such as dressing neatly and fashionably, and to engage in more time wasting during work (Engle-Friedman et al., 2003). These choices seem logical because they dovetail with subjective perceptions of increased effort following lost sleep, evident in higher perceptions of difficulty for athletic challenges, physical tasks, and intellectual problems (Engle-Friedman et al., 2003). These consequences carry direct implications for people's motivation and ability to pursue numerous social goals. Dressing less neatly and fashionably lowers perceptions of status and competence, while loafing or avoidance of taxing tasks such as exercise creates opportunities for sedentary social behaviors such as texting or use of social media. In short, the reduced effort and amotivation following sleep loss impacts how individuals allocate their time, which can produce a wide variety of social and health consequences.

Second, in concert with feelings of fatigue and lack of drive, many of the cognitive and emotional effects of sleep loss broadly impair self-regulation, namely, the ability to select, enact, and monitor progress toward important goals (Krizan & Hisler, 2016). Sleep loss not only saps energy and motivation needed to enact goal-directed behavior but also impairs vigilance and executive functions (i.e., selective attention, working memory, task switching) needed to appropriately select and monitor goals (Killgore, 2010). For instance, poorly slept individuals are less aware of abstract goals or standards such as morals, perceive less value in rewards that require effort, fail to incorporate feedback into ongoing goal pursuit, and prefer riskier courses of action.

A key aspect of how sleep loss hinders optimal goal selection and pursuit involves blunted positive emotions necessary for goal pursuit (e.g., desire and enthusiasm) and heightened negative emotions that often impede goal striving (e.g., anxiety). Specifically, those who are sleep deprived tend to report more negative affect and less positive affect, perceive neutral stimuli as having negative connotations, have more intense emotional reactions, and show an impaired capacity to reappraise and inhibit these emotions (Tempesta et al., 2010). The importance of sleep for effective self-regulation is further suggested by broader links between sleep and interpersonal aggression, relationship satisfaction and conflict, and unethical behavior (Barnes, Schaubroeck, Huth, & Ghumman, 2011; Krizan & Herlache, 2016; Troxel, 2010). As many health behaviors require self-regulation because they are burdensome (e.g., exercising, getting a mammography) or require restraint (e.g., not smoking, not eating fast food), how sleep relates to self-regulation is key for understanding initiation and maintenance of health behaviors.

Third and finally, all these findings underscore that losing sleep (or experiencing fragmented sleep) impairs vigilance, working memory, monitoring of changes in oneself and the environment, and the ability to change thinking strategies or inhibit automatic responses. At a more basic level, then, disrupting an individual's sleep seems to compromise the person's ability to engage in reflexive, rule-based processing of social information that requires effort and is dependent on motivation and cognitive capacity (Kahneman & Frederick, 2005). As a result, individuals may be more likely to engage in low-effort intuitive and associative processing of social information while pursuing social goals. Because processing of social information central to understanding most social phenomena (e.g., social judgment, attribution, persuasion, aggression, emotions) involves a more intuitive, associative system (impulsive; System 1) and a more rational, rule-based system (reflexive; System 2), sleep may be one key factor in how these systems are deployed in service of social cognition (Kahneman & Frederick, 2005). Although these implications of sleep for social processing are largely unexplored, existing evidence does suggest that losing sleep due to daylight savings (i.e., moving the clock forward in the spring) increases police officer's reliance on racial stereotypes when making traffic stop decisions (Wagner, Barnes, & Guarana, 2016), while a night of poor sleep impairs individuals' stop decisions and undermines taking the perspective of one's romantic partner (Gordon & Chen, 2014). How sleeplessness impacts elaboration of persuasive messages, attitude change, activation of stereotypic knowledge representations, and social perceptions of warmth and competence remains to be investigated. How sleep affects these social cognitive processes is of particular importance to health intervention endeavors as the cognitive and affective repercussions of sleep loss during exposure to health interventions likely represent an often overlooked barrier to health change.

Conclusion

Sleep is intrinsically tied to social behavior—socializing shapes chronic and acute sleep patterns, and how and when people sleep impacts their ability to regulate social behavior. Because sleep is an essential health outcome in itself while influencing many other health outcomes and behaviors, the dynamics between sleep and social behavior represent key considerations in theories of health behavior and their application toward interventions.

Author Biographies

Zlatan Krizan, PhD, is an associate professor of psychology and an affiliate for the Center for Study of Violence at Iowa State University in Ames, Iowa. He directs the Sleep, Self, and Personality Laboratory that investigates how sleep and dreams intersect with social behavior and individual differences in personality. A key focus of the research is how sleep intersects with self-control processes, personality, and health behaviors.

Garrett Hisler, MS, is a McNair scholar who is currently completing his doctoral training as a graduate assistant in Dr. Zlatan Krizan's Sleep, Self, and Personality Laboratory at Iowa State University's Department of Psychology. His research focuses on the bidirectional relationship of sleep and self-regulation and the role of personality in these dynamics.

Social Identity

S. Alexander Haslam, Catherine Haslam, Jolanda Jetten,
Tegan Cruwys, and Genevieve A. Dingle

Faculty of Health and Behavioural Sciences, School of Psychology, University of Queensland, St. Lucia, QLD, Australia

People's social lives and the social worlds they inhabit have a critical bearing on their health. For most health psychologists this is an uncontroversial observation, as there is abundant evidence both (a) that social contact, social connections, and a rich social life are good for one's well-being and (b) that those who are impoverished in this respect (e.g., because they are socially isolated as a result of poverty, prejudice, or other forms of social exclusion) suffer from relatively poor health outcomes. However, the social identity approach to health provides a more nuanced analysis of such patterns in suggesting that particular forms of social interaction have an especially important role to play in health dynamics. These are those that are grounded in shared social identity—a person's internalized sense of shared group membership and an associated sense that they are part of an "us" that is bigger than "me" alone.

This argument lies at the heart of the social identity approach to health: a theoretical perspective on health and well-being that has become increasingly influential in recent years. In what follows, we set out the core tenets of this approach and explain why its ideas are so central to a range of issues that are central to health psychology.

Social Identity as a Basis for Group Behavior

When people refer to "the self," they are typically referring to something singular about a person. A person who is self-confident, for example, is understood to be assured of their personal place in the world. Importantly, though, we also talk about the self in the first-person plural, in terms of our social identities as "us" and "we." Accordingly, we can define ourselves as "us Australians," "us psychologists," "us Democrats," and so on and be self-confident as members of these groups. The fact that we do this speaks to the capacity for the self to be

defined not only in unique terms but also in terms of attributes and qualities we share with other people.

The significance of this point for psychology was first illustrated in a famous series of experiments conducted by Henri Tajfel and his colleagues that came to be known as the minimal group studies. In these, schoolboys were assigned to essentially meaningless groups (e.g., supposedly on the basis of their liking for abstract paintings by Klee or Kandinsky) and had the task of assigning points (signifying small amounts of money) to other members of both their own group (their ingroup) and another group (the outgroup). What the researchers found was that even these most minimal of conditions were sufficient to produce group behavior—with many of the boys adopting a strategy in which they awarded points preferentially to members of their ingroup than to those in the outgroup. Moreover, they did so even if this meant their group would end up with worse outcomes than it might have had otherwise (e.g., if the participants had adopted a strategy in which both groups received a high number of points). Seeking to make sense of these findings, researchers came to understand that they reflected the fact that for participants in the studies, the process of acting in terms of their group membership was a way of making an otherwise meaningless situation meaningful. In particular, the actions they engaged in were part of a strategy to attain and maintain a positive and distinctive social identity (as "us in the Klee group" as opposed to "them in the Kandinsky group").

Building upon this analysis, John Turner subsequently noted that it was the participants' capacity to act in terms of social identity that made this group behavior possible (Turner, 1982). In other words, it was only because the boys could categorize themselves as "us in the Klee group" that they were able to act as members of the Klee group. This, he argued, is true of all other groups too. So it is only because (and to the extent that) Australian people can define themselves in terms of a social identity as Australians that they are able to behave as an organized, coordinated national entity. And the same is true for all other groups—teams, clubs, societies, communities, unions, churches, and so on.

Social Identity as a Basis for Health

The foregoing observation is clearly important when it comes to understanding the psychology of group behavior—for example, if we want to explain why people sometimes engage in social competition and conflict. But why is social identity important for health? The core reason is that humans are social animals who live, and have evolved to live, in social groups. In short, group life makes us human and is a key source of personal meaning, purpose, and worth. Among other things, this means that, like hunger and thirst, physical and psychological isolation are inimical to our makeup and design. And in this regard, the fundamental significance of social identity is that, without it, as Turner (1982) argued, group behavior is impossible.

If one considers a football team, for example, it is the fact that its members share social identity that allows them to coordinate their play and function as a meaningful social and psychological entity. Shared social identity (as "us members of Team X") thus allows team members to harness the power and access the benefits of the group, and this at least partly explains why feeling part of a team is generally good for health and well-being (Steffens, Haslam, Schuh, Jetten, & van Dick, 2016). Moreover, the more that team members define themselves in terms of shared identity—that is, the higher their social identification—the more true this will tend to be.

Of course this point is not restricted to football teams, but is true of all collectives (e.g., recreational, religious, occupational, political, and community groups). The general point here, then, is that social identities and social identifications allow us to fulfill our potential as humans and hence will have important—and generally positive—implications for health. Consistent with this point, recent meta-analyses have found (a) that people's social identification with a broad range of groups is negatively and reliably associated with depression ($r = -.25$; Cruwys, Haslam, Dingle, Haslam, & Jetten, 2014) and (b) that employees' social identification with work teams is positively and reliably associated with both psychological well-being and the absence of stress ($r_s = .27$, .18, respectively; Steffens,Haslam, et al., 2016).

Further support for this proposition comes from research that used data from the English Longitudinal Survey on Ageing to examine the power of different types of social connection to predict the cognitive health of more than 3,000 English adults over time (Haslam, Cruwys, & Haslam, 2014). Contrary to the idea that all forms of social connection are equally protective of health, this analysis found that social group ties proved far more beneficial than individual ties. Indeed, only group engagement made a significant and sustained contribution to subsequent cognitive function, and this contribution became more pronounced as people became more vulnerable (i.e., with increasing age). Similarly, a study of over 800 Australian high school students showed that psychological health (in the form of personal self-esteem) was predicted not by students' interpersonal social network ties, but only by the quality of the students' group-based ties (Jetten et al., 2015).

Stated slightly differently, the social identity approach to health suggests that social identities are beneficial to health because they are the basis for meaningful forms of group life and hence give people access to important social and psychological resources (Jetten, Haslam, Haslam, Dingle, & Jones, 2014). Consistent with this idea, evidence from a large number of studies supports the argument that the more social identities a person has access to (i.e., the more group memberships they have internalized as part of their self), the better their physical, mental, and cognitive health. This prediction is confirmed by research with multiple populations including high school students (Jetten et al., 2015), retirees (Steffens, Cruwys, Haslam, Jetten, & Haslam, 2016), people recovering from a stroke (Haslam et al., 2008), or people staving off depression (Cruwys et al., 2013).

However, it also follows from this analysis that if our capacity to form meaningful social connections is compromised (e.g., because we lose or lack social identities or because our social identities are stigmatized), then this will limit our access to these same social and psychological resources and hence will threaten psychological and social functioning (e.g., Cruwys et al., 2014). This can also be true if, as a function of their particular nature, groups exert a negative influence on our lives because the content of a given social identity (e.g., "us depressives," "us heroin users") is harmful in some way (e.g., because it has negative connotations or prescribes toxic behavior; Dingle, Stark, Cruwys, & Best, 2015). A key point here, then, is that much of the power of the social identity approach to health derives from its capacity to understand the ways in which group and identity processes are implicated in negative health-related dynamics as well as those that are more positive (Haslam, Jetten, Cruwys, Dingle, & Haslam, 2018).

Social Identity as a Health-Enhancing Resource

Social identity theory (Tajfel & Turner, 1979) and self-categorization theory (Turner, 1982; Turner, Hogg, Oakes, Reicher, & Wetherell, 1987) together comprise the social identity approach.

Work informed by this approach is generally concerned with exploring the determinants of social identity (and social identification) as well as its consequences for social behavior (e.g., Haslam et al., 2018; Jetten et al., 2017). As well as having broad implications for the analysis of social behavior, this work has particular relevance for clinical and health psychology in allowing us to understand both the origins and the impact of health-related social identity resources.

Social Connection

One of the primary consequences of coming to see ourselves as sharing social identity with others is that this draws them closer to us psychologically. As spelled out within self-categorization theory, a key reason for this is that shared social identity transforms people who, as individuals, are different from the self (i.e., "others") into people who, as group members, are part of the self (Turner et al., 1987).

By way of illustration, as individuals, passengers on the London Underground have no connection to each other and treat each other as strangers—with indifference. However, if circumstances were to lead them to see themselves as sharing social identity, then passengers would tend to see themselves as having much more in common, and their psychological orientation to each other would become much more positive as a result. This point was supported in research that documented the sense of solidarity and shared resolve that emerged among passengers who were victims of the London bombings in 2005. It has also been documented in work that examines passengers' experiences of sharing train carriages with football supporters when those passengers are supporters of the same team, a different team, or no team at all. More prosaically, a range of controlled experimental studies—including those that involve minimal groups—show that manipulations that make salient a social identity that is shared with another person (e.g., as Australians, team members, or Klee likers) serve to make that person appear more similar to the perceiver.

Furthermore, as well as changing abstract perceptions of similarity and connectedness, such manipulations also change our openness and receptivity to others, as evidenced in perceptions of liking and trust. Not only do we understand others to be more yoked to us in such circumstances, but once we relate to them as ingroup members we also embrace them more enthusiastically. Consequently, we also experience a greater sense of belonging and feel more comfortable in their company. Indeed, one key reason why social identity (and social identification) tends to have positive implications for health is that it serves to counteract—and indeed is inherently antithetical to—a sense of psychological isolation (Cruwys et al., 2014).

Effective Social Support

As people come to define themselves in terms of shared group membership, it is not simply their perceptions of each other that change. So too does their behavior. Not least, this is because social identity provides group members with the motivation to engage with each other in ways that advance the identity they share—so that if a person sees themselves as part of a given group (e.g., a family, a team, an organization), then they are motivated to "do what it takes" to help the group thrive. One obvious way they can do this is by helping each other out by providing social support when it is perceived to be needed (e.g., if a member of the group is in difficulty). Such support can take an emotional, intellectual, or material form and again flows from the fact that shared social identity transforms "others" into "self."

Another large body of empirical work supports this claim (for a review see Haslam, Reicher, & Levine, 2012). For example, studies show that when a football fan trips and falls, a passerby is far more likely to stop and help them if the victim appears to be a supporter of the same team rather than of a rival one. However, if the observer's more general social identity as a football fan is made salient (rather than their identity as a supporter of a specific team), then they are more likely to help the supporter of the rival team than someone who appears not to support any team.

On a larger scale, studies of international aid show that charitable giving also follows the contours of shared identity. However, a person's status as an ingroup or outgroup member (and hence the amount of support they receive) varies as a function of the specific identity lens through which they are viewed. Studies have shown, for example, that British people donate more money to Italian earthquake victims if they are encouraged to define themselves as European (in which case they share identity with Italians) rather than as British (where they do not).

Importantly, though, effective support is not just a matter of aid provision; it also depends on recipients being receptive to such charity. And this receptiveness too is structured by shared social identity. Studies thus show that people are more positively oriented to support when it is offered by ingroup rather than outgroup members—in large part because they are more trusting of the motives that lie behind it (Haslam et al., 2012).

Together then, these two sides of the support equation combine to mean that support tends both to be more forthcoming and to be more effective when it occurs within, rather than across, the boundaries of social identity. The same is true for the process of *social influence* that is implicated in most forms of support (and in all forms of leadership; Haslam, Reicher, & Platow, 2011). In particular, whether people give useful advice, and whether others take it on board, depends very much on the degree to which they see themselves as sharing social identity. This is another point that has broad relevance for health psychology. For example, it helps us understand the therapeutic alliance between practitioners and clients as something that is predicated on social identity. And it also helps us understand why interventions tend to be less successful when they occur across identity fault lines (e.g., of ethnicity, culture, and social class).

Meaning and Worth

We noted above that within the minimal groups studies, Tajfel observed that it was the process of acting as group members (in terms of social identity) that allowed participants to make an otherwise meaningless task meaningful. At the time he did not make too much of this, but it turns out that this is largely true of most other forms of social behavior. Looked at from the outside, many (if not most) social activities have the capacity to appear meaningless—whether they involve kicking a football, singing an operatic aria, or playing board games. What makes them meaningful (and enjoyable) is the process of identifying with the groups that engage in these activities.

In this regard too, it is obviously the case that what people do in their groups (and as individual group members) is largely informed by the *content* of their identity and what it means to be part of that group. Football teams play football, choir members sing, and board gamers play board games. The significance of this observation for health and well-being is that in this way, social identities lend meaning, direction, and purpose to actions that would otherwise be meaningless. This point was brought home in Durkheim's groundbreaking study of suicide in which he noted that people are far less likely to kill themselves during wartime—a pattern that he attributed to the fact that war had the power to bring people together and focus their energies on a common goal. At the same time, the process of contributing to such goals (e.g., by exerting oneself in a football match, by singing enthusiastically in a concert, by taking a board game seriously) tends to be valued and valorized by those with whom one shares social identity, and hence it instills in group members a sense that they and their efforts are worthwhile.

Control, Efficacy, and Power

Finally, because it provides a basis for people to participate in, and promote, collective projects, it is also the case that shared social identity tends to give people a sense of agency and control. As social identity theory suggests, at a group level, this should furnish them with a sense of being in charge of their own destiny and of having power in the world (Haslam et al., 2008, 2011). This is seen in a range of studies that show that as people's sense of social identity increases, so too does their sense of agency and power. Moreover, as studies of protest groups have shown (and as fans of perennially underperforming sports teams understand), it is not necessary for a group to achieve its aims in order for these benefits to accrue.

At an individual level too, shared social identity also furnishes group members with a sense of efficacy and of personal control over their lives. Research thus shows that people report a greater sense of personal control to the extent that they identify highly with their community, with a political party, with their nation, or with humanity as a whole (Greenaway et al., 2015). Again, this pattern is not contingent on group success—being apparent, for example, among highly identified Republicans immediately after their party had failed to win the 2012 presidential election. Here, then, internalized social identities help group members to interpret, understand, and recover from such failure.

An abundance of work on the importance of a sense of control for health underlines the importance of this observation. Indeed, the *World Happiness Report* identifies control as one of the "six pillars" of life satisfaction. Yet while perceived control is generally thought to have personal origins, social identity research suggests that it often has its basis in group identities and identifications.

Intervention: Groups 4 Health

A key message of the social identity approach to health is that social connectedness, and group connectedness especially, is central to health behavior and health outcomes. But how might we translate knowledge of group and social identity processes into applied interventions?

Evidence from group-based interventions points to three features that appear to be shared by those that are the most effective. First, interventions seem to be more effective to the extent that they have an integrated focus on issues of social process, cognition, and behavior—rather than looking at any one of these things in isolation. Second, interventions tend to be more effective to the extent that the groups at their heart are meaningful to their members and involve activities they value, rather than having an arbitrary or trivial basis. Third, more effective interventions create a sense of shared purpose that binds people together and enables them to work collectively toward common goals.

Building on these insights, researchers have used social identity theorizing as a basis for developing a manualized intervention—Groups 4 Health (G4H)—that seeks to improve health by enhancing people's group-based social connectedness in the context of a non-stigmatizing in vivo group experience (Haslam, Cruwys, Haslam, Dingle, & Chang, 2016). G4H is composed of five modules—the 5Ss—as shown in Figure 1. Together, these aim to give people the knowledge and skills not only to understand the nature and importance of their social identity resources but also to manage them effectively in the long term.

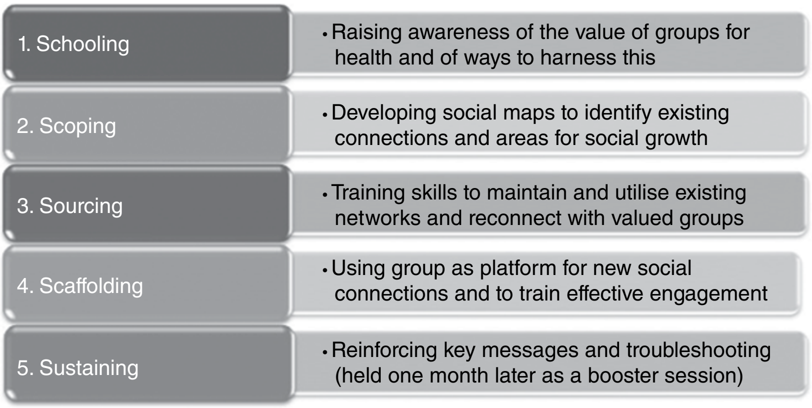

Figure 1 The modules in Groups 4 Health: the 5Ss (Haslam et al., 2016; see also Haslam et al., 2018).

A proof-of-concept trial with participants experiencing social isolation and affective disturbance indicated that G4H reduced clinical symptoms of depression as well as anxiety and stress (Haslam et al., 2016). In addition, it proved enjoyable for both participants and facilitators and led to significant improvements in social anxiety, social functioning, self-esteem, and life satisfaction. Importantly too, follow-up analysis indicated that most of these improvements were sustained—or even enhanced—6 months after the program had ended (see Haslam et al., 2016). The reason for this, we suggest, is that, because they are foundational to adaptive social functioning, groups are an especially sustainable source of psychological health.

Future Directions

Because the social identity approach to health is relatively new, it is clearly the case that more work needs to be done to test and validate its core assumptions and to establish their practical relevance. Work of this form is currently underway in relation to a range of health topics including social disadvantage, stigma, stress, trauma, aging, depression, chronic mental health, eating behavior, brain injury, acute pain, addiction, and physical health (see Haslam et al., 2018). In order to establish the generalizability and robustness of G4H, further validation studies are also currently in progress to establish its applicability to a range of populations (e.g., students, new mothers, people recovering from addiction, retirees).

Conclusion

The theorizing and evidence that supports the social identity approach has been built up over nearly half a century. However, it is only in the past decade that the approach has been applied specifically to the domain of health (e.g., see Haslam et al., 2018; Haslam, Jetten, Postmes, & Haslam, 2009; Jetten, Haslam, & Haslam, 2012). Nevertheless, in this short time, the evidence base and impact of the approach has increased exponentially, with the result that there are now well over 500 publications that speak to its utility.

The model that this work supports is represented schematically in Figure 2. This points to the fact that there are important (if complex) interconnections between social identity, group

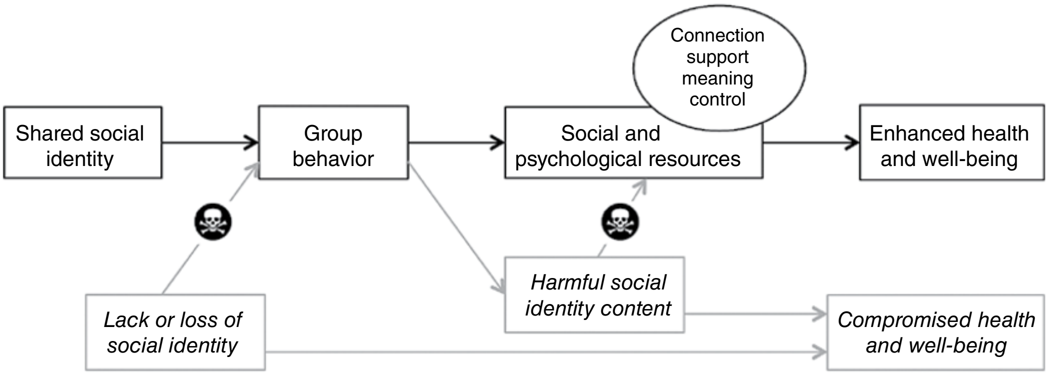

Figure 2 Schematic representation of the social identity approach to health.

behavior, and health and that the capacity for social identity to deliver positive health outcomes rests on its capacity to give individuals access to important social and psychological resources. However, it also suggests that health benefits can only be reaped from groups that are psychologically important for their members and, more generally, that the extent to which groups influence health—whether for good or for ill—depends on individuals' strength of identification with them.

Importantly, the resources that social identities provide are not only psychological but also material. They thus relate not only to people's sense of connection, support, meaning, and control but also to the social reality of these things. This is because, as social identity theorists grasped from the outset, groups are fundamental not only to our sense of self but also to our capacity to do things with others in the world and by this means to contribute to both social change and social progress (Tajfel & Turner, 1979). It is for this reason, then, that social identities are vital not just for the health of individuals but for that of society as a whole.

Author Biographies

S. Alexander Haslam is a professor of psychology and Australian Research Council Laureate Fellow at the University of Queensland. His research focuses on the study of group and identity processes in social, organizational, and health contexts. Together with colleagues he has written and edited 11 books and over 200 peer-reviewed articles on these topics including, most recently, *The New Psychology of Leadership: Identity, Influence and Power* (Psychology Press, 2011, with S. Reicher & M. J. Platow).

Catherine Haslam is professor of clinical psychology at the University of Queensland. Her research focuses on the social and cognitive consequences of identity-changing life transitions (e.g., trauma, disease, aging). She is an associate editor of the *British Journal of Psychology* and co-author of *The New Psychology of Health: Unlocking the Social Cure* (Routledge, in press; with J. Jetten, C. Cruwys, G. A. Dingle, and S. A. Haslam).

Jolanda Jetten is a professor of social psychology and research fellow at the University of Queensland. She is a former editor of the *British Journal of Social Psychology*. She has published over 140 peer-reviewed articles on topics related to social identity, group processes, and intergroup relations and previously co-edited *The Social Cure: Identity, Health and Well-Being* (Psychology Press, 2012; with C. Haslam & S. A. Haslam).

Tegan Cruwys is a lecturer in the School of Psychology, University of Queensland, a practicing clinical psychologist, and a recipient of an Australian Research Council Discovery Early Career Research Award. Her research investigates the social-psychological determinants of health, with a particular focus on health behaviors, mental health, and vulnerable populations.

Genevieve A. Dingle is a senior lecturer in the School of Psychology, University of Queensland. Her research focuses on social factors in addiction, depression, and chronic mental health problems, people experiencing homelessness, and the recovery process. She is on the editorial board of the *British Journal of Clinical Psychology*.

Social Influence

Karen S. Rook, Dara H. Sorkin, and Kelly Biegler

Department of Psychological Science, University of California, Irvine, CA, USA

People who have more social ties are known to have a significantly lower risk of mortality and morbidity, and this lower risk is usually attributed to the health-protective benefits of social support provided by others (Cohen, 2004). Social support refers to the aid and care that social network members often provide in times of need, and it is important in helping to buffer people from the harmful effects of life stress. Providing support is not the only process, however, by which social network members may contribute to health. They can also be a source of social influence, as people monitor each other's health behavior and seek to foster change when a health behavior (or set of behaviors) is perceived to be health damaging. A wife who is concerned about her husband's smoking, for example, might tell him how upset she feels when he smokes, might warn him of the long-term negative consequences of smoking, or might otherwise try to convince him to discontinue smoking. Researchers use different terms to describe such attempts to exert social influence, but a commonly used term is social control. Social control refers to efforts by social network members to monitor each other's health behavior and to intervene to discourage health-damaging behavior (Lewis & Rook, 1999; Umberson, 1987). Social control, like social support, could be an important mechanism that explains why having close relationships is associated with better health and greater longevity. The two kinds of interpersonal processes differ, however, in other respects.

By serving as a source of aid and care in time of need, social support is typically experienced as welcome and affirming. Social control, in contrast, involves efforts to change or constrain a person's health behavior, which can be experienced as unwelcome and critical, rather than affirming (Rook, 2015). Yet theorists have argued that social control attempts have the potential to benefit health, even when they are not affirming. Pressuring a family member to follow a prescribed treatment regimen more closely may help to prevent serious illness complications, even if the pressure is frustrating or irritating. The idea that social control may contribute to improved health behavior even while it arouses psychological distress has come to be known as the dual effects hypothesis (Lewis & Rook, 1999). Researchers have recently extended this reasoning to suggest that social control might detract from a recipient's feelings of self-efficacy,

---

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

even though it is intended to benefit the recipient's health by fostering improved health behavior. Specifically, others' social control attempts may convey implicitly (or sometimes explicitly) the message that the recipient's self-control is poor, which could erode his or her feelings of self-efficacy (e.g., Franks et al., 2006) and could kindle feelings of guilt or embarrassment.

Does social control have these hypothesized dual effects? Existing evidence is somewhat mixed, but it currently suggests three conclusions. First, social control is sometimes associated with better health behavior, but it is often associated with worse health behavior. For example, more frequent social control has been related to less health-damaging behavior (such as smoking) and more health-enhancing behavior (such as exercise, sleep, sound dietary practices) in some studies, but it has been related to worse, rather than better, health behavior in numerous studies. Moreover, more frequent social control has been found to be related to hiding of unsound health behavior and pretended adoption of sound health behavior in some studies (Lewis & Rook, 1999; see review by Craddock, van Dellen, Novak, & Ranby, 2015).

Such evidence casts doubt on one component of the dual effects hypothesis—the idea that others' social control attempts tend to encourage better health behavior. Much of the evidence that casts doubt on this conclusion is derived from cross-sectional studies, however, and cross-sectional designs introduce ambiguity with respect to temporal order. Do unsound health behaviors encourage others to engage in social control attempts, or do others' social control attempts encourage people to engage in unsound health behaviors (e.g., by undermining self-efficacy or provoking behavioral reactance)? Longitudinal studies generally yield less ambiguous evidence, and some (though not all) longitudinal studies do suggest that greater social control is associated with improved health behavior over time (e.g., Knoll, Burkert, Scholz, Roigas, & Gralla, 2012; Stephens et al., 2009).

A second conclusion suggested by existing research is that social control attempts are often associated with psychological distress, including not only feelings of resentment and irritation but also feelings of guilt and shame (e.g., Rook, August, Stephens, & Franks, 2011). Links between greater social control and lower feelings of self-efficacy have also been reported (e.g., Berg et al., 2013). It is worth noting, however, that participants in some studies express appreciation for others' efforts to monitor their health behavior and nudge improvements (Rook et al., 2011). Individual differences exist in how people react to others' social control attempts, with evidence suggesting that factors such as gender (e.g., August & Sorkin, 2011; Martire et al., 2013), ethnicity (e.g., August & Sorkin, 2011), and expectations about the appropriateness of others' involvement in one's health (e.g., Rook et al., 2011) influence whether people react favorably or unfavorably to social control attempts. Similarly, features of the broader context in which social control attempts occur may also influence how people react to them. People in more satisfying relationships appear to respond more favorably to their partner's social control attempts, exhibiting greater health behavior change and little psychological distress (e.g., Knoll et al., 2012; Tucker, 2002). The specific health context in which social control occurs also appears to influence how people react. Individuals with a serious chronic illness who face the task of adhering to a complex set of health behaviors as part of their day-to-day illness management may understand that their partners' efforts to prompt or urge adherence, even if unwelcome, are well-intentioned (e.g., Badr, Yeung, Lewis, Milbury, & Redd, 2015). Similarly, if couples regard the day-to-day tasks of managing a chronic illness as a collaborative rather than an independent endeavor, patients may react more favorably to their partners' involvement in their health (Berg et al., 2008).

A third conclusion suggested by existing research is that the nature of the social control attempts themselves influence how people respond, with positive and negative strategies of social control eliciting markedly different responses. Positive control strategies refer to others' attempts to persuade or motivate a person to improve his or her health behavior, whereas negative control strategies refer to others' attempts to pressure or coerce a person to make improvements (Stephens et al., 2009). Examples of positive strategies include reminding, persuading, bargaining, modeling, and providing contingent positive feedback. Examples of negative strategies include criticism, guilt induction, nagging, pressure, and withdrawal (Lewis & Butterfield, 2005). For example, a wife might try to persuade her husband to improve his adherence to a prescribed diet by reminding him of the health benefits of making better dietary choices, or, on the other hand, she might subtly criticize his food choices ("Are you really going to eat that?") or express exasperation ("I just do not understand how you can keep eating food that you know is bad for you.") Some researchers favor the terms persuasion and pressure to refer to these two different categories of social control tactics to avoid potential confusion between the nature of the influence attempt and its presumed effect on the recipient (Stephens et al., 2013). Across many studies, positive strategies have been found to be more likely to elicit improved health behavior and to avoid arousing psychological distress compared with negative strategies (Craddock et al., 2015). One challenge confronting researchers, however, in their efforts to identify distinctive effects of specific tactics of social control is that social network members frequently use multiple strategies of influence (Lewis & Butterfield, 2005).

The dual effects model of social control has continued to be elaborated in recent studies, with researchers investigating moderators that may indicate when the hypothesized effects are most likely to occur and mediating mechanisms that may explain why observed effects occur. Relationship characteristics and the health context of social control attempts, as noted earlier, are examples of potentially important moderators. The emotions aroused by social control attempts are examples of potentially important mediators, with social control expected to be more effective to the extent that the tactics used (such as reminders and explanations) elicit positive emotions and less effective, in contrast, to the extent that the tactics used (such as criticism or coercion) elicit negative emotions (e.g., Okun, Huff, August, & Rook, 2007; Tucker, Orlando, Elliott, & Klein, 2006). In the context of a serious chronic illness, however, even social control that arouses frustration or resentment may, nonetheless, help to foster adherence to a demanding self-care regimen (Badr et al., 2015). Thus, the specific health context in which social control attempts occur may influence the emotional and behavioral responses they elicit. Researchers have also begun to investigate the joint effects of social support and social control, positing, for example, that social control attempts may elicit more favorable responses in social relationships that also serve as a source of support (e.g., Khan, Stephens, Franks, Rook, & Salem, 2013).

Researchers have recently extended research on health-related social control to examine potential effects on the individuals engaged in social control attempts, such as spouses. It is plausible, for example, that having to monitor and seek to influence a partner's health behavior can be stressful for spouses, perhaps especially in the context of a chronic illness. Evidence consistent with this idea has emerged in studies of couples in which one individual is coping with type 2 diabetes (e.g., August, Rook, Franks, & Stephens, 2013; August, Rook, Stephens, & Franks, 2011). Whether negative effects of engaging in persistent health-related social control attempts would emerge in other health contexts is a question that warrants investigation in future studies.

Although most work on health-related social influence has emphasized actions by social network members that are intended to discourage health-compromising behavior, it is also important to note that others' social influence sometimes serves to encourage health-compromising behavior. In adolescence and young adulthood, for example, peer influence is known to play a role in the initiation of substance use (e.g., Wills, McNamara, Vaccaro, & Hirky, 1996). Even in the context of illness management, friends and family members sometimes undermine rather than bolster adherence to a treatment regimen. For example, spouses of individuals with type 2 diabetes are known to tempt their partners occasionally to eat unhealthy food, thereby undermining the partner's adherence to a recommended dietary regimen (Henry, Rook, Stephens, & Franks, 2013). The particular circumstances that prompt such undermining remain poorly understood and represent a valuable focus of future research.

Social influence, like social support, is a common element of many close relationships. Health-related social control and social support often co-occur in close relationships, but these interpersonal processes differ conceptually and empirically and exhibit distinctive associations with health behavior (Rook, 2015). Social support has been investigated more extensively than has social control. Yet across different community samples, as many as 70–86% of participants report experiencing health-related social control attempts from their social network members (e.g., August & Sorkin, 2011; Lewis & Rook, 1999). Given how common this form of social influence is in close relationships, it warrants greater attention from researchers in future studies. It is particularly important to gain an understanding of the dynamics of health-related support and control as they unfold over the course of a chronic illness or other significant health transition. Initial expressions of social support may give way over time to increasingly insistent, and even caustic, forms of social control when individuals experiencing a serious health challenge exhibit limited interest or history of success in initiating and sustaining health behavior changes that are crucial to their health. Future research will hopefully shed light on ways that social network members can avoid engaging in caustic or coercive social influence attempts and, instead, can foster successful health behavior change and maintenance while preserving self-efficacy in the recipient and good will in the relationship.

Author Biographies

Karen S. Rook is a professor of psychology and social behavior at the University of California, Irvine. Her research investigates the role of social relationships in fostering or interfering with health-enhancing behavior, particularly in the context of chronic illness. Other research examines the effects of interventions designed to strengthen social relationships as a resource for successful health behavior change.

Dara H. Sorkin is an associate professor of medicine at the University of California, Irvine. Her research interests focus on social relationships and health, particularly as they may play a role in health disparities. She also conducts and evaluates behavioral health interventions in community settings that seek to reduce health risks and poor health outcomes among under-resourced populations.

Kelly Biegler is a research scientist at the University of California, Irvine. Her research focuses on examining the impact of health behaviors, quality of life, and chronic stress on disease management, clinical outcomes, and neurophysiologic and immunologic processes in patient populations. She also investigates the effects of community interventions on the health and well-being of at-risk, low-income populations.

Social Isolation and Health

Mona Moieni and Naomi I. Eisenberger

Psychology Department, University of California Los Angeles, Los Angeles, CA, USA

> I don't know if anyone has noticed, but I only ever write about one thing: being alone. The fear of being alone, the desire to not be alone… the devastation of being left alone. The need to hear the words: You are not alone.
>
> —Shonda Rhimes, television writer and producer

What drives a compelling story? What pushes people to tune in each week to watch a story unfold on their televisions? Shonda Rhimes, an award-winning writer, producer, and creator of multiple widely successful television shows such as *Grey's Anatomy* and *Scandal,* revealed her secret for creating a narrative that millions of people around the world want to follow each week: writing about loneliness. Her answer also tapped into the idea that humans have a "need to belong"—a fundamental need or drive to seek out and maintain social relationships. It has been suggested that this desire to connect with others is as essential to our existence as other basic needs such as food, water, and shelter, providing us with advantages for survival (Baumeister & Leary, 1995).

If being social is such a crucial aspect of being human, then we would expect that not having social relationships would be associated with disadvantages and detrimental outcomes for our health and survival. Indeed, decades of research support the notion that lacking social connections has consequences for physical and mental health, including a significantly higher risk for all-cause mortality. In this chapter, we first briefly discuss measurement issues relevant to social isolation and then highlight health outcomes associated with social isolation. We follow this by a discussion of mechanisms that have been proposed to explain the relationship between social isolation and health, as well as consideration of interventions to reduce social isolation.

Measuring Social Isolation

Social isolation can be conceptualized in many ways. To assess whether an individual is socially isolated, we could ask whether she is living with other people, how often she gets together

with or talks to people, or in how many organizations or social activities (e.g., work, volunteering) she participates. These kinds of measures that tap into an individual's social network size are typically referred to as measures of *objective social isolation*. Thus, someone who lives alone, has few social ties, participates in few social activities, and/or has minimal contact with others would be considered objectively socially isolated.

Rather than asking how many people comprise a person's social network, we could also ask about how satisfied the person is with their network by asking them how connected they feel. We could ask them things like "How often do you feel alone?" or "How often do you feel that your relationships with others are not meaningful?" (Russell, 1996). These subjective feelings of social disconnection, or loneliness, are measures of perceived or *subjective social isolation*. Loneliness is distress resulting from the discrepancy between what an individual wants out of social relationships and what he or she is receiving. For example, people who say they often lack companionship, feel isolated from others, and feel there is no one they can turn to would be considered lonely.

Although these variables are related, they are separable and distinct. For example, it is possible to imagine someone who has only one confidant (and thus may appear socially isolated on objective measures) but feels perfectly content and socially satiated. Conversely, someone may be surrounded by people and participate in numerous social activities but still feel isolated or unsatisfied with these social relationships and thus feel lonely. While it is important to note that social isolation can be measured in numerous ways, this chapter covers the effects of isolation on health regardless of the way it was measured.

Impact of Social Isolation on Health

Starting with Berkman and Syme (1979) and House, Robbins, and Metzner (1982) and continuing through today, decades of work have documented the impact of social isolation on morbidity and mortality. In fact, social isolation is a mortality risk factor comparable with traditional risk factors such as smoking or obesity (see Holt-Lunstad, Smith, Baker, Harris, & Stephenson, 2015). Interestingly, a recent meta-analysis also found that there was no difference between objective and subjective measures of social isolation in terms of predicting mortality risk (see Holt-Lunstad et al., 2015), suggesting that social isolation is a powerful predictor of mortality regardless of how it is measured.

In addition to mortality, social isolation is related to lower levels of self-rated physical health, risk of cardiovascular disease, elevated blood pressure, risk of poor outcomes post-stroke, metabolic syndrome, increased frequency of doctor visits, and functional decline and disability (see Cacioppo, Grippo, London, Goossens, & Cacioppo, 2015).

There are also many associations between social isolation, in particular subjective social isolation or loneliness, and mental health. Loneliness is associated with depressive symptoms, suicidal ideation, social anxiety, substance abuse, eating disorders, and psychosis. Loneliness is also related to poorer cognitive performance, cognitive decline, and increased risk of Alzheimer's disease (see Hawkley & Cacioppo, 2010).

Potential Mechanisms

Overall, social isolation is associated with a wide array of mental and physical health issues, as well as mortality. Many mechanisms have been proposed to explain the relationship between social isolation and adverse health outcomes. We briefly outline some of the theorized behavioral, psychological, and biological mechanisms below. Although we discuss these mechanisms separately for ease of presentation, in reality one mechanism is unlikely to fully explain the complex relationships between social isolation and health. These proposed pathways, along with other mechanisms not mentioned here, likely interact with and build off each other.

Behavioral

Health behaviors have been discussed as potential pathways through which social isolation can impact health (see Hawkley & Cacioppo, 2010; Thoits, 2011). For example, friends and family can help individuals start and maintain healthy habits, and they can also provide meaning in life, which can have a positive impact on health behaviors. Socially isolated individuals may thus be at risk for poor health outcomes in part because they are lacking a significant source of modeling of good health behaviors and a sense of purpose related to having close relationships.

Additionally, loneliness may impair executive control and self-regulation (see Hawkley & Cacioppo, 2010), which could have a direct impact on health behaviors such as substance use, physical activity, and eating behavior. Indeed, social isolation is related to smoking and drinking more (Broman, 1993), and there also appears to be a relationship between loneliness and alcohol abuse (Åkerlind & Hörnquist, 1992). In addition to substance use, loneliness is related to obesity. Lonely individuals are more likely to be overweight than non-lonely individuals (Lauder, Mummery, Jones, & Caperchione, 2006). Furthermore, feeling disconnected can also impair self-control over eating behavior (Baumeister, DeWall, Ciarocco, & Twenge, 2005), and loneliness is predictive of reductions in physical activity (Hawkley, Thisted, & Cacioppo, 2009).

Sleep is another behavior that may be a potential mechanism through which social isolation can impact health. Loneliness is related to poor sleep quality throughout the lifespan, and it is also associated with fatigue and low energy (Hawkley, Preacher, & Cacioppo, 2010). Given the importance of sleep for health and mortality, this may be another behavior that may partially explain the social isolation–health association.

Psychological

Many potential psychological mediators of the social ties–health link have also been proposed (see Hawkley & Cacioppo, 2010; Thoits, 2011). One psychological mechanism that has been proposed is maladaptive social cognition. That is, lonely individuals may have certain social cognitive biases, such as generally seeing the world as a more socially threatening place, which may set off a vicious, self-feeding cycle of psychobiological reactions that may ultimately contribute to poor health outcomes. Socially isolated individuals may also lack the sense of purpose or meaning in life that is provided by social connection, which can lead to impairments in psychological well-being and physical health. Those who are isolated may also lack socially supportive others who may "buffer" the impact of stressful life events on well-being and health (Cohen & Wills, 1985).

Besides these mechanisms, some other proposed psychological mediators explaining the impact of social isolation on health include positive affect, social influence, self-efficacy, and self-esteem (see Thoits, 2011). However, some have found that existing models of psychological mechanisms linking social ties to health are generally not supported by evidence, indicating that there is still room for further research to better understand the psychological pathways that may underlie the social isolation–health link.

Biological

Numerous biological pathways have also been proposed to explain the effect of social isolation on health (see Hawkley & Cacioppo, 2010). For example, lonely individuals have immune system impairments (Glaser, Kiecolt-Glaser, Speicher, & Holliday, 1985), suggesting that immune alterations may be one pathway through which loneliness operates to damage health.

Inflammation, the body's first line of defense against infection or injury, is one potential immunological process through which loneliness may exert its effects. Inflammatory processes are implicated in a wide array of physical and mental health conditions, as well as mortality (Emerging Risk Factors Collaboration, 2010). Lonely individuals have increased pro-inflammatory reactivity (Jaremka et al., 2013), as well as upregulated pro-inflammatory gene expression (Cole et al., 2007). This heightened inflammatory activity in lonely individuals indicates that inflammation may be mediating some of the effects of social isolation on health. Interestingly, inflammation can also lead to feelings of social disconnection (Eisenberger, Inagaki, Mashal, & Irwin, 2010; Moieni et al., 2015), suggesting that inflammation and loneliness may engage in a dangerous, mutually reinforcing cycle.

Related to inflammation, loneliness may also operate through neuroendocrine pathways. For example, lonely individuals have impairments related to the hypothalamus–pituitary–adrenal (HPA) axis, including increased levels of cortisol (Adam, Hawkley, Kudielka, & Cacioppo, 2006). Chronic social isolation may also lead to glucocorticoid insensitivity (see Hawkley & Cacioppo, 2010), inhibiting the ability of cortisol to have an anti-inflammatory effect.

Finally, neural mechanisms have also been proposed to mediate the social isolation–health link. A set of neural regions which are involved in threat detection, including the amygdala, dorsal anterior cingulate cortex (dACC), anterior insula, and periaqueductal gray, are thought to play a role in the relationship between social isolation and health (Eisenberger & Cole, 2012). These regions may serve as a neural alarm system to detect social threat (e.g., social isolation, social exclusion), and in turn, activation of these regions may have an impact on HPA and sympathetic nervous system activity, ultimately impacting health. For example, social exclusion or rejection activates the dACC and anterior insula (Eisenberger, 2015; Eisenberger, Lieberman, & Williams, 2003). Activation of these neural regions is related to both heightened inflammation, which is involved in many physical and health disorders, and cortisol, a hormone involved in the body's stress response.

While the existing evidence lends support to these particular biological mechanisms, more work is needed to flesh out the details of these pathways, as well as how they may interact with behavioral and psychological processes, to impact health.

Interventions

Given the influence of social isolation on health, it is not surprising that multiple types of interventions targeted at reducing social isolation have been conducted. Interventions have included offering social skills training, social cognitive training, mind–body interventions, opportunities for social contact or activities, or social support programs. The mode of delivery has ranged from group interventions to one-on-one interventions, from in person to online, and lasting from a few weeks to multiple years. There have been multiple reviews on this topic (e.g., Dickens, Richards, Greaves, & Campbell, 2011; Masi, Chen, Hawkley, & Cacioppo, 2010), so we will highlight a few examples of effective interventions that have been tested using randomized trials.

One type of intervention that has shown positive effects on social isolation are those promoting social support and social activities. In one study, older adults who were randomly assigned to an intervention intended to increase peer support and social activity showed decreases in social isolation (Routasalo, Tilvis, Kautiainen, & Pitkala, 2009); those in the intervention group became more socially active and found new friends significantly more often than the control group. However, the intervention did not lead to decreases in loneliness or increases in social network size. Other interventions have examined the effect of animal-assisted therapy to increase socialization and decrease loneliness (Banks & Banks, 2002; Banks, Willoughby, & Banks, 2008). Participants who were randomly assigned to the animal-assisted therapy group (i.e., regular visits from a dog) showed decreases in loneliness (Banks & Banks, 2002).

Another type of intervention that has shown promise for reducing loneliness is social cognitive training (Masi et al., 2010). For example, one study examined the effect of "reminiscence therapy" (vs. a wait-list control) on loneliness in nursing home patients (Chiang et al., 2010). Over the course of 8 weeks, those in the therapy condition participated in activities such as discussing how to be more aware and expressive of feelings, identifying positive social relationships, and recalling family history and life stories; those in this condition showed improvements in loneliness. Although these interventions have shown promise in reducing feelings of isolation, additional studies examining the effect of this type of intervention, particularly in different samples (e.g., isolated adolescents), are still needed.

Creswell et al. (2012) took yet another approach, examining the effect of a mindfulness-based stress reduction (MBSR) training on loneliness in older adults. They found that an 8-week MBSR program, compared with a wait-list control, led to reductions in loneliness, as well as reductions in pro-inflammatory gene expression. This finding suggests that other mind–body interventions may be successful in reducing loneliness, as well as biological mechanisms such as inflammation that may be driving some of the health effects associated with social isolation.

Indeed, there is certainly room to develop additional targeted interventions addressing social isolation based on these kinds of successful interventions. Some have suggested that interventions that incorporate some sort of social cognitive training are likely to be the most effective (Masi et al., 2010), while others have found that interventions with a social activity or social support component, and delivered at a group level (compared with one-on-one), may be the most effective (Dickens et al., 2011). Still others have suggested tailoring new interventions for particular developmental stages and thus focusing interventions on aspects of social isolation that are most important across different times of the lifespan (Qualter et al., 2015). Overall, it appears that testing new evidence-based interventions, particularly using randomized trials, is an important area for future research in this field.

Conclusion

In summary, social isolation has detrimental effects on a wide range of physical and mental health problems, as well as mortality. Numerous mechanisms have been proposed for the relationship between social isolation and health, but future work is needed to more fully flesh out these pathways. Finally, some interventions aimed at decreasing social isolation have been successful. However, given that social isolation can have such a powerful influence on our physical health and well-being, developing new low-cost, effective, and easy-to-implement interventions is an important area for further research that could ultimately have significant public health implications.

Author Biographies

Mona Moieni is a postdoctoral scholar in the Department of Psychology at the University of California, Los Angeles (UCLA). Her research focuses on the relationships between biological and social psychological processes, as well as how these relationships may be relevant for physical and mental health.

Naomi I. Eisenberger is an associate professor of psychology at the University of California, Los Angeles (UCLA). She specializes in social neurocognitive aspects of emotion and behavior and how these processes relate to health-relevant biomarkers.

Social Support and Health

Marci E. J. Gleason and Jerica X. Bornstein

Department of Human Development and Family Sciences, University of Texas at Austin, Austin, TX, USA

Social support has been consistently shown to be beneficial for both physiological and psychological health. A meta-analysis of 148 studies investigating the influence of social relationships on mortality found that social support was highly protective (Holt-Lunstad, Smith, & Layton, 2010). Those who reported low levels of social support had an approximately 50% increase in mortality risk compared with those high in social support. These findings investigated individuals across the lifespan (ages ranged from 6 to 92) and were robust regardless of the sex or initial health status of the participants. However, as with most findings, the effect of social support on health is complicated and can range from very positive to neutral and even become negative depending on how social support is measured.

Social support has been measured in a myriad of ways and studied in various disciplines across multiple decades. Perhaps the earliest work that identified a type of social support as beneficial to health was Durkheim's (1897/1951) report that suicide risk was reduced among those who were socially integrated. He argued that individuals who were more embedded in social networks were more tied into society and were therefore less likely to kill themselves. He cited the higher suicide rate among single compared with married individuals as one example of the power of social ties. In line with this research, many studies of social support have focused on the size of individuals' social networks and the presence and number of close friends and family members in an individual's life, often referred to as "close ties." The size of an individual's social network is determined by a count of all the people that an individual typically interacts with and can include everyone from a spouse to the mailman. Although social network size has been linked to beneficial health outcomes, those linkages become stronger when one refines this measurement to include information on the strength of the ties between the focal individual and their social network (Holt-Lunstad et al., 2010). Researchers examining "close ties" gather information on the number of people in an individual's social network and will often measure the frequency of interaction with network members, as well as the depth and closeness of those relationships. Importantly, the quality of an individual's

relationships is a key enhancer of the gains associated with network ties: having close friends is more protective than having many friends.

The use of network ties as a proxy for social support has become less prevalent in the research literature and replaced with the idea that social support is composed of specific support behaviors, such as giving advice, listening, and providing monetary aid. These behaviors could be ones that have occurred within an individual's social relationship in the past or that the individual believes would be available to them in the future. This characterization of social support is often referred to as *perceived social support* or the *availability of social support*. Individuals who report high levels of perceived support, regardless of the number of actual social ties individuals have, report better mental and physical health.

Thus the benefits of social support and more specifically perceived social support are well documented, and several mechanisms to explain the association between social support and health have been posited. The dominant explanation is the stress-buffering hypothesis that contends that social support protects recipients from the negative effects of stress by helping the recipient cope more effectively with that stress—essentially providing extra resources for coping through practical means, such as lending money, or emotional means, by listening or offering comfort. Although numerous studies have shown that the effect of stress on health is buffered by perceived support, few studies have demonstrated that this buffering is the only or even the primary way in which perceived support is protective. In other words, it is not only that those who are high in perceived support seem to be less affected by the stress in their lives but also that regardless of stress level, those high in perceived support report better mental and physical health.

Such findings have led others to argue that support, specifically perceived support, reflects an individual difference variable or personality trait. Levels of perceived support are not strongly related to the number of specific support events individuals report receiving, suggesting that people differ in the amount they believe people will be there for them regardless of their actual support experiences. However, studies have failed to find evidence that perceived support operates as a personality characteristic. Instead, research on the source of perceived support has demonstrated that specific relationships create a sense of supportiveness, rather than certain individuals having a tendency to view others as supportive. This idea is explored in relational regulation theory (RRT) that posits that the extent to which someone perceives support is dependent on interactions with individuals that are specific to that particular recipient (Lakey & Orehek, 2011). A sense of perceived support arises when an individual has access to supportive relationships, and that sense of perceived support will not exist in the absence of those specific relationships. Unlike a personality trait that would be fairly consistent across time, RRT predicts that one's sense of perceived support will vary depending on one's current social context and relationships.

These findings suggest that regardless of how social support promotes positive health and how the perception of social support is formed, increasing social support in individuals' lives should lead to both mental and physical health benefits. However, there is a clear and established paradox in the social support literature. The perception of social support is positive, but when individual instances of support are investigated, receiving support is often associated with *negative* outcomes including emotional distress, poorer physical health, and increased mortality risk. This link between single instances of social support or enacted support and negative outcomes has been demonstrated in observational, experimental, and correlational studies. Work in the helping behavior literature corroborates this finding; being helped is associated with decreased self-esteem and increased depressed mood in recipients. Moreover, these negative outcomes are more pronounced when help is received from a close other such as a relationship partner.

Social support researchers have suggested many reasons for why enacted support is often associated with negative outcomes. Perhaps the explanation that has received the most attention both in the social support and helping behavior literature is that the receipt of support may undermine the recipient's sense of efficacy and/or control. Receiving support itself may signal to the recipient that the provider perceives them to be struggling or even incapable of coping with the stressor, therefore exacerbating the recipient's anxiety rather than alleviating it (Bolger & Amarel, 2007). Despite this general tendency for an instance of social support to be ineffective, research on enacted social support has identified specific types of support, referred to as skillful support, that are often associated with positive outcomes. Four types of skillful support—matched support, invisible support, supportive reciprocity, and capitalization—have been well documented in the literature, and we briefly describe these below.

Stressors can be categorized as controllable or uncontrollable, and this distinction is important for determining what type of enacted support is likely to promote positive health outcomes for the recipient. Controllable stressors are likely to benefit from informational support. For example, an individual who is trying to obtain a new passport is likely to find it helpful when a friend who recently renewed a passport tells them the various steps needed to obtain one. Alternatively, uncontrollable stressors, such as the stress associated with waiting to find out whether one has been promoted, are more likely to be alleviated by a friend providing a distraction or reassurance that the recipient is worthy of the promotion. Unfortunately, studies of support matching suggest that people struggle to identify the types of support their relationship partners actually desire. This results in high levels of unmatched support (Cutrona, 1996), rendering those support attempts ineffective and even detrimental to the receiver.

Overly visible or directive support has also been linked to negative outcomes, perhaps because these types of overt support decrease recipients' sense of control and increase their feelings of indebtedness to their providers as well as draw attention to the struggle an individual is undergoing. For instance, in an experimental study, participants were asked to give a difficult and impromptu speech. Those individuals who reported that they were given advice from a confederate during this task reported higher levels of anxiety than those who heard the same advice, but did not think it was directed at them (Bolger & Amarel, 2007). This latter type of support, known as invisible support, has been shown to ameliorate daily anxiety, increase goal attainment, and increase feelings of self-efficacy in the recipient.

Findings from studies examining equity and reciprocity in support, as well as ones examining the effects of provision on the provider, indicate that the costs of receiving support can also be lessened when there is an opportunity to reciprocate by providing support to one's partner. Interestingly, the provision of social support has generally been found to be highly beneficial to the provider and has been associated with positive outcomes. Further, whereas most of the literature addressing partner support focuses on support provided in response to stressors or hardships, recent research has demonstrated the importance of examining support provided in response to positive events or uplifts. Sharing positive experiences in the hope of getting a receptive, supportive audience is called a capitalization attempt. When the support that follows such attempts (i.e., capitalization support) is both active and positive, it yields strong personal and relational benefits (Gable, Gosnell, Maisel, & Strachman, 2012).

The field continues to explore other ways in which support can be both received and perceived positively. One promising approach is that of affectionate and physical touch in adult close relationships, which has been shown to help promote high quality relationships, physical well-being, and psychological outcomes in adulthood (Jakubiak & Feeney, 2016). Recent research has also suggested that the link between actual interactions and perceived support may come from common everyday conversation rather than actual support attempts. Perhaps it is those we can speak comfortably and freely with about everyday matters, regardless of whether those individuals have actually provided support, that create a sense of perceived support in individuals (Lakey & Orehek, 2011).

The majority of the current social support literature has focused on in person interactions. However, the ways with which we communicate are changing rapidly, and many individuals now communicate with their closest social ties in part or even largely through email, text, and social networks. Physical proximity to our social networks may become both less common and potentially less important as online communication provides a new avenue through which to receive support. In addition, social networking platforms allow individuals to routinely request and receive support not only from current social network members but also from people they don't know outside of on online communication. Such communication has the potential to be positive: research has shown that those who engage in more supportive interactions on social networking sites have greater levels of positive affect (Oh, Ozkaya, & LaRose, 2014). However similar to earlier work on social networks, the quality of online support interactions matters. As society's communication habits and norms shift, so will the experience of social support. Whether the current shift to online communication creates an opportunity for individuals to gain access to better and more frequent supportive interactions remains to be seen. However, it is clear that social support researchers will have to address the implications of the online world on mental and physical well-being.

Social support has been repeatedly and strongly linked to positive health outcomes, but exactly why social support is beneficial is still being explored. In particular, the paradox that while perceived support is almost universally positive, enacted support is often negative has complicated the field's understanding of social support processes. Researchers continue to explore new mechanisms and types of social support and continue to gain new insights into the importance of social ties to individuals' health outcomes.

Spirituality/Religiosity and Health

Kevin S. Masters and Stephanie A. Hooker

*Psychology Department, University of Colorado at Denver –
Anschutz Medical Campus, Aurora, CO, USA*

Religiosity and spirituality (R/S) are important to individuals worldwide. It is estimated that 80% of people identify with a religious group and many who are not members of a religious faith still hold to some religious or spiritual teaching. About 60% of Americans report that they regularly feel a deep sense of "spiritual peace and well-being" (Pew Research Center for Religion in Public Life, 2014).

An important issue that confronts empirical investigators is defining religiosity and spirituality and distinguishing between them. This has proven to be a difficult task and one that continues to evolve. Closely related is the problem of measurement: How is one to measure constructs that prove so elusive to consensual definition? Kapuscinski and Masters (2010) recently discussed these issues in detail and provided historical context. They also reviewed measures of spirituality. Though some individuals find their spirituality and religiosity to be inextricably intertwined, the more recent trend is to view them as related, or overlapping, but differentiated concepts. Both share a sense of being concerned with understanding and experiencing the sacred or the ultimate. However, religiosity undertakes this search within the context of an institution or group, whereas spirituality is viewed as a more personal journey, which may or may not take place within an organized religion. Other connotative differences found in the literature include the relative importance of codes of conduct (higher in religion) and the issue of externality (religion) versus internality (spirituality). There also seems to be an inclination among some social scientists to view religion as more likely "bad" and spirituality as more likely "good." Scholars in the area, however, warn against this use, noting that most of the research to date has been done on religious constructs, and both religiosity and spirituality are complex and multidimensional.

Individuals who have a sense of R/S often believe that their spirituality influences their health as a result of the peace or well-being that their faith affords, religiously based behavioral practices (e.g., refraining from smoking, moderate use of alcohol, vegetarianism based on religious beliefs), or divine intervention. There is reasonably strong empirical evidence, some of it at the population level and other evidence from meta-analyses, generally suggesting a modest positive relationship between religiosity and health with the suggestion, not yet confirmed, of a beneficial effect of religiosity on health. The most studied variable, with the most consistently positive

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

findings, is religious service attendance. Attendance has been found, after controlling for relevant confounds, to predict a number of beneficial outcomes including decreased mortality (Chida, Steptoe, & Powell, 2009). Research on health and spirituality per se is only beginning. (Spiritually relevant practices such as meditation or yoga have their own bodies of literature.)

We refer those interested in comprehensive reviews of the empirical literature investigating the relationships between R/S and various health outcomes to Koenig, King, and Carson (2012). Park et al. (2017) provide a more recent review with specific emphasis on cardiovascular disease, cancer, and substance abuse. As important as these general findings are, however, the question posed to contemporary investigators is this: What aspects of R/S are related to what aspects of health for what types of people? A sophisticated literature at this level of specificity does not yet exist but is clearly an important direction for future work. One aspect of work aimed at greater specificity and understanding, currently underway, concerns investigation of mechanisms or processes that may account for relationships between aspects of R/S and health indicators. We now turn our attention to this literature.

Mechanisms Linking R/S to Health

R/S likely influences health through a number of different mechanisms, and given the multidimensional nature of R/S, different facets of R/S may influence these mechanisms differently. Three primary mechanisms discussed by empirical investigators include social support, health behaviors, and psychological processes. We will review the literature in these areas but openly acknowledge that there are likely other plausible mechanisms.

Social Support

One of the primary hypothesized mechanisms linking R/S to health is social support. Ample evidence has shown that social support is beneficial for a number of health outcomes. This mechanism is primarily found in the context of a religious community and, to this point, has not been viewed as a strong mechanism linking spirituality to health. For instance, those who regularly attend religious services have larger social networks, are more likely to stay in contact with other people, report greater perceived social support, are more likely to feel valued by their social group, tend to believe their religious congregations are more cohesive, and are more likely to stay married.

Interestingly, religious support has also been shown to be related to another hypothesized mediator of the relationship between R/S and health: health behavior. That is, individuals who feel more support from their congregation are more likely to engage in health-promoting behaviors such as better diet and increased physical activity. However, those who do not perceive this support or have negative interactions with fellow parishioners may engage in less healthy behavioral practices. Though social support may be important in terms of understanding the relationship between R/S and health, it does not account for a large portion of the variance between the two. Consequently, other factors have also been hypothesized to mediate the R/S and health relationship.

Health Behaviors

As noted previously, many religious teachings have health implications; therefore, health behaviors have been hypothesized as a mechanism linking R/S to health. Certainly, religious leaders have great potential for influencing the healthy behaviors of their congregations. Given the multiple pathways by which R/S could influence health-promoting and health-compromising behaviors, it is not surprising that there are many studies linking R/S to health behaviors. Religious service attendance is an often-studied variable that is related to a number of healthy behaviors and less engagement in health-compromising behaviors. There is, however, also evidence that religious importance is associated with greater use of preventive healthcare services, including mammograms, flu shots, cholesterol screening, and prostate cancer screening (Benjamins & Brown, 2004). Additionally, R/S variables, including religious involvement, religious service attendance, personal spirituality, and religious community support, are associated with a healthy lifestyle or engaging in many different health-relevant behaviors (Hooker, Masters, & Carey, 2014). In general, positive R/S variables are related to increased engagement in health-promoting behaviors and reduced likelihood of engaging in health-compromising behaviors, whereas negative R/S variables are related to reduced engagement in health-promoting behaviors and increased engagement in health-compromising behaviors.

In chronic illness patient populations, R/S may be related to treatment adherence. One study of patients with congestive heart failure (CHF) demonstrated that religious commitment predicts greater adherence to CHF-specific behaviors over 6 months even when controlling for initial levels of adherence (Park, Moehl, Fenster, Suresh, & Bliss, 2008). In cancer survivors, daily spiritual experiences and spiritual well-being are related to health-promoting behaviors, including eating five or more servings of fruits and vegetables a day, engaging in moderate to vigorous physical exercise, adhering to doctors' orders, and making overall positive changes in behavior (e.g., avoiding alcohol, cigarettes, and sun exposure, using sunscreen and sun-protective clothing; Park, Edmondson, Hale-Smith, & Blank, 2009). Conversely, religious struggles are related to less adherence to doctor's advice and less medication adherence (Park, Edmondson, Hale-Smith, & Blank, 2009). These studies suggest that R/S variables also influence health behaviors in the context of a chronic illness.

Psychological Processes

In addition to social support and health behaviors, a variety of psychological processes, including stress reduction and coping, reduced depressive symptoms, and enhanced self-regulation, have been proposed to mediate the relationship between R/S and health.

R/S may be a buffer against the effects of stressful life events. Religious coping, in particular, has been studied as a protective factor for coping with life stressors. Religious coping behaviors may be thought of as positive (e.g., religious purification or forgiveness, collaborative religious coping) and negative strategies (e.g., spiritual discontent, viewing God as punishing) that individuals use to mitigate the effects of stress. One meta-analysis has shown that positive religious coping behaviors are positively related to better psychological adjustment (e.g., optimism, happiness, hope, life satisfaction) and negatively related to negative psychological adjustment (e.g., depression, anxiety, burden, distress), whereas negative religious coping behaviors are positively related to negative psychological adjustment (Ano & Vasconcelles, 2005). Moreover, negative religious coping is related to greater perceived stress and to less use of problem-focused coping strategies, which are related to less perceived stress. Recent experimental studies have begun to examine the effects of religious behaviors, such as prayer, on the effects of cardiovascular reactivity to stress. In an experimental study in our lab, we found that devotional prayer reduced stress reactivity to a provocative religious interview in a group of self-identified Christians; however, more work is needed to understand the pathways between religious behavior and stress reduction.

Another psychological process linking R/S and health may be a reduction in depressive symptoms. R/S involvement is shown to be positively related to mental health. One very large meta-analysis of 147 studies shows that R/S variables are negatively correlated with depressive symptoms (Smith, McCullough, & Poll, 2003). Interestingly, prayer has been shown to be related to fewer depressive symptoms and less distress in patients postcoronary artery bypass graft (Ai et al., 2006). Conversely, religious struggles and negative religious coping are related to increases in depressive symptoms in patients with congestive heart failure (Park, Brooks, & Sussman, 2009). In general, positive R/S variables are protective against depressive symptoms, whereas negative R/S variables are related to greater depressive symptoms.

A new and particularly interesting hypothesis is that R/S may be related to health through enhanced self-regulation. McCullough and Willoughby (2009) offer a number of testable hypotheses in this area that are substantive and potentially important in guiding future research. Deciphering temporal precedence and cause and effect relationships will likely prove challenging. It may be that individuals who are better self-regulated are more likely to engage in regular behaviors (such as attending services and engaging in healthy behaviors) but are also better at controlling their emotions and coping with stress. However, it is also likely that the doctrines, messages, and practices of religious faiths reinforce and normalize self-regulatory behavior and provide social support for its maintenance. More work is needed in this area, but we find this mechanism to be a particularly exciting advancement of this field.

Special Topics in R/S and Health Research

Distant Intercessory Prayer

A topic that, perhaps surprisingly, has garnered significant attention in both the popular and scientific press is the possibility that distant intercessory prayer (i.e., prayer said on another's behalf and without the intended beneficiary present) can bring about healing or relief of symptoms. There is no question that religious individuals, and many nonreligious individuals, are more prone to pray both for themselves and others when there is an immediate health concern, and those prayers are often for healing or relief of disabling symptoms. The topic of prayer and health is important and worthy of investigation on its own. The focus of this section of our entry, however, is on the potential effects of distant intercessory prayer.

In a typical study on this topic, investigators recruit "intercessors" who will pray for a group of patients. In almost all studies, the patients did not know whether they were being prayed for or not and in some cases did not know that they were even in a research study. Some early reports suggested beneficial effects for those who were prayed for versus a control group that did not receive prayer, but a careful analysis of these studies suggests that failure to consider multiple comparisons and other concerns render the results less compelling. Subsequently, Masters, Spielmans, and Goodson (2006) conducted a meta-analysis and concluded that there was no evidence to suggest any beneficial effects for those who received prayer versus non-prayed-for controls. A subsequent Cochrane review (Roberts, Ahmed, & Davison, 2009) reached a similar conclusion, and both reviews recommended that further research in this area not be supported largely because of a serious methodological impediment that cannot be overcome. Regardless of whatever one may think about distant intercessory prayer per se, there is simply no way to conduct a meaningful controlled investigation because there is no practical (or ethical) means to ensure that the control group does not receive prayers of its own from family, friends, clergy, or congregations, and there is no plausible rationale to suggest that the prayers of unknown intercessors would somehow have greater efficacy than the prayers of those who know the patient. In this regard, it is interesting to note that in one of these studies, one of three experimental groups knew that they were receiving prayer from study intercessors. This group demonstrated a higher incidence of complications than did two other groups who did not know whether they were receiving prayer (one group was, the other was not).

Spirituality in Cancer Patients and Survivors

Research in R/S and health, and in particular spirituality and health, has been embraced within the cancer literature, and there has been a surge of findings in this area in recent years. Indeed, one analysis of the literature shows that the number of abstracts regarding R/S and cancer have increased more than 2.5 times over previous decades (Salsman, Fitchett, Merluzzi, Sherman, & Park, 2015). A series of recent meta-analyses (Jim et al., 2015; Salsman, Pustejovsky, et al., 2015; Sherman et al., 2015) show that across 44,000 cancer patients, R/S dimensions are positively related to physical, mental, and social health. The strongest relationships are seen in affective dimensions of R/S, or the emotional experience of R/S including "a sense of transcendence, meaning, purpose, or connection larger than oneself" (Salsman, Fitchett, et al., 2015, p. 3). There are small associations for cognitive (e.g., R/S beliefs, religious orientation, R/S problem solving) and other dimensions of R/S (e.g., composite indexes, social support, religious affiliation) in relation to all three dimensions of health. Behavioral factors, including R/S coping and public and private R/S activities, demonstrated a small, positive relationship with social health but were not significantly related to physical or mental health. This literature could be greatly enhanced with studies that are more rigorous in their design (e.g., less reliance on cross-sectional data) and attend in greater detail to the possible moderators and mediators of these relationships (Park et al., 2017).

Future Directions

The topic of R/S and health has experienced significant growth over the past two decades, resulting in greater understanding of the relationships and implications of what the next steps should be. Clearly, much more needs to be done. We offer suggestions for future research in this area and refer interested readers to Park et al. (2017) for a more detailed discussion.

As noted above, future work that aims for greater specificity is needed, for example, to specify the particular aspects of R/S that are beneficial, the particular components of health most likely to be associated with R/S, the relevant theoretical mechanisms, and the particular groups of people most likely to benefit. This work must consider both the socioeconomic and cultural context in which R/S takes place, as well as the aspects of R/S that themselves constitute cultural variables. This kind of detailed work can only be properly conducted as part of an ongoing program of research wherein the relationships between R/S and health are the focus of investigations.

Though it is not always possible, depending on what aspects of R/S and health are being studied, greater use of experimental studies is encouraged. Nearly all of the existing work on R/S and health is observational. To some degree, observational work will always play a prominent role in this area because it is simply not possible to randomly assign individuals to, for example, certain religious beliefs or groups. However, some aspects of religious practice (e.g., scripture reading or other private religious practices) are amenable to randomized controlled study when carried out in sensitive ways among members of proper groups (i.e., those willing to engage in the particular practice).

Greater use of large-scale longitudinal research designs is strongly indicated. Though these studies are not capable of determining causality, they may be able to establish temporal precedence, an important factor in many areas of R/S and health research and a preliminary step toward drawing causal conclusions. Further, longitudinal designs, particularly those that are carried out over the long term, have the potential to shed light on developmental trends in relationships between R/S and health.

Finally, we recommend that investigators partner with theologians or become more familiar with theological constructs themselves, as these constructs pertain to the particular groups that are the focus of study. In this way, a deeper understanding of the workings of religion and health is likely to develop, one that may ultimately have practical implications for clergy and their congregants.

Author Biographies

Kevin S. Masters, PhD, Professor of Psychology, Program Director, Clinical Health Psychology, University of Colorado Denver, Denver, Colorado, USA. Dr. Masters' research investigates religious and spiritual factors and processes as they relate to health, in particular cardiovascular responses to psychological stress and healthy behavior change. Recently he has begun investigations of meaning in daily life and its possible effects on health variables. Dr. Masters is past president of the Society for Health Psychology.

Stephanie A. Hooker, MS, MPH, Clinical Health Psychology PhD Candidate, University of Colorado Denver, Denver, Colorado, USA. Ms. Hooker's research investigates positive psychosocial predictors of health behavior change and maintenance. She is interested in translating her basic research findings to develop and evaluate theory-driven behavioral interventions for obesity and cardiovascular disease prevention and treatment. Her recent research has focused on daily meaning in relation to physical activity.

Pregnancy is the period during which offspring develop in their mother's womb. In humans, a full-term pregnancy lasts 40 weeks and is divided into three trimesters. The first trimester begins at conception and goes through 12 weeks, the second trimester is 13–28 weeks, and the third trimester is 29 weeks through the birth of the baby. The normative physiological changes in pregnancy are well established, and most pregnancies result in a healthy infant born at full term, of normal weight. However, there is substantial variability in pregnancy outcomes. Infants born prior to 37 weeks of gestation are preterm or premature, and those born weighing less than 2500 g (5 lb, 8 oz) are low birthweight. These unfavorable birth outcomes occur for 8 and 12% of pregnancies worldwide. These birth outcomes are consequential with respect to infant mortality and developmental problems in offspring and incur high emotional and economic costs for families (Butler & Behrman, 2007). The etiology of adverse birth outcomes is not well determined. However, the life experiences of women during pregnancy have been clearly implicated. Today, scientists across disciplines are working together to increase our understanding of biopsychosocial and sociocultural influences on pregnancy and birth.

Pregnancy is stereotyped as a happy time and for many, it is. The image of a mother and her partner preparing to welcome a child they want is prevalent, but it does not reflect that many pregnant women's lives are affected by socioeconomic disadvantages, life stress, and emotional distress. During pregnancy, women may face a variety of major stressors, like the death of a family member and legal problems including with their own or family members' immigration status, relationship conflict, and financial hardship. The impact on pregnancy and birth of these surprisingly common stressors cannot be underestimated. For example, most of the studies on major life events including major catastrophes such as earthquakes show an effect on preterm birth. Additionally, in recent years, stress research has broadened its focus to include the reverse—resilience in the face of chronic stress—defined here as the ability to withstand and

cope with ongoing or repeated demands (Schetter & Dolbier, 2011). Resilience resources that a woman has may benefit her emotional welfare, coping, and the outcomes of her pregnancy.

Mood Disorders

Affective disorders are more prevalent during pregnancy and postpartum than other times in women's lives. Prenatal and postpartum affective disorders and symptoms are noteworthy because they can have potentially deleterious effects on women, infants, and families. Depression and anxiety during pregnancy have been implicated in poor birth outcomes, namely, preterm birth and low birthweight (Schetter & Tanner, 2012). Pregnancy and the postpartum period are marked by increased risk of negative mood states including depressive and anxiety disorders, partly related to the extensive physiological changes that can adversely affect mood and often due to changes in life circumstances. Additionally, when women discontinue medications for mood disorders in pregnancy to protect their fetus from risk, their mood may become a risk factor.

Pregnancy Anxiety

Up to one in four women experience prenatal anxiety, though prevalence depends on the type of anxiety symptoms and disorders studied (Schetter & Tanner, 2012). *Pregnancy anxiety* refers to specific fears or worries about a current pregnancy, including about the health of one's baby, labor, delivery, and parenthood. These pregnancy-specific worries are associated with increased risk of preterm birth. Elevated levels of pregnancy anxiety also predict infant and child developmental outcomes, especially poorer cognitive and motor performance, and more negative temperament in infancy (Blair, Glynn, Sandman, & Davis, 2011). Little research links prenatal anxiety to low birthweight (Accortt, Cheadle, & Schetter, 2015).

Prenatal and Postpartum Depression

Conservative estimates of rates of postpartum depression (PPD) range from 7 to 13% (Rich-Edwards et al., 2006), making this type of depression as prevalent as major depressive disorder among nonpregnant women. A recent systematic review found prenatal depression to be consistently associated with increased risk of low birthweight possibly as a result of adverse health behaviors that affect growth. The overall evidence on preterm birth is less conclusive with some studies suggesting a link and most suggesting no link (Accortt et al., 2015). PPD is also consequential for women. Women who experience postpartum affective disorders are more likely to have difficulty returning to prepregnancy levels of general well-being and employment functioning and to experience relationship stress (Abrams & Curran, 2007). PPD is associated with increased risk of poor infant–parent attachment and low rates of breastfeeding that can lead to greater risk of cognitive, psychological, and behavioral problems in childhood and beyond (Paul, Downs, Schaefer, Beiler, & Weisman, 2013). It is important for women and health providers to pay attention to depressive symptoms preceding and following birth—even if they are not clinically significant.

Health Disparities

Socioeconomic status (SES) is a clear risk factor for preterm birth and low birthweight. Low SES can lead to life conditions such as unemployment and crowding, which in turn predict poor birth outcomes including low birthweight (Borders, Grobman, Amsden, & Holl, 2007). SES also works in combination with other risks, such as race/ethnicity, for adverse birth outcomes.

Ethnic/racial disparities are evident in the numbers and types of stressors and the emotional experiences of pregnancy and birth outcomes. Regarding PPD, the majority of evidence suggests that African American and Latina women experience higher rates than non-Hispanic White women (e.g., Rich-Edwards et al., 2006). This disparity persists even when SES is taken into account (e.g., McLennan, Kotelchuck, & Cho, 2001). In addition, African American women have higher rates of poor birth outcomes with rates nearly twice as high as those of other groups, even after controlling for SES. Perceived racism and discrimination during pregnancy and over a mother's lifetime may contribute to this disparity (e.g., Parker-Dominguez, Schetter, Mancuso, Rini, & Hobel, 2005). Importantly, these effects are independent of other stressors.

Mexican American women, or those born in the United States of Mexican descent, have higher levels of perceived social stress, have more exposure to chronic stressors, and may be more likely to be depressed than Mexican immigrant women. However, pregnant Mexican immigrant women have been found to experience higher levels of pregnancy-related anxiety (Fleuriet & Sunil, 2014). Finally, all Latinas (foreign born and US born) report feeling more pregnancy anxiety than European American women living in California (Campos et al., 2008).

Close Relationships

Partners, family, and friends are common sources of support in life especially during pregnancy. Social support refers to perceived available and received, or enacted, support, both of which can have an impact on the emotional experiences and outcomes of pregnancy. Support may be material, task, emotional, or informational (i.e., advice), and it may be effective or ineffective (Rini, Schetter, Hobel, Glynn, & Sandman, 2006). Generally speaking, greater prenatal support appears to predict better birth outcomes including better fetal growth and higher birthweight (e.g., Hedegaard, Henriksen, Secher, Hatch, & Sabroe, 1996).

Social support may also moderate, or buffer, the negative influences of stressors on the emotional experience and outcomes of pregnancy. Some support for this exists. For instance, in a study of pregnant women, social support was associated with higher birthweight, but this effect existed only for those women who reported experiencing high numbers of stressful life events (Collins, Schetter, Lobel, & Scrimshaw, 1993).

Though relationships can be sources of support, relationships can also be sources of stress in general and for pregnant women specifically. When a woman has few social connections or support from family and friends is inadequate, poorer birth outcomes are more likely including shorter gestational length, smaller size at birth, and preterm birth.

Perhaps the most important relationship during pregnancy is that between the mother and the baby's father. Fathers who provide material and task assistance and who are perceived as emotionally supportive can be key to a healthier pregnancy. On the flip side, negative interactions and, in the extreme, intimate partner violence can negatively impact a mother's health and that of her infant (e.g., depressive symptoms; Urquia, O'Campo, Heaman, Janssen, & Thiessen, 2011).

Health Behaviors

Smoking during pregnancy is associated with increased risk of giving birth to an infant of low birthweight and with premature delivery (Butler & Behrman, 2007). Low maternal education, low income, and non-Hispanic White ethnicity as well as stress are predictors of smoking during pregnancy (Mathews, 2001). The mechanisms by which unhealthy behaviors during pregnancy explain the influence of stress on adverse birth outcomes remain largely unknown. Nonetheless, there is evidence that expecting mothers who experience high levels of pregnancy-specific stress, e.g., concerns about medical care, physical symptoms, and bodily changes during pregnancy, smoke cigarettes more often during pregnancy and are more likely to deliver a low birthweight infant (Lobel, 2008). Regular and moderately intense physical activity throughout pregnancy is associated with optimal pregnancy and delivery outcomes (Clapp, Kim, Burciu, & Lopez, 2000). For example, women who begin exercising regularly early in pregnancy and continue to delivery have given birth to higher birthweight infants compared with women who did not exercise regularly.

Sociocultural Influences

Researchers have explored the extent to which an expectant mother's cultural background positively influences the support she receives throughout her pregnancy and even affects her pregnancy health and birth outcomes. Of particular interest is *familism*, a cultural value that is high among Latinos and highlights the importance of emotionally positive, supportive family relationships (Freeberg & Stein, 1996). In a sample of foreign-born Latina, US-born Latina, and European American pregnant women, familism was positively associated with social support and negatively associated with stress and pregnancy anxiety (Campos et al., 2008). Interestingly, for foreign-born Latinas only (not those born in the United States), social support predicted higher infant birthweight. Thus, sociocultural factors as they influence close relationships figure prominently in both maternal mental health and healthy outcomes such as birthweight.

Religiousness and Spirituality

Pregnancy and childbirth are times in the lives of women and families when religiousness and spirituality are especially salient. The birth of a child often occasions discussions of religious issues including religious rituals surrounding birth and parental decision making about religious rearing of children. A small literature shows that religious participation and spiritual behaviors and experiences are associated with lower PPD. Recently, work by our group with African American women found that both religiosity and spirituality independently predicted favorable trajectories of depressive symptoms over the 6 months after the birth of their children (Cheadle et al., 2015). These studies and others indicate that religiousness and spirituality have implications for better emotional experiences of pregnancy.

Conclusions

In summary, pregnancy and birth outcomes are impacted by many complex factors in the lives of mothers at the individual, family, and sociocultural levels that can be sources of stress and of resilience. During pregnancy, women are at greater risk of mood disorders and experiencing pregnancy-related anxiety and depressive symptoms with consequences for birth outcomes and, ultimately, for the well-being of children and families. Low SES and its sequelae also have extremely adverse and sometimes compounding effects on birth and developmental outcomes. There are also ethnic/racial disparities both in terms of mental health during pregnancy and birth outcomes with African American and Latina women experiencing worse mental health and poorer birth outcomes, whereas cultural factors such as familism and collectivism are associated with better mental health during and after pregnancy. In general, resilience resources may enable poor and lower educated women to function well despite low SES. Women's close relationships can also have positive influences on pregnancy and birth outcomes; however, unsupportive or abusive relationships are clearly harmful. Some health behaviors such as smoking, use of other substances, and unhealthy diet are associated with poorer birth outcomes, whereas positive health behaviors like moderate exercise are associated with better outcomes.

The physiological changes of pregnancy are relatively well established and normative, yet knowledge on psychological and sociocultural factors and how they interact with biological processes to impact mental and physical health during and after pregnancy and birth outcomes is underdeveloped. Past research clearly demonstrates that stress and resilience matter to the experience and health of a pregnancy, yet there is much we still can learn and use to help women and their families including how to have a healthy preconception period. Future research should focus on the physiological impacts of stress on mothers, pregnancy experiences, and infants and the interaction of these effects with resilience factors.

Author Biographies

Alyssa C. D. Cheadle, PhD, is an assistant professor in the Psychology Department at Hope College in Holland, Michigan. She received her PhD in Psychology from the University of California, Los Angeles, in 2016. She conducts research on religiousness, spirituality, and mental and physical health and mechanisms underlying the effects. Her previous research focused on these topics in pregnant and postpartum women, and she has studied the health effects of forgivingness.

Isabel F. Ramos, MA, is a doctoral student in Health Psychology at the University of California, Los Angeles. She received her BA in Psychology from UC Riverside. Isabel now investigates stress and anxiety in pregnant women of diverse ethnicities. Her research examines ethnic and racial disparities in maternal health and cultural factors that influence perinatal biopsychosocial processes. Her work has shown that pregnancy anxiety predicts the timing of delivery in Latina, White, and Black women.

Christine Dunkel Schetter, PhD, is a professor of psychology and psychiatry at the University of California, Los Angeles. She received her PhD from Northwestern University and completed postdoctoral training at UC Berkeley with Richard Lazarus. Her research expertise is in stress, coping, and social support in a variety of health and mental health contexts with primary focus on stress processes in pregnancy. She is proud of her many lab members, past and present, including Dr. Cheadle and Ms. Ramos.

Subjective Health Norms

Allecia E. Reid[1], Molly B. Hodgkins[2], Carly A. Taylor[3], and Alexandra A. Belzer[1]

Psychologists, sociologists, and others interested in human behavior have long recognized that the attitudes and behaviors of others bear influence on our own attitudes and behaviors. These social norms reflect common standards for behavior, set by and for members of a social group. Although a number of types of social norms have been examined, a large body of research has specifically focused on Cialdini, Reno, and Kallgren (1990) distinction between descriptive and injunctive norms. Descriptive and injunctive norms capture the distinction between the *is* and the *ought* of behavior. That is, while descriptive norms reflect perceptions of how most others behave in a given situation, injunctive norms capture perceptions of what is commonly approved or disapproved by most others. For example, a descriptive norm might reflect that most individuals in an environment smoke cigarettes. However, the corresponding injunctive norm might reflect that most individuals disapprove of smoking due to its negative health effects.

Much research has also examined subjective norms, a construct proposed as a determinant of intentions to engage in a behavior in the theories of reasoned action and planned behavior. Subjective norms differ from the broader conceptualization of injunctive norms in that they assess whether specific valued individuals (e.g., family members, one's doctor) approve of a behavior, rather than whether a generalized group of others approve of the behavior. The present entry focuses on the broader conceptualization of injunctive norm, incorporating research that has assessed subjective norms where appropriate.

Descriptive and injunctive norms have distinct motivational underpinnings and therefore are likely to operate under different circumstances (Cialdini & Trost, 1998; Jacobson, Mortensen, & Cialdini, 2011). Descriptive norms are most likely to motivate behavior when accurate decision making is of importance and are particularly influential in novel situations or when the appropriate course of action is unclear. Injunctive norms, on the other hand, exist to support the formation and maintenance of social bonds with important groups or individuals.

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.
General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

As a result, injunctive norms motivate behavior primarily through the threat of social disapproval for inappropriate behavior or the promise of approval for conformity. Conformity to injunctive norms is therefore most likely when social approval concerns are heightened.

Questions have been raised about the distinctiveness of descriptive and injunctive norms. Indeed, the manner in which others behave is often consistent with what is approved of by most others. However, confirmatory factor analyses examining descriptive and injunctive norms for calcium consumption, exercise, and eating behaviors, among others, support that the two are distinct, unitary constructs. Further, as demonstrated in the smoking example above, descriptive and injunctive norms can convey opposing information for the same behavior. This contradiction is often evident in public service announcements and health interventions that depict unhealthy behaviors as regrettably common, conveying a favorable descriptive norm, but widely disapproved, conveying an unfavorable injunctive norm.

Influences of Norms on Health Behaviors

Previous research has examined whether descriptive and injunctive norms predict intentions or behavior with respect to health risk, health protective, and health screening behaviors.

Health Risk Behaviors

In the context of health risk behaviors, perceptions of norms play particularly prominent roles in use of cigarettes, alcohol, and other drugs among adolescents and young adults. Research has documented associations of descriptive norms with increases in substance use up to 2 years later. Supporting the view that descriptive norms are particularly influential in novel situations, preexisting perceptions of descriptive norms influence alcohol use across transitions into new situations, such as matriculating to college and studying abroad. The literature is mixed regarding the influence of injunctive norms on alcohol and drug use relative to descriptive norms. Prospective research has demonstrated roles for both norms in alcohol and cigarette use, only an influence of descriptive norms on alcohol use, and only an influence of injunctive norms on alcohol use. Although much of the health risk literature focuses on adolescents and young adults, norms also influence adults' behaviors. For example, descriptive but not injunctive norms longitudinally predict sharing needles and other drug equipment among middle-aged injection drug users.

The trend toward finding associations between substance use outcomes and descriptive but not injunctive norms may reflect that these behaviors often occur with peers in social settings, a situation that likely enhances the salience and therefore the impact of descriptive norms relative to injunctive norms (Cialdini et al., 1990). Moreover, recognizing and conforming to others' behaviors requires less cognitive processing and potentially engages a faster motivational system than considering others' approval of the behavior (Cialdini, 2003; Jacobson et al., 2011). As a result, descriptive norms may generally more strongly influence behaviors that occur primarily in social contexts.

Health Protective Behaviors

Descriptive and injunctive norms also both play roles in health protective behaviors. This literature, drawing heavily on the theories of reasoned action and planned behavior, has demonstrated that the influence of norms on behavior is fully mediated by intentions. As a result, cross-sectional examinations of the relationships between norms and intentions are common, with longitudinal examination of the influence of intentions on behavior.

Descriptive and injunctive norms have demonstrated associations with intentions and occasionally behavior for a range of health protective behaviors, including sun protection, fruit and vegetable consumption, diet, and physical activity. Meta-analysis also supports cross-sectional and longitudinal associations of both norms with condom use. Both norms also relate to intentions for receiving vaccinations to protect against human papillomavirus and swine flu, with injunctive norms predicting later uptake of the HPV vaccine. Among the limited studies that have simultaneously examined both descriptive and injunctive norms, the balance indicates that descriptive norms are more strongly associated with intentions to engage in healthy eating, calcium consumption, exercise, and other health behaviors. The salience of others' behavior may explain the stronger influence of descriptive norms on outcomes that are publicly visible. Ceiling effects may also mitigate the role of injunctive norms in this domain, with individuals perceiving little, if any, disapproval for protecting one's health by eating healthily, exercising, etc.

Screening Behaviors

Injunctive and descriptive norms are also both related to screening behaviors. However, research has found that injunctive norms bear stronger influence on intentions to obtain a mammogram, a colonoscopy, and prostate cancer screening than descriptive norms. Likewise, only injunctive norms predict intentions to undergo screening for sexually transmitted infections or uptake of prostate or colorectal cancer screening. Of course, alternative findings exist. Nonetheless, the stronger influence of injunctive norms on screenings may reflect lack of confidence in perceptions of the extent to which others engage in these private behaviors. Indeed, lack of confidence in norm perceptions has been found to weaken the impact of norms. On the other hand, we may infer that health screenings are widely approved of by others, as conveyed by public service announcements encouraging monitoring one's health. The types of behaviors for which injunctive versus descriptive norms are likely to influence intentions and behavior require more careful scrutiny in future research.

Using Norms to Change Behavior

Whether norms can be used to change behavior, which typically requires prolonged effort and self-regulation, is ultimately of interest. Social norms theory (Perkins & Berkowitz, 1986) forms the basis of most research that uses social norms to promote healthier behaviors. From the perspective of this theory, perceptual biases and reliance on heuristics lead to a general tendency to overestimate the extent to which others engage in and approve of risky behaviors but underestimate others' engagement in and approval of protective behaviors. For example, young adults overestimate the level of sexual activity among peers and underestimate peers' condom use. Misperceptions have also been documented with respect to alcohol, tobacco, marijuana, and other drug use. Women also incorrectly believe that other women are thinner than they themselves are and that men find overly thin women attractive.

Given the existence of these misperceptions, the social norms approach proposes that making individuals aware of the true norms in their environment should recalibrate their perceptions of the norms, producing positive changes in behavior. These norm reeducation approaches have primarily been applied to health risk and health protective behaviors. Most studies have taken either a social norms marketing or personalized normative feedback approach, with fewer studies utilizing alternative methods.

The social norms marketing approach simply presents participants with information about the norms for behavior among peers, without addressing participants' own behavior or misperceptions of the norm. For example, this type of message might state, "More than 90 percent of the time, people in this building use the stairs instead of the elevator," communicating a descriptive norm that favors staircase over elevator use (Burger & Shelton, 2011). Social norms marketing messages are often delivered via advertisements placed in key locations but may also be delivered individually. Descriptive social norms marketing has demonstrated efficacy in increasing occupational physical activity, fruit consumption, salad consumption, and interest in chemotherapy. This approach has also demonstrated efficacy in improving alcohol use, intervening with friends who may be drinking too much, and intentions for condom use. Although descriptive social norms marketing has been applied to encouraging cancer screening, its efficacy in that domain remains unclear. Importantly, social norms marketing has been shown to alter perceptions of the descriptive norms, and in turn, changes in descriptive norms fully mediate or account for intervention-induced change in behavior.

The few studies that have used social norms marketing to address injunctive norms have documented mixed efficacy. Thus, additional research is needed to clarify whether this is a viable means for altering injunctive norms. It should be noted that the studies described above differ from mass media marketing campaigns in that they either delivered interventions to participants individually or displayed messages in conspicuous locations and also observed participants' behaviors in the same setting. Mass media efforts that employ normative information can be efficacious (Perkins, Linkenbach, Lewis, & Neighbors, 2010) but may also prove ineffective (Wechsler et al., 2003) because the target audience may not sufficiently processes these messages.

Personalized normative feedback, a complementary approach for altering normative perceptions, typically compares three pieces of information: (a) the individual's perceptions of the norms in his or her environment (e.g., perceptions of the extent of alcohol use among peers), (b) the actual descriptive norm in the environment (e.g., actual level of alcohol use among peers derived from surveys), and (c) the individual's own behavior. A comparative efficacy trial found social norms marketing and personalized normative feedback to be similarly efficacious (Neighbors et al., 2011). However, the use of individually tailored content in personalized feedback should hypothetically enhance the self-relevance of the message, thereby encouraging both greater depth of processing and better maintenance of behavior change over time.

As with the social norms marketing approach, personalized normative feedback studies have primarily focused on descriptive norm information. This type of feedback has been utilized both individually and in a group setting as a stand-alone intervention to reduce college students' alcohol use. It is also the primary active ingredient through which multicomponent interventions reduce college students' alcohol use. Personalized descriptive norm feedback was also recently shown to reduce alcohol-induced risky sexual behavior. Further, personalized descriptive norm feedback, whether in single or multiple component interventions, is efficacious because it alters perceptions of the descriptive norms, which in turn drive behavior change. Personalized injunctive norm feedback has received little attention but has been shown to improve women's sun-protective behaviors. Future research might examine whether personalized injunctive norm feedback reliably alters behavior.

The large literature examining the use of personalized normative feedback in the context of college student drinking provides insight into conditions that maximize its impact (Reid &

Carey, 2015). Specifically, although normative information is highly portable and can be delivered via the web or mail, normative feedback is in fact less effective when delivered remotely, rather than by a counselor or computer in person. Remotely delivered interventions suffer because recipients often engage in other activities (e.g., texting, listening to music) while completing the intervention (Lewis & Neighbors, 2015). In addition, it is important to choose the optimal referent group to serve as the basis for the normative message. In general, normative data referencing peers in the same environment is more effective than norms derived from national data. Gender differences in alcohol consumption necessitate providing gender-specific norms, but the utility of this specification likely varies by behavior. It is possible, however, that a referent group might be too specific. LaBrie et al. (2013) found that students held more accurate perceptions of the norms for students of the same gender, ethnicity, and Greek status, relative to norms for "the typical student." Given that there was little to correct, feedback on the gender–ethnicity–Greek specific norms was associated with *decreased* likelihood of behavior change. It is therefore important to identify the optimal referent group for each behavior of interest.

As noted above, alternative methods exist for altering perceptions of norms in service of behavior change. One unique approach centers on labeling undesirable behaviors as normative among members of an out-group. Berger and Rand (2008) provided undergraduates with information that high-fat food consumption and heavy alcohol use were common among out-groups with which they did not want to be associated. This increased selection of healthy foods and reduced alcohol use among message recipients as a means to avoid being incorrectly labeled as members of these undesirable groups. A second alternative method focuses on aspirational peers and demonstrates that norms have shifted over time. Jackson and Aiken (2006) improved sun protection among young women through photographs demonstrating that tanned skin was common in the past but was no longer popular among present day actresses. This approach might be extended to address other observable behaviors. A third alternative approach involves facilitating structured interactions with peers in group settings such that healthy norms are elicited and supported. Participating in intervention sessions with peers has been shown to alter perceptions of norms for healthy eating among firefighters, safe injection practices among injection drug users, and thin-ideal endorsement and dieting among women with eating disorders (e.g., Ranby et al., 2011). Mediation analyses supported that the effects of these peer-centered interventions on behavior change were explained by changes in normative perceptions.

Moderators of Norm-Based Interventions

Previous research examining individual differences that may moderate the effect of norms on behavior change have fallen into three main categories: level of identification with the referent group, sensitivity to external pressures, and extent of discrepancy between perceptions and the true norms. Consistent with social identity theory (Tajfel & Turner, 1979), research has found descriptive norm interventions to be particularly efficacious for individuals who identify most strongly with the referent group. Similarly, norm interventions show increased efficacy among individuals who are more sensitive to social pressures because they fear being negatively evaluated, drink alcohol primarily for social reasons, or seek out cues in the environment to determine how to behave. Finally, consistent with social norms theory, the more individuals misperceive the norms in their environment, the more likely they are to change their behavior after having their perceptions corrected. Given these moderators, researchers should be attentive when selecting a referent group and might maximize discrepancy by selecting cognitions for feedback that evidence the largest discrepancies at the individual level, rather than at the group level. Additional research is needed to determine whether social norms interventions can be enhanced for those less sensitive to social forces or if an attitudinal appeal is more appropriate for these individuals.

Future Directions and Conclusions

As indicated above, few studies have utilized injunctive norms to change behavior. While additional research is needed on injunctive norms, normative information is likely to be most influential when descriptive and injunctive norms correspond with one another (Cialdini, 2003). Accordingly, research that compares a combined norms condition against separate descriptive and injunctive norms conditions may find support for this contention, as in previous research on sun protection.

An additional consideration is whether altering normative perceptions affects other psychosocial constructs en route to behavior change. Reid and Aiken (2013) demonstrated that the effect of injunctive norm feedback was mediated by not only change in injunctive norms but also change in attitudes. Exploring whether additional psychological constructs transmit the effects of descriptive and injunctive norms will aid in identifying conditions that are likely to maximize their impact.

In sum, correlational and experimental research support that social norms influence health behaviors. Though unresolved issues remain, research confirms descriptive and injunctive norms are indeed strong motivators of behavior that have much to offer in both characterizing and improving health behaviors.

Author Biographies

Allecia E. Reid is an assistant professor of psychology at Colby College. Her research examines the influences of social norms and peer social networks on health behaviors. She studies mediators and moderators of the influences of these social factors, the use of social norms information for motivating healthier behavior, and techniques for protecting individuals against the negative influence of peers.

Molly B. Hodgkins completed a bachelor's degree in psychology from Colby College in 2015. She is currently pursuing a master of social work at the University of Maine. Molly's research has primarily focused on how feelings of social belonging influence well-being in college students.

Carly A. Taylor completed a bachelor's degree in psychology from Colby College in 2015. She is currently a patient navigator at Boston Medical Center. Carly's research interests include developing interventions to reduce stigma associated with mental illness. Consistent with her goal of becoming a medical doctor, she is also interested in improving doctor–patient interactions as a means for improving patient outcomes.

Alexandra A. Belzer is an undergraduate at Colby College, where she is a research assistant in Dr. Reid's lab. Alexandra is broadly interested in the connection between psychological factors and health outcomes. Her research interests focus on understanding and reducing the negative influence of social norms on health behaviors.

Temptation

David A. Kalkstein[1] and Kentaro Fujita[2]

[1]*Department of Psychology, New York University, New York, NY, USA*
[2]*Department of Psychology, The Ohio State University, Columbus, OH, USA*

Temptations are stimuli in one's immediate environment that prompt thoughts, feelings, and behavior that are contrary to one's goals and values. Temptations rest at the heart of self-control dilemmas—decisions that require choosing between smaller-immediate and larger-distal outcomes (e.g., Mischel, Shoda, & Rodriguez, 1989). Motivationally, self-control can be understood as a conflict between competing motivations—a desire for something now versus a desire for some other outcome of greater magnitude (Fujita, 2011). The ability to secure some small outcome immediately may tempt people to forgo outcomes that are more valuable yet not immediately available. Dieters, for example, might be tempted to abandon their weight-loss efforts when presented with an opportunity to eat chocolate cake now. Substance abusers may struggle to advance their desire to be sober when their drug of choice is freely available. The end of a long, hard day in the office may tempt the sedentary to watch TV rather than work out at the gym. Successful self-control requires overcoming temptations, advancing the pursuit of larger-distal ends over these smaller-immediate outcomes. The omnipresence of temptations in one's social environment poses one of the greatest challenges to achieving and maintaining personal health. Although people may value health, securing and maintaining this end requires overcoming numerous temptations—that is, self-control.

It is important to observe that temptations are subjective in nature. What constitutes a temptation depends on idiosyncratic motivations, values, goals, and desires, which vary from person to person. What represents a temptation for one person may not necessarily represent a temptation for another. First, people must find temptations appealing in some way. Chocolate cake may represent a temptation for someone who likes chocolate. This same object, however, would not represent a temptation for someone who dislikes the taste of chocolate. Second, even when the immediate outcome is desirable in some way, it is only a temptation to the extent that it competes with or undermines some more valuable end. For example, although the allure of cake may represent a temptation for someone concerned with weight loss, it would not represent a temptation for someone unconcerned about their weight. Without this

General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

conflict, rewarding stimuli are simply rewarding stimuli, not temptations. What makes a stimulus a temptation is that it idiomatically makes people "want their cake and eat it too"—it evokes a situation in which two competing desires are activated, only one of which can be satisfied. Critically, of these two competing desires, one can be satisfied immediately yet is of lesser value, whereas the other cannot be satisfied immediately yet is of greater value. In short, for a stimulus to be considered a temptation, it must *both* appeal to immediate desires and impede progress toward more distal but more valued ends.

Self-control is not generally viewed as a problem of knowledge. Self-control failure is defined by acting on a temptation despite knowing in some way that doing so is detrimental to securing more valuable outcomes. To take an extreme example, suppose some dieters erroneously believe that eating donuts will lead to weight loss. It would be inappropriate to label these donuts as temptations for these individuals, just as it would be inappropriate to label their behavior as a self-control failure, since they did not know that eating donuts would harm their weight-loss goals (in this example, the dieters actually thought that eating these donuts would help advance those valued goals). Objects are not temptations if individuals acting on them are not aware implicitly or explicitly that acting on them is detrimental to their broader objectives.

A final, often overlooked, aspect of temptations that is important to consider is that temptations come in the form of both positive *and* negative incentives. One can be tempted by a desire to obtain some smaller yet immediate rewards at the expense of larger yet not immediately available rewards. Examples of this type of temptation include the enjoyment of consuming tasty yet unhealthy food, the highs substance abusers experience from taking harmful drugs, or the hedonic pleasure of engaging in risky sexual behaviors. One might also, however, be tempted by a desire to avoid some smaller yet immediate cost. Examples of this type of temptation include wanting to avoid the discomfort associated with strenuous exercise, the inconvenience and anxiety associated with diagnostic medical tests, and the negative minor side effects of drug regimens. In short, temptations can correspond to desires to obtain proximal rewards or to avoid proximal costs, as both forms have the potential to conflict with and derail more valued goals and objectives.

Deleterious Effects of Temptations

Much of the work done on self-control in the field of psychology has focused on the deleterious impacts of temptations on people's goal-directed behavior (Kelley, Wagner, & Heatherton, 2015). Generally, this work tends to argue that exposure to temptations leads to self-control failure because it triggers cravings and urges to act on immediately gratifying motivations. For example, tobacco users and drug addicts report the strongest urges to use drugs during, or immediately following, exposure to temptation cues such as drug paraphernalia, pictures of drugs, or *in vivo* presentations of drugs or tobacco (see Carter & Tiffany, 1999).

This research argues that these cravings and impulses influence thoughts, attitudes, and behaviors in the direction of favoring indulgence in the temptation. Evidence for this idea comes from the finding that exposing dieters to tempting food cues (e.g., the smell of fresh baked pizza) leads dieters to report stronger cravings to indulge, which subsequently predicts greater consumption of unhealthy foods (for review, see Kelley et al., 2015). At the neural level, researchers have shown that increases in activity in regions of the brain that process rewards (the nucleus accumbens) in response to temptation cues predict future indulgence in those temptations (Kelley et al., 2015). Indeed, a great deal of research across a variety of health domains has documented cases in which exposure to a temptation cue increases the likelihood of indulgence in that temptation and hence self-control failure.

Underlying much of this work is an implicit (or sometimes explicit) assumption that exposure to temptations automatically activates positive thoughts, feelings, and behavioral tendencies that promote indulgence (e.g., Baumeister & Heatherton, 1996; Fujita, 2011). These automatic impulses influence behavior unless people inhibit or override them. This inhibition process, however, is believed to be effortful, requiring sufficient cognitive and motivational resources. It follows from these premises that any burden on these resources, such as cognitive load or distraction, reduces the likelihood that people will successfully inhibit these impulses, thus leading to an increased likelihood of indulging in temptation.

One especially influential line of research has proposed that this effortful inhibition process not only requires having sufficient cognitive resources but also depletes a motivational resource, much like a battery or muscle (Baumeister & Heatherton, 1996). Proponents of this limited resource model of self-control suggest that all acts of self-control draw on the same limited supply of energy and that an initial exertion of self-control will result in a period of depletion and thus a temporarily diminished capacity to inhibit further automatic impulses that favor temptations. For example, Vohs and Heatherton (2000) showed that dieters who restrained from eating popcorn in an initial task subsequently ate more ice cream on a following task. Similarly, Hofmann, Rauch, and Gawronski (2007) showed that after regulating their emotional responses during an initial movie viewing task, participants' candy consumption was predicted by their automatic attitudes toward candy (which tended to be positive) rather than their dietary restraint standards. These findings support the idea that when people lack the requisite energy to engage in effortful inhibition and are thus "depleted," their behavior is more susceptible to automatic temptation impulses and self-control failure.

Overcoming Temptations

Despite the abundance of research demonstrating the deleterious consequences of exposure to temptations, people also possess a remarkable array of psychological mechanisms and behavioral strategies at their disposal for dealing with temptations.

Motivation to Overcome Temptations

The question of how to overcome and resist temptations is fundamentally a question about how to maintain the motivation to behave in line with valued ends when confronted with the opportunity to indulge in more immediate rewards. The more motivated people are to achieve these more distal ends, the more likely they will be to initiate, engage, and persist in coping behaviors and strategies to deal with and overcome temptations (Trope & Fishbach, 2000). The role of motivation is particularly evident in situations that research suggests people are most vulnerable to temptations—when their cognitive and motivational resources are taxed. For example, providing monetary incentives to increase people's motivation to resist temptation has been shown to improve people's self-control even following periods of depletion (for review, see Masicampo, Martin, & Anderson, 2014). The nature of people's motivation also appears to play an important role in self-control. Research suggests that when people are intrinsically rather than extrinsically motivated—when they are pursuing an end that they are personally relevant and important—they are less susceptible to depletion (see Masicampo et al., 2014).

Research, moreover, indicates that people's beliefs about themselves can impact their motivation to exert the necessary effort to overcome temptations. Motivational theories suggest that bolstering people's beliefs that they are indeed capable of resisting temptation and procuring more desirable end states (i.e., self-efficacy; Bandura, 1977) should increase their self-control motivation and help them resist temptations. Indeed, it has been shown that increasing people's self-efficacy beliefs about their ability to quit smoking and their ability to lose weight results in greater smoking reduction and more weight loss (for review, see Strecher, DeVellis, Becker, & Rosenstock, 1986).

Beyond self-efficacy, research also points to the important role of people's beliefs about the nature of self-control in their successful resistance to temptations. Research indicates that some endorse a limited view of self-control—a belief that one's ability to resist temptations is finite and can be depleted—whereas others do not (Job, Dweck, & Walton, 2010). Endorsing the view that self-control is limited appears to lead people to give in to temptation more readily, whereas endorsing a more unlimited view appears to motivate more sustained effort to overcome temptation. For example, those who endorse a limited versus unlimited view of self-control tend to eat less healthily, achieve poorer grades, and show less persistence in the face of difficulty (Job, Walton, Bernecker, & Dweck, 2015). Research, moreover, indicates that these beliefs can be changed, suggesting the possibility of leveraging these beliefs about the nature of self-control as a potential point of intervention (Job et al., 2010).

Cognitive Habits

Given sufficient motivation, research suggests that people can develop what might be termed "cognitive habits" to enhance resistance to temptation. In other words, although self-control is often believed to be effortful and involve intensive use of psychological resources, research suggests that people can automate their psychological responses to temptations and be successful in self-control without such resource-intensive effort. Those highly committed to dieting goals, for example, evidence a cognitive readiness to evaluate tempting foods negatively (Fishbach & Shah, 2006). These automatically activated attitudes induce a readiness to resist temptations without requiring effortful deliberation and control.

Beyond evaluations and attitudes, research suggests that sufficiently motivated individuals also develop cognitive associations that bias their thoughts in favor of valued ends rather than more immediate smaller rewards. Self-control should be enhanced to the extent that thoughts about temptations cue thoughts about overriding goals (e.g., "cake" cues "weight loss"), whereas thoughts about those overriding goals does not reciprocally cue thoughts about temptations (e.g., "weight loss" does not cue "cake"). This asymmetric pattern of activation should in turn bias more frequent thoughts about overriding goals rather than temptations. Indeed, research suggests that those committed to their goals are those most likely to display these adaptive asymmetric temptation–goal associations (Fishbach, Friedman, & Kruglanski, 2003). Importantly, people display these associations even under suboptimal processing conditions, such as states of cognitive load—suggesting that these processes may enhance self-control efficiently and without requiring the intensive effort that is commonly assumed necessary for resisting temptations.

It is often assumed that "cognitive habits" to overcome temptations require repeated practice over time, much like a learned skill. However, research suggests that these habits can develop relatively quickly through what is referred to as "implementation intentions" (Gollwitzer & Sheeran, 2006). Implementation intentions are simple "if-then" action plans that link anticipated situations or cues with goal-directed behavior (e.g., "If I'm bored and want a snack, then I will eat an apple!"). They are designed to automate goal-directed behavior such that when a given cue is encountered (e.g., "I am bored"), people will automatically react with their stated intention (e.g., "eat an apple"). Research has shown that these simple plans can increase health behaviors such as cancer screenings, exercise and physical activity, and dietary restraint and appears to do so by promoting self-control in the face of temptations and under suboptimal processing conditions such as resource depletion (for a review of findings, see Gollwitzer & Sheeran, 2006).

Prospective Control

The most effective strategies that one can employ to overcome temptation may be those involving prospective control. Prospective control seeks to combat the allure of immediate temptations by developing strategies to overcome them prior to exposure. Classic research on self-control has shown that decisions that are made for the future and in the absence of temptations tend to be more in line with people's valued goals and best interests (Ainslie, 1975). Prospective control facilitates the overcoming of temptation by encouraging people to make decisions to pursue their more valued ends and committing to these decisions in advance of encountering temptations.

Prospective control strategies can be divided into two classes: strategies that seek to regulate the availability of temptations and strategies that seek proactively to regulate responses to temptations. Regulating the availability of temptations involves modifying behavior or selecting situations that make it less likely that one will be encountering temptations and thus less likely that they will feel impulses or desires to indulge the temptations. For example, a dieter who takes an alternative route to work in the morning to avoid the donut shop is utilizing prospective control. In this example, the dieter is purposefully avoiding the sight and smell of donuts that may serve as cues that trigger cravings to eat the donut. By reducing the availability of temptations and avoiding temptation cues, the dieter decreases the likelihood of breaking his diet by eating a donut. Other examples of regulating the availability of temptations and exposure to temptation cues would be a recovering alcoholic staying at home on New Year's Eve instead of going out to the bars, or a past drug addict refraining from hanging out with drug-using friends. Avoiding temptations from the outset is one of the most effective strategies that people can employ to decrease the likelihood of succumbing to temptation (Mischel et al., 1989). Individuals cannot give in to temptations upon which they never have the opportunity to act.

A second prospective self-control strategy that people can employ to overcome temptation is to regulate potential responses to temptations and precommit oneself to behavior in line with more valued ends. A typical precommitment strategy involves manipulating the contingencies and outcomes associated with acting on the temptation through means such as self-imposed penalties and success-contingent rewards (also referred to as "side bets"; Ainslie, 1975). In one demonstration of self-imposed punishment, Trope and Fishbach (2000) presented people with a medical screening opportunity that promised to provide accurate and useful health information but entailed uncomfortable procedures. To protect their health goals from the temptation of averting physical discomfort, participants agreed to pay higher monetary fines for failing to meet their screening appointment. People also will structure self-control decisions to render rewards contingent on success. In another study by Trope and Fishbach, participants preferred to delay receiving a monetary reward until after (rather than before) they completed the medical screening. By self-imposing penalties and making rewards contingent on success, these strategies served to precommit people to a course of action that served their more valued health goals.

Implementation intentions, which were discussed earlier, can be viewed as a form of prospective control in that they are designed to regulate responses to temptations proactively by specifying action plans prior to exposure. So while self-imposed penalties and success-contingent rewards regulate responses by changing the cost–benefit contingencies of acting on temptation, implementation intentions regulate responses by automating responses to be in line with more valued ends. As reviewed earlier, research suggests that implementation intentions are indeed an effective means of countering negative influence of temptations, particularly in the health domain (e.g., Gollwitzer & Sheeran, 2006).

The Role of Construal

Another major factor that influences people's motivations to overcome or indulge in temptations is their construal of the temptation. It is a truism of modern psychology that people's understanding and experience of the world is subjective in nature. The same object or situation can be construed and experienced by different people in different ways or by the same person in different ways depending on the context and that person's motivations. For example, consider a candy bar. A candy bar can be construed as "tasty snack" or as a "fattening overindulgence." Clearly, these different construals have different evaluative connotations and suggest divergent responses to the same target. Construing the candy bar as a "tasty snack" promotes consumption and may promote self-control failure among those concerned about weight loss. By contrast, construing the candy bar as a "fattening overindulgence" promotes restraint and may promote self-control success among those concerned about weight loss. In this way, how people construe temptations may impact their self-control decisions.

Research suggests that changing people's construals of temptations is a particularly effective strategy for dealing with and overcoming temptations. The less people incorporate the alluring and rewarding features of the temptation into their construals of it, the less likely people are to want and pursue the temptation (Mischel et al., 1989). Similarly, the more people think about the temptation in terms of the more valued ends that it threatens to undermine, the less appealing it is and the less likely they are to succumb to it (Fujita & Carnevale, 2012).

However, one of the major challenges of self-control is that the immediacy of temptations available in the here and now often prompts people to construe them in concrete ways, leading them to be viewed as an isolated opportunity for visceral, tangible, and immediate reward. Such concrete thought tends to lead people to act on these more proximal motivations and indulge in the temptation. Research suggests that key to overcoming this tendency is adopting a more abstract construal (Fujita & Carnevale, 2012). Abstract construals extract the central, stable, and enduring aspects of a target or situation. Consider a choice between a candy bar and an apple. Whereas a concrete construal might focus deliberations on the pros and cons of "this candy" vs. "that apple," a more abstract construal focuses decision-making processes instead on the more essential, global features of the choice—namely, "hedonism" vs. "heath." In general, whereas concrete construals of temptations tend to highlight their rewarding properties, abstract construals relate temptations to a person's more valued goals and motives. These construals in turn change the experience of temptations by changing what the temptations mean to people. Abstract relative to concrete construals help individuals transcend the pull of the immediate situation to see the bigger picture and thus to evaluate, plan, and act in accordance with more global, superordinate goals and motives. Extensive research has shown that abstract construals help people resist alluring temptations and enhance self-control (Fujita & Carnevale, 2012).

Of note, research suggests that implementation of many of the psychological mechanisms and behavioral strategies discussed earlier (i.e., cognitive habits, prospective control) may be contingent on more abstract rather than concrete construals. Abstract rather than concrete construals of temptation, for example, lead people to associate temptations with negativity, which in turn promotes self-control (Fujita & Han, 2009). Similarly, asymmetric temptation–goal associations are more evident when people adopt more abstract versus concrete construals of temptations (Fujita & Sasota, 2011). Moreover, abstract rather than concrete construals promote the use of prospective self-control (Fujita & Roberts, 2010). Thus, people's construal of temptations appears to represent a key variable in promoting resistance to temptations.

Importance

The ubiquity of temptations in people's environments makes maintaining and sustaining personal health and well-being goals challenging. Although temptations can undermine health goals, people have at their disposal a wide variety of psychological tools to combat them. Indeed, research suggests that those better able to resist temptations are healthier, happier, and more well adjusted (e.g., Mischel et al., 1989). This link would thus suggest that understanding how people react to temptations and how they successfully overcome them is key to promoting and supporting health behavior change.

Author Biographies

David A. Kalkstein is a doctoral candidate in social psychology at New York University. David's research focuses primarily on how cognitive processes of abstraction aid in self-regulation, self-control, and social exchange.

Kentaro Fujita is an associate professor of psychology at the Ohio State University. His research focuses on why people so often make decisions and behave in ways that they know are contrary to their goals and values. To understand these self-control failures, Dr. Fujita's research draws from a number of areas in psychology, including motivation, cognition, self-regulation, and judgment and decision making.

Terror Management Health Model

Patrick Boyd and Jamie L. Goldenberg

Department of Psychology, University of South Florida, Tampa, FL, USA

The terror management health model (TMHM) builds on terror management theory (TMT), a social psychology theory concerning how people manage the psychological awareness of their own mortality, to offer unique insights into how concerns about mortality affect decision making with respect to health. The model assumes that in the context of health decision making, thoughts of death are likely to be activated; before the TMHM was introduced, no theory in health psychology had been offered to account for the unique defensive responses associated with the awareness of mortality.

Origins of the TMHM

In the early 1970s, cultural anthropologist Ernest Becker (e.g., 1973) was arguing that cultures provide belief systems that enable individuals to derive meaning and a sense of personal value in the face of existential uncertainty, brought about by the awareness of death. Then, in the late 1980s, a team of social psychologists (Greenberg, Pyszczynski, & Solomon, 1986) extended Becker's theorizing and developed TMT, providing an empirical framework for Becker's ideas. The first of two primary hypotheses proposed by this research team was that if culture functions to help individuals cope with death, cultural investments (or derogation of cultural belief systems that threaten one's own) should increase when death is salient. The second hypothesis concerned self-esteem striving: because self-esteem is derived from the cultural system within which one is embedded, attempts to bolster self-esteem by living up to cultural standards should also increase in response to the awareness of death.

After a decade of research supporting TMT, the theory underwent some conceptual fine-tuning. The researchers observed that worldview defense and self-esteem striving occurred reliably when individuals were reminded of their mortality and then distracted from it, or when death was subliminally primed. A dual-defense model was proposed (Pyszczynski, Greenberg, & Solomon, 1999) to explain the time course of worldview defense and

The Wiley Encyclopedia of Health Psychology: Volume 2: The Social Bases of Health Behavior, First Edition.

self-esteem striving, and critically, specifying that symbolic defenses concerning meaning and self-esteem are most strongly manifested when thoughts of death are activated outside of focal awareness. Specifically, the dual-defense model explains that when death thoughts are in focal awareness, individuals focus their cognitive resources on suppressing death thoughts. After suppression, worldview defense and self-esteem striving occur to ameliorate the residue of unconscious death thoughts.

Overview of the TMHM

Jamie Goldenberg and Jamie Arndt (2008) developed the TMHM to extend TMT to the health domain—a seemingly obvious but unexplored application of TMT. The TMHM begins with the assumption that health conditions have varying potential to make people think about death. The model then provides a formal framework for explaining, predicting, and ultimately intervening in behavioral health outcomes as a function of the accessibility of death thoughts.

Integrating the insights from the dual-defense model of TMT, the TMHM specifies that when mortality concerns are conscious, health decisions will be guided by the *proximal* motivational goal of removing death-related thoughts from focal attention by reducing perceived vulnerability to the health threat. This process can entail efforts to better one's health, but perceptions of vulnerability can also be reduced through less productive means, such as denial. In contrast, when mortality concerns are active but outside of focal attention, health relevant decisions are guided by the *distal* motivational goals of bolstering self-esteem and maintaining one's symbolic conception of self. Again, the implications can be both good and bad for health (e.g., sun protection or sun tanning)—but here motivations are focused on the value and meaning of the self.

Proximal TMHM Responses

To examine responses to conscious death thoughts with experimental methods, participants are typically asked to contemplate their mortality, usually with open-ended questions (e.g., "Jot down, as specifically as you can, what you think will happen to *you* as you physically die and once you are physically dead"), and immediately thereafter health responses are assessed. Perhaps not surprisingly, under such conditions people increase their intentions to exercise (Arndt, Schimel, & Goldenberg, 2003) and protect their skin from the sun (Routledge, Arndt, & Goldenberg, 2004) and also deny their vulnerability to health risk factors (Greenberg, Arndt, Simon, Pyszczynski, & Solomon, 2000).

Moreover, supporting the assumption that such responses reflect efforts to reduce perceived vulnerability to the health threat, variables relevant to coping with the health threats have been shown to moderate health outcomes when thoughts of death are conscious. This has been demonstrated by measuring perceived vulnerability (Arndt, Cook, Goldenberg, & Cox, 2007), response efficacy (Cooper, Goldenberg, & Arndt, 2010), active coping strategies (Arndt, Routledge, & Goldenberg, 2006), and health optimism (Arndt et al., 2006; Cooper et al., 2010). These studies converge to indicate that when individuals maintain optimism about their health, perceive a health response as effective, or approach health situations with active coping strategies, they respond to conscious reminders of death with health promotion. For example, Cooper et al. (2010) found that when death was in conscious awareness, participants high in health optimism responded with increased intentions to screen for cancer, whereas individuals low in this resource decreased their intentions. Moreover, these moderating effects were not found when death thoughts were allowed to recede from consciousness, nor were they observed in a health domain unrelated to death (i.e., cavity protection), further supporting the assumption that these defenses are aimed at managing death-related thoughts.

Distal TMHM Responses

When mortality concerns are active but outside of focal attention, the TMHM predicts that health decisions will be guided by the implications of the behavior for meaning and self-esteem rather than by the relevance for health. This research has examined the moderating potential of worldview beliefs (e.g., the effects of religious fundamentalism on prayer as a medical substitute; Vess, Arndt, Cox, Routledge, & Goldenberg, 2009) and the potential for physical inspection of the body (e.g., breast self-exams) to undermine symbolic value (e.g., Goldenberg, Arndt, Hart, & Routledge, 2008).

The lion's share of research, however, has focused on esteem contingencies. For example, in contrast to the immediate increase in sun protection intentions when death thoughts were conscious, Routledge et al. (2004) found that the women in their study (who had previously indicated being tan as relevant to their self-esteem) increased their intentions to tan when a delay followed the mortality salience prime and thoughts of death were presumably no longer in consciousness. Likewise, Arndt et al. (2003) not only found increased intentions to exercise immediately following the mortality reminder, but after a delay, participants who derived self-esteem from exercising also increased their intentions to exercise, whereas those low in fitness-contingent self-esteem did not. Similarly, Hansen, Winzeler, and Topolinski (2010) first identified individuals who derived self-esteem from smoking and then showed that they had more positive responses toward questions assessing smoking attitudes after viewing anti-smoking packaging that reminded them of their mortality. In another series of studies, women restricted their consumption of a healthy but fattening food when mortality concerns were activated, a behavioral decision presumably driven by esteem concerns rather than health (men's eating was unaffected; Goldenberg, Arndt, Hart, & Brown, 2005).

Interventional Potential of the TMHM

The TMHM framework informs what health outcomes can be expected as a function of the consciousness of death thoughts, and it also provides a framework for intervening in such outcomes. One interventional direction is to use conscious death-related thoughts to bolster the influence of more conventional health cognitions. For example, Cooper, Goldenberg, and Arndt (2014) found that presenting beach patrons with a communication that highlighted risk of death from cancer and simultaneously framed sun protection as effective resulted in increased sun protection intentions compared with when sun protection was framed as ineffective. This relationship was not observed in the non-death condition, or when a delay followed the cancer prime.

Given the finding that responses to nonconscious death thoughts depend on esteem contingencies and cultural beliefs, a complementary and more extensive wave of research targets the malleability of these bases so as to affect more productive health outcomes. In the domain of tanning, for example, Cox et al. (2009) found that participants given a mortality prime followed by a delay, who also read a fashion column touting "bronze is beautiful," increased tanning intentions, whereas participants primed with "pale is pretty" decreased intentions to tan under the same conditions. These findings were replicated among beach patrons in South

Florida who, in response to "pale is pretty" and nonconscious death thought activation, indicated that they would prefer sample lotions with higher SPFs.

Along similar lines, when thoughts of mortality are accessible but not conscious, smokers have been shown to be more persuaded by health communications highlighting the social disadvantages of being a smoker (Arndt et al., 2009), and women are more persuaded by feedback targeting appearance rather than health consequences of tanning (Morris, Cooper, Goldenberg, Arndt, & Gibbons, 2014). People are also more willing to get a flu shot when it is endorsed by a cultural icon (e.g., a celebrity) than when it is endorsed by a doctor, but only when death thoughts are outside of conscious awareness (McCabe, Vail, Arndt, & Goldenberg, 2014). This pattern is reversed when death thoughts are conscious, with participants showing greater willingness to get a flu shot when a doctor endorses it. In a naturalistic setting, supermarket shoppers were found to make healthier purchases when they were exposed to a questionnaire that nonconsciously primed mortality and then asked them to visualize a prototypical healthy eater (McCabe et al., 2015). These studies indicate that targeting social norms and bases of self-esteem can be effective routes to influencing health decisions and, importantly, that these motivations are most influential when death thoughts are activated but not conscious.

Implications and Conclusion

Integrating insights about how people manage existential concerns into a model of health decision making, the TMHM connects previously unconsidered factors influencing health decision making. Research in health psychology has identified important health cognitions (e.g., perceived vulnerability) and concerns about esteem and social norms, but until the TMHM was developed, the impact of mortality awareness on health had not been investigated. The TMHM offers a framework for understanding how conscious and nonconscious death thoughts interact with these other variables and identifies when health risk and health promotion outcomes will occur.

In addition, the TMHM offers insights that explain why some health promotion efforts fail. Consider the tactic of fear appeals. Though people may very well heed a cancer warning and put down their cigarette or lather on sunscreen, the TMHM predicts that these effects may be short lived. Once death thoughts have been suppressed, self-esteem concerns become paramount, and smoking or tanning efforts may increase to the extent that a person derives self-esteem from looking cool as a smoker or appearing bronzed and beautiful.

Since the inception of the TMHM in 2008, a growing body of support has accumulated. In addition, there is evidence documenting the effectiveness of an interventional approach informed by the TMHM. Going forward it will be important to investigate the durability of TMHM effects, as well as to continue to apply interventions utilizing the TMHM in naturalistic settings.

Author Biographies

Patrick Boyd received a BA in psychology from the University of Southern California in 2007 and an MA in social psychology from San Francisco State University in 2012. He began pursuing his PhD at the University of South Florida in 2013. His research generally focuses on terror management theory, and within this paradigm he has explored how self-worth that is contingent upon being healthful can globally predict behaviors in a variety of health contexts.

Jamie L. Goldenberg is a professor of psychology at the University of South Florida. Her area of specialization is social psychology with a focus on health behavior and women's health in particular. She is the developer of the terror management health model (TMHM) along with coauthor Arndt. Research on the TMHM has been funded for 10 years by the *National Cancer Institute* (*NCI*) and has resulted in dozens of publications, including a manuscript in *Psychological Review* depicting the model.

The Role of Persuasion in Health-Related Attitude and Behavior Change

Colin A. Zestcott and Jeff Stone

Psychology Department, University of Arizona, Tucson, AZ, USA

Persuasion processes play a central role in the public's health. Most health professionals, from doctors and nurses in a clinic to public health officials, rely on persuasion to prevent disease and illness and to gain compliance with health recommendations. Achieving these public health goals often requires getting people to change their health-related attitudes and behaviors. The goal of this entry is to review the major techniques for persuading health attitude and behavior change and the psychological processes that determine how and when people make changes.

For the purposes of this entry, we define *persuasion* as any attempt by an external source, or by the individual, to change a health-related attitude, behavioral intention, or behavior. Research on persuasion and health tends to target two types of behavioral outcomes: changing behavioral intentions, defined as a person's deliberate plan to adopt a specific health behavior, and changing the health behavior directly. Thus, the present entry will cover both types of behavioral outcomes. In addition, while many persuasive strategies are designed to change an individual's behavior, theories in psychology such as the theory of planned behavior illuminate the importance of understanding how attitudes guide future intentions and behavior. Thus, focusing solely on behavior as a main outcome of persuasion techniques in a health context may fail to provide a thorough understanding of the underlying mechanisms, such as the importance of attitude change, when evaluating the effectiveness of health behavior interventions.

In line with the broader literature, persuasion processes that target health attitude change tend to define *attitudes* as an evaluation of an object. According to Eagly and Chaiken (1993), an attitude is "a psychological tendency that is expressed by evaluating a particular entity with some degree of favor or disfavor" (p. 1). However, contemporary research in psychology also delineates between explicit, or directly measured, attitudes and implicit, or indirectly measured, attitudes. While explicitly measured attitudes are primarily based on self-report, most implicit attitudes are measured via reaction time tasks. There remains considerable debate about the psychological nature of implicit attitudes and the reliability and validity of measures

like the Implicit Association Test. Nevertheless, because research on the role of implicit attitudes in health has greatly expanded in the past decade, we believe this entry would be incomplete if it did not also examine implicit attitude change.

Finally, the literature suggests that the source of a persuasive message can stem from external or internal sources. External sources for persuasive messages can include mass media public health campaigns, warning labels on cigarette packs, or a doctor's advice to get more exercise. In contrast, the individual may serve as the source of persuasion in that individuals may think or act in ways that motivate change in health-related attitudes or behavior (Aronson, 1999). This entry will address external versus internal sources of persuasion separately.

Persuasion to Change Explicit Health-Related Attitudes and Behaviors

In the early 1950s, the experimental examination of persuasion began to focus on the ways in which external message sources, message recipients, and the content of the message contributed to attitude change. Many of the early studies examined communication strategies designed to change health-related attitudes and behaviors.

Role of Fear Appeals in Persuasion

The formal study of health persuasion in psychology began with research on fear to motivate health-related attitude and behavior change. When facing a fear appeal, individuals are exposed to a fear-inducing message that is perceived as a serious threat to one's health or well-being. Based on drive model theorizing (Hovland, Janis, & Kelly, 1953), the unpleasant emotional state of experiencing fear motivates individuals to alleviate or eliminate the source of the threat. Meta-analyses covering a range of health issues such as exercise, sunscreen use, and cigarette smoking suggest that fear appeals can change an individual's attitudes, behavioral intentions, and behaviors to be more favorable toward the health topic (e.g. Witte & Allen, 2000). According to the drive model, fear appeals effectively reduce defensiveness and reactance to a message if an individual is provided with information that moves them toward the intended outcome. Consequently, fear appeals are most effective at changing health-related attitudes and behavior when recipients believe the threat of the message is severe and relevant (i.e., recipients believe they are vulnerable), the message provides an effective solution to reduce or eliminate the threat, and recipients perceive that they possess efficacy to mitigate the threat (Witte & Allen, 2000).

The Elaboration Likelihood Model

While early health persuasion techniques focused on the role that motivation can play in changing health attitudes and behavior, subsequent research took a broader approach to the concept of motivation and at the same time explored the possibility that people could be persuaded to change their health attitudes and behaviors when their motivation was low. The development of a "dual-process" approach to persuasion led to novel predictions regarding the factors that affect the persistence of health attitude and behavior change.

One of the most influential dual-process theories of persuasion is the elaboration likelihood model (ELM; Petty & Cacioppo, 1986). Based on the cognitive response approach to attitude change, the ELM stipulates that persuasion occurs along a continuum of elaboration or thinking. On the high end of the elaboration continuum, often referred to as the "central route," persuasion occurs when people generate relatively many positive thoughts after thinking carefully about the content of the message. In order to think carefully about the message, people must be motivated and have the ability to think about the information in the communication. In addition, in order to assure that a highly thoughtful audience generates positive responses to the message, the content of the message must contain strong arguments; otherwise, the audience will counterargue and dismiss the information. Individual difference variables, such as increased involvement with an issue and increased need for cognition, are also associated with more central route processing (Petty & Cacioppo, 1986). Attitude change that follows from careful scrutiny of a strong message tends to endure over time and is more highly predictive of subsequent behavior, which is an important outcome when the goal is to alter future health outcomes.

Research in the ELM tradition also shows that people need not think carefully about the message in order for a message to be persuasive. On the lower end of the elaboration continuum, where people are paying attention but not scrutinizing the arguments in the message, factors that work on the periphery of the message can cause attitude change. The "peripheral route" to persuasion occurs when people either do not care about the message content or care but are unable to process the information. Persuasion in the absence of much thinking occurs when the message and its delivery include simple cues (e.g. "he has a nice smile"; "she is really funny") or heuristics (e.g. "he graduated from Harvard"; "she is a doctor") that lead to a positive conclusion about the message without considering the arguments. Whereas new attitudes formed through the peripheral route do not last long nor predict future behavior, such outcomes may not be relevant if the goal is to achieve a momentary attitude and behavior shift, like when trying to sign someone up for a new health club membership.

The principles stipulated by the ELM are useful for understanding multiple processes by which health attitudes and behavior change. For example, research on AIDS prevention by Bakker (1999) shows that adolescents high in need for cognition report more positive attitudes toward using condoms in the future if they are exposed to a clear and concise written brochure compared with a humorous cartoon brochure with the same information. However, this pattern reversed for those low in need for cognition such that their knowledge and behavioral intentions to use condoms increased when viewing the cartoon brochure rather than the written brochure.

The ELM also provides an explanation for why health campaigns show greater success when they tailor and target their messages to specific audience characteristics. Tailoring uses information about an individual to determine the content and delivery that will gain the most attention. Targeting refers to customizing messages for broader population subgroups that share certain characteristics. Consistent with the message-matching application of the ELM, research shows that tailored messages increase positive thoughts and personal connections about weight-loss information (Kreuter, Bull, Clark, & Oswald, 1999).

Self-Affirmation

One limitation to using threat, such as fear appeals, to motivate health behavior change is that in some situations, people cope with the threat by denying that the health issue applies to them and avoiding the issue altogether. One way to reduce denial and avoidance responses is by providing a self-affirming buffer. According to self-affirmation theory, individuals can bolster the positive integrity of the self-system by reflecting upon their most cherished positive values, actions, or attributes (Steele, 1988). Consequently, affirming values boosts the psychological resources needed to manage a threat and leads to a separation (i.e. a buffer) of the threat from the self.

Studies on self-affirmation and health show that participants who self-affirm, typically in the form of reflecting on important values, are more likely to change their health-related attitudes and behavior (see Jessop & Harris, this volume). For example, females who suntan and self-affirm report more positive attitudes toward sunscreen and are more likely to acquire a sunscreen sample than those who do not self-affirm after reading a pamphlet about the risks of sun exposure (Jessop, Simmons, & Sparks, 2009). Other studies show that individuals who self-affirm are more likely to accept threatening health risk information and are less likely to derogate a message than those who do not self-affirm (Jessop et al., 2009).

Persuasion to Change Implicit Health-Related Attitudes

Research over the past two decades in psychology has examined the ways in which implicit, or introspectively inaccessible constructs, can be measured to assess topics such as prejudice, stereotyping, and self-esteem. While most research in the health domain assesses explicit attitudes, other research suggests that self-presentational concerns may cause a dissociation between an individual's implicit and explicit attitudes (e.g. Fazio & Dunton, 1997). For example, an individual who enjoys suntanning may express positive explicit attitudes toward sunscreen to others yet still hold negative implicit attitudes toward sunscreen. Consequently, implicit attitudes may be a better predictor of health-related attitudes compared with explicit attitudes.

The most common way to examine implicit attitudes an individual may hold is through indirect measures that assess reaction times and categorization biases. Using reaction time procedures, research shows that implicit attitudes may be more predictive of behavior than explicit attitudes. For example, researched by Sherman, Chassin, Presson, Seo, and Macy (2009) shows that implicit attitudes toward cigarette smoking are more predictive of later smoking than explicit attitudes.

If implicit attitudes are more predictive of health behavior than explicit attitudes, it is important to determine the processes by which implicit attitudes can change. For example, persuasive campaigns that describe the negative health effects of drugs like marijuana and tobacco induce more negative implicit attitudes toward the drugs by creating stronger associations between drug-related images and negative words (Czyzewska & Ginsburg, 2007). The context in which information is presented may also affect implicit attitudes. Sherman, Rose, Koch, Presson, and Chassin (2003) show that individuals express more negative implicit attitudes toward smoking when the presentation highlights informational aspects of smoking (e.g., pictures of cigarette packs) compared with sensory aspects (e.g., a cigarette burning in an ashtray). Directly changing associative pairings can also affect implicit attitudes. For example, participants in an evaluative conditioning paradigm who paired images of unhealthy snack foods with aversive health consequences were subsequently faster to associate negative words with snack-related words and positive words with fruit-related words (Hollands, Prestwich, & Marteau, 2011).

Self-Persuasion to Change Health-Related Attitudes and Behavior

A parallel tradition in the study of persuasion in health focuses on the processes by which people convince themselves to change their health-related attitudes and behavior. According to Aronson (1999), self-persuasion occurs when individuals take a certain course of action and, as a result, change their health-related attitudes and future behaviors. Thus, the primary source of influence to pursue health-related attitude or behavior change stems from the individual rather than an external source. Researchers interested in the health changes that people make for themselves have primarily focused on the role of cognitive dissonance and self-perception processes.

Cognitive Dissonance Theory

Cognitive dissonance theory stipulates that individuals feel an unpleasant state of tension when they possess two inconsistent cognitions, which motivates them to reduce or eliminate the inconsistency (Festinger, 1957). For example, when people who smoke cigarettes are exposed to information regarding the negative health effects of smoking, the inconsistency between their smoking behavior and knowledge of the health risks can induce a state of psychological discomfort, which they become motivated to reduce. Smokers may alleviate the inconsistency in a number of ways, such as changing the behavioral cognition (e.g., quitting smoking), changing their knowledge about the risks of smoking (e.g., challenging the research on the relationship between smoking and cancer), or by recruiting new cognitions that place the inconsistency in a larger framework of consistency (e.g., "I would quit, but then I will gain weight, and that is worse"). Thus, the key to successful intervention rests in channeling dissonance reduction toward the targeted health attitude or behavior change.

One way to use cognitive dissonance to motivate people to change their attitudes toward unhealthy behavior is to have them argue against performing the behavior that they wish to change. A well-established example of this approach involves women's perceptions of their bodies and the thin ideal imposed by many societies. Stice and colleagues (for a review, see Stice, Shaw, Becker, & Rohde, 2008) predict that women who voluntarily adopt an anti-thin position in a group should perceive inconsistency between their positive attitude toward the thin ideal and their present behavior of taking an anti-thin stance during the small group discussion. Several studies by Stice and colleagues show that following the intervention, women reported more positive body images, reduction in the thin-ideal internalization and body dissatisfaction, less negative affect, less bulimic symptoms, and less eating disorder risk factors compared with control conditions.

Another way to use dissonance to motivate change is through an act of hypocrisy. In the hypocrisy approach, individuals first advocate for a health behavior about which they hold a positive attitude. Dissonance occurs when they are then reminded of times they failed to perform the advocated behavior in the past. The inconsistency between their advocacy about the importance of the target health behavior, and their past failures to perform the target act, makes people aware that they have acted in an insincere fashion. In order to reduce the dissonance and restore their self-integrity, people become motivated to change their own health behavior so they can bring it into line with the good health advice they were willing to give others.

In studies designed to motivate sexually active college students to practice safer sex, individuals who videotaped a speech about the importance of using of condoms, and were then reminded of past failures to use condoms during sexual intercourse, were more likely to purchase condoms at the completion of the study, compared with control conditions (Stone, Aronson, Crain, Winslow, & Fried, 1994).

Self-Perception Processes

Whereas dissonance processes change attitudes and behavior by getting people to act in ways that causes psychological discomfort, it is also possible to promote more healthy attitudes and behaviors by getting people to act in ways that induce them to draw a new conclusion about their own behavior. According to self-perception theory, when people do not already hold an attitude toward an object, they can infer their attitude through an examination of their own behavioral interactions with the object (Bem, 1972). People then develop new positive attitudes toward the topic, which can subsequently guide new behavior.

One way in which self-perception can cause health-related attitude and behavior change is through the foot-in-the-door (FITD) technique. The FITD predicts that when an individual agrees to a request that is easy to comply with, they are more likely to comply with a second, more difficult request (e.g., Freedman & Fraser, 1966). As a result of complying with the second request, people infer that their behavior must reflect a positive attitude toward the issue or object. In the domain of health, studies show that individuals who complete a questionnaire about organ donation express greater willingness to be an organ donor compared with those that do not complete the initial questionnaire (e.g. Carducci & Deuser, 1984).

Conclusion and Future Considerations

The research in this entry indicates that there are a number of mechanisms that effectively persuade people to adopt new attitudes and behaviors that support good health. However, it is important to note that few of the findings above show evidence for changes in health attitudes and behaviors that last beyond the immediate experimental context; with a few notable exceptions (e.g., Stice et al., 2008), most of the studies in the health persuasion literature focus more on questions about basic process than on the critical question of what is necessary to create lasting attitude and behavior change. Thus, at present, the utility of the health persuasion literature for use by public health officials, healthcare providers, and educational institutions is not well understood. The question of when and how health persuasion processes lead people to maintain new changes over time deserves more empirical attention.

Author Biographies

Colin A. Zestcott, MA, is a doctoral graduate student in the Department of Psychology at the University of Arizona. His research interests include stereotyping and prejudice, implicit attitudes, and the function of metaphor in social cognition.

Jeff Stone, PhD, is a professor of psychology in the College of Science, and professor of psychiatry in the College of Medicine, at the University of Arizona. Dr. Stone's research investigates mechanisms of health attitude and behavior change, prejudice and stereotyping, stereotype threat processes, and the reduction of intergroup bias. Dr. Stone's current NIH-funded research focuses on documenting and reducing the implicit bias processes that contribute directly to ethnic and racial disparities in health.

The Theories of Reasoned Action and Planned Behavior

Christina Nisson and Allison Earl

Department of Psychology, University of Michigan, Ann Arbor, MI, USA

The ability to understand the fundamental causes of public health problems and develop interventions to address those problems is important to a range of researchers involved in the study of health psychology. Two of the most widely tested models of this nature are the theory of reasoned action (Ajzen & Fishbein, 2005; Fishbein & Ajzen, 1975) and the theory of planned behavior (Ajzen, 1991; Ajzen & Fishbein, 1980, 2005). The theory of reasoned action posits that behavior is a function of behavioral intentions that are, in turn, a function of attitudes and subjective norms. The theory of planned behavior took the components of the theory of reasoned action but added perceived behavioral control as an additional factor predicting both behavioral intentions and behavior. In recent years, these models have been collapsed under the umbrella of the reasoned action approach.

Description of the Models

Theory of Reasoned Action

Both the theory of reasoned action and the theory of planned behavior developed out of a theoretical tradition that considered attitudes as a major influence on human behavior (e.g., Smith, 1932; Stagner, 1942). However, other contradictory research emerged suggesting that the link between attitudes and behavior was tenuous at best (e.g., Corey, 1937; LaPiere, 1934), with some researchers even calling for abandonment of the attitude construct altogether (Wicker, 1969). However, Fishbein and Ajzen (1974) noted that the inconsistency between attitudes and behaviors could be improved by measuring attitudes and behaviors at the same level of specificity. Thus, rather than using global attitudes (e.g., attitudes toward condoms) to predict specific behaviors (e.g., condom use during the next sexual encounter), Fishbein and Ajzen (1975) posited that researchers should focus on the specific antecedents of

---

General Editor: Lee M. Cohen. Volume Editors: Kate Sweeny and Megan L. Robbins.

specific behaviors (e.g., attitudes toward condom use during the next sexual encounter predicting condom use during the next sexual encounter).

Furthermore, Fishbein and Ajzen (1975) posited that the link between attitudes and behavior might best be explained by an appeal to specific behavioral intentions. That is, attitudes about performing a behavior would predict behavioral intentions to enact the behavior, which would in turn predict behavior. In addition, because one may also take into account how others perceive one's actions, subjective norms about how to behave were also included as a predictor of behavioral intentions. Behavioral intentions were then identified as the best predictor of behavior (Fishbein & Ajzen, 1975). In this model, *attitudes toward the behavior* were defined as an aggregate of readily accessible or salient beliefs about the likely outcomes of performing the target behavior, whereas *subjective norms* were defined as the perceived social pressure to perform or not perform the target behavior and *behavioral intentions* were defined as the perceived likelihood of performing the target behavior.

Theory of Planned Behavior

One factor that may limit the translation of intentions to behavior is one's ability to enact the desired behavior. As such, the theory of planned behavior updated the theory of reasoned action to include a component of *perceived behavioral control*, which specifies one's perceived ability to enact the target behavior. In fact, perceived behavioral control was added to the model to extend its applicability beyond purely volitional behaviors. Prior to this addition, the model was relatively unsuccessful at predicting behaviors that were not mainly under volitional control. Thus, the theory of planned behavior proposed that the primary determinants of behavior are an individual's behavioral intention and perceived behavioral control.

As such, according to the theory of planned behavior, behavioral intentions are framed as the motivational component of the model, or one's conscious plan or decision to exert effort to perform the target behavior. Behavioral intentions are determined by *attitudes toward the behavior* (e.g., whether engaging in the behavior is evaluated to be positive or negative), *subjective norms* surrounding the behavior (e.g., beliefs about whether others think one should engage in the behavior), and *perceived behavioral control* (e.g., beliefs regarding how easy or difficult performing the behavior is likely to be). In this context, perceived behavioral control reflects both external factors (e.g., availability of time or money, social support) and internal factors (e.g., ability, skill information). In other words, low perceived behavioral control exists in situations in which performance of the target behavior is dependent upon a number of other factors, which may or may not be within an individual's control. For example, one may experience low perceived behavioral control for the target behavior of eating healthy if constraints such as time, affordability, access, and temptation are viewed as obstacles to engage in the behavior despite strong intentions. As a result, the greater the perceived behavioral control for a target behavior, the stronger the predictive power of behavioral intentions for that behavior.

Reasoned Action Approach

In recent years, the theory of reasoned action and the theory of planned behavior have fallen under the umbrella of the *reasoned action approach* (Ajzen & Albarracín, 2007; Fishbein & Ajzen, 2010). The reasoned action approach encompasses all of the components proposed by earlier models (e.g., attitudes toward the behavior, subjective norms, perceived behavioral control, and intentions) while also including additional factors such as *actual control*, defined as skills, abilities, and environmental factors that influence one's ability to enact a target behavior. As such, the theory of reasoned action and the theory of planned behavior will be referred to jointly as the reasoned action approach throughout this entry.

Ability to Predict Health Intentions and Behaviors

A series of meta-analyses and reviews examining the application of the reasoned action approach to health behaviors have now been published, including ones focusing on multiple health domains (e.g., Armitage & Connor, 1999; Godin & Kok, 1996; McEachan, Conner, Taylor, & Lawton, 2011; Webb, Joseph, Yardley, & Michie, 2010) and ones focusing on specific behaviors (e.g., exercise; Hagger, Chatzisarantis, & Biddle, 2002; condom use; Albarracín, Johnson, Fishbein, & Muellerleile, 2001). Such reviews have shown the reasoned action approach to be a relatively successful predictor of health intentions and behavior, explaining 32–44% of the variance in intentions and 15–41% of the variance in behavior.

One important moderator of the predictive ability of the reasoned action approach is behavior type. For instance, the reasoned action approach appears to be particularly successful in the prediction of diet and exercise behaviors, as well as condom use. In a recent comprehensive meta-analysis, McEachan et al. (2011) found that the reasoned action approach was able to explain 21 and 24% of the variance in dietary and exercise behaviors, respectively. At the same time, the reasoned action approach appears to be less successful at explaining the variance in addictive and clinical screening/detection behaviors. The same meta-analysis revealed that the reasoned action approach was able to explain only 15 and 14% of the variance in such behaviors, respectively. It is not surprising that the reasoned action approach is better at predicting some behaviors than others. Looking at the categories in which the reasoned action approach is more versus less successful in predicting behavior, it follows that the model is less predictive of addictive and clinical screening behaviors, as these behaviors are likely to be low in perceived and actual behavior control, affected not only by personal motivation and desire but also other factors (e.g., biological aspects of addiction, access to treatment and health services, financial resources to engage in screening behaviors).

Along with behavior type, there are also two important methodological moderators to consider when examining the ability of the reasoned action approach to predict health behavior: length of follow-up and method of measurement (objective vs. self-report). The amount of time between measurement of reasoned action approach variables and assessment of behavior is an inherent limiting condition of the reasoned action approach. Ajzen and Fishbein have repeatedly stressed that the measurement of behavior should occur as close as possible to the measurement of the reasoned action approach variables, as the model is only able to predict behavior to the extent that the reasoned action approach variables remain consistent from the time of measurement to the time of assessment of behavior (Ajzen, 1985; Ajzen & Fishbein, 1980). Given that it is less likely for the reasoned action approach variables to remain stable as the length of follow-up increases, it is not surprising that the overall ability of the model to predict health behavior decreases over time (Albarracín et al., 2001; McEachan et al., 2011).[1] For dietary and exercise behaviors, McEachan et al. (2011) found that the reasoned action approach was only able to predict 18% (dietary) and 16% (exercise) of the variance in behavior when follow-up occurred more than 5 weeks after initial measurement, compared with 23% (dietary) and 32% (exercise) when follow-up was less than 5 weeks after initial measurement.

Like many models of human behavior, a long-standing concern regarding the ability of the reasoned action approach to predict health behavior, and behavior in general, is its frequent reliance on self-reported measures of behavior. A primary concern regarding reliance on self-reported behavior is the vulnerability of self-report measures to social desirability bias, or the tendency to over-report desirable behavior and underreport undesirable behavior (Edwards, 1953; Schroder, Carey, & Vanable, 2003). This may be particularly problematic for the prediction of health behavior given the tendency for many health behaviors to be viewed as either desirable (e.g., healthy eating, exercise, condom use) or undesirable (e.g., drug and alcohol use). Given the prominent role of attitudes in the reasoned action approach, individuals' inclination to maintain attitudinal and behavioral consistency (Hessing, Elffers, & Weigel, 1988; Kiesler, 1971) is also of particular concern. Thus, the model may overstate the intention–behavior relation due to individual's desire to maintain consistency in their reported intentions and behaviors. Two large meta-analyses support this concern. Armitage and Conner (1999) found that reasoned action approach explained 31% of the variance in self-reported behavior but only 20% of the variance when behavior was directly observed. Specific to health behavior, McEachan et al. (2011) found that reasoned action approach variables explained 26% of the variance in self-reported physical activity but only 12% of the variance in objectively measured physical activity. Although the reasoned action approach is able to predict a significant amount of variance in behavior regardless of length of follow-up or method of measurement, it consistently shows greater efficacy in situations with short follow-up periods and self-reported measurement of behavior.

Interventions to Change Behavior

Although the reasoned action approach was originally presented as a tool to "understand" and "predict" behavior (Ajzen & Fishbein, 1980), there is growing interest in the theory's possible utility in designing behavioral interventions. Ajzen and Fishbein (2005) agree that successful modification of predictors specified by the reasoned action approach should lead to a corresponding change in behavior. McEachan et al. (2011) found encouraging evidence for the model's ability to identify important targets for interventions to change health behaviors. Although their meta-analysis of health behaviors found that past behavior exhibited the strongest correlation with current behavior (mean $\rho = 0.50$),[2] intention was also a strong predictor of behavior (mean $\rho = 0.43$) and remained so after controlling for past behavior. From a behavioral intervention perspective, intentions are more relevant than past behavior as they are susceptible to change, whereas past behavior is not. Thus, it is encouraging that intentions remain a strong predictor of behavior even when controlling for past behavior (McEachan et al., 2011).

In 2002, Hardeman and colleagues published a review of behavior change interventions using the reasoned action approach (Hardeman et al., 2002). The review identified 21 interventions targeting health-related behaviors, including smoking cessation, exercise, and testicular self-examination. Of the 21 interventions identified, only 10 actually used the reasoned action approach to develop the intervention; the remaining 11 interventions simply used the reasoned action approach for measurement and therefore should not be considered a valid assessment of the theory's ability to help change behavior. It is important to note that even the 10 theory-based interventions often focused on selected reasoned action approach components only. Furthermore, the descriptions of the interventions were limited, and it was often difficult to assess the specific manner in which the reasoned action approach informed the intervention design. Nonetheless, among the 10 theory-driven interventions, 4 (40%) reported a positive change in behavioral intentions as a result of the intervention, 3 (30%) reported no difference in behavioral intentions, and 3 (30%) did not measure intentions. In terms of behavior change, three (30%) of the interventions reported a positive change in behavior as a result of the intervention, two (20%) reported no difference in behavior, and five (50%) did not measure behavior.

In the domain of condom use, Albarracín and colleagues (Albarracín et al., 2005) examined the efficacy of the reasoned action approach by examining the link between intervention components and change in model constructs, as well as the links with behavior change. In line with the reasoned action approach, attitudinal arguments about condom use did indeed change attitudes toward condom use, which in turn led to changes in condom use. In additional, self-management training led to changes in perceived behavioral control, which in turn facilitated change in condom use (Albarracín et al., 2005).

Although it may be argued that the mixed results of the Hardeman et al. (2002) review suggest that the reasoned action approach is far better suited to predict behavior than to help change it, it is important to remember that there were only 10 studies in which the reasoned action approach was used to develop the intervention, the interventions often focused only on selected reasoned action approach components, the descriptions of the interventions were limited, and evidence about mediation of effects by reasoned action approach components was rare. McEachan and colleagues' (2011) finding that behavioral intentions remain a significant predictor of behavior even when controlling for past behavior, combined with evidence indicating that a change in individuals' beliefs can bring about changes in attitudes, intentions, and behavior (Ajzen & Fishbein, 2005), lends support to the potential for the reasoned action approach to inform behavioral change interventions.

Author Biographies

Christina Nisson received her BA in psychology and economics from Cornell University in 2009 and her MS and PhD in social psychology from the University of Michigan in 2011 and 2014, respectively. Broadly, Christina is interested in applying social psychological research to health messaging and health behaviors. Her primary line of research examines the role of health message characteristics (e.g., approach vs. avoidance goals; action vs. inaction orientation) on message processing and healthy eating behaviors.

Allison Earl received bachelor's degrees in anthropology and psychology from the University of Florida and a PhD in psychology from the University of Illinois. She is an assistant professor of social psychology at the University of Michigan and director of the Health, Attitudes, and Influence Lab (HAILab). Dr. Earl's research program focuses on understanding what we pay attention to and why and how to best increase attention to health promotion programs, particularly for high-risk audiences.

Notes

1 Randall and Wolff (1994) conducted a meta-analysis of 98 studies and found no significant relationship between length of follow-up and the strength of the intention–behavior relationship. It is important to note, however, that this meta-analysis did not focus specifically on health behavior and only looked at the correlation between intentions and behavior, not the overall predictive power of the model.

2 McEachan et al. (2011) used mean true score correlations corrected for sampling and measurement error (mean ρ).

Thriving in Life

Margaret L. Kern[1] and Jessie Sun[1,2]

Introduction

People experience life in a myriad of ways. For some, life is an adventure. They are optimistic, socially engaged, physically healthy, and active participants. For others, life is a daily grind. Work consumes a large portion of time and is simply something to endure each day. And for others, life is a struggle, with physical or psychological disability making it a challenge to function in daily life.

Considerable individual and societal resources are spent addressing the needs of those afflicted by physical and mental illness and disability. Medicine has made great strides in restoring normal function for those who suffer. Research and practice within health psychology has successfully identified ways to alleviate distress, helping patients to enjoy the highest quality of life possible, within the constraints of physical or mental disability.

But what about the majority of people who are not distressed, but also not functioning as well as they could be? A growing body of literature suggests that individuals who proactively approach life experience lower rates of physical and mental disabilities. It is shortsighted to take action only when symptoms appear. Rather, a proactive approach that builds internal and external resources over time will allow as many people as possible to not only survive but to truly thrive throughout life.

Thriving Defined

Thriving can be defined as a state at a single point in time or as a trajectory over time. As a state, thriving refers to current success or prosperity. As a trajectory, thriving refers to successful progression toward a desired goal or outcome, despite obstacles that might occur along the

way. The definition of success, prosperity, and desirable outcomes depends on the field of study.

The traditional medical perspective defines success in terms of biological function. Thriving can be observed objectively based on organic characteristics. “Failure to thrive” describes infants and children who do not develop as expected and fail to gain and maintain weight. The cause may be physical or emotional, but early diagnosis is important before permanent damage to the child occurs. Failure to thrive is also used in gerontology to define progressive physical and cognitive decline. In contrast, thriving is a normal state of health with no detectable signs of disease.

The traditional psychological perspective similarly defines success in terms of the lack of disability and disease but focuses on mental and social health rather than physical conditions. It is more subjective in nature—an organic cause of suffering might not exist, but the individual fails to function well in society.

Over the past few decades, there has been growing interest in a positive psychology perspective, which similarly focuses on mental and social health but argues that success is more than the lack of disease and disability. Thriving involves high levels of positive emotions, satisfaction with one’s life, positive social relationships, and the presence of other positive constructs such as a sense of meaning, mastery, personal growth, engagement in life, and accomplishment.

From an economic perspective, success is defined in terms of financial outcomes, such as income, gross domestic product, or profit. A thriving business is growing and building financial capital. A thriving economy has low levels of unemployment and performs strongly in the international market.

In the 1940s, the World Health Organization defined health as a complete state of physical, mental, and social well-being, not only the absence of disease and disability. This perhaps best captures the health psychology perspective, which includes physical, mental, and social aspects. Thriving is defined in terms of high quality of life and active engagement in life, despite the possible presence of physical and/or mental disorder. The aim of thriving is to allow a person to live as long as possible with the least physical, psychological, and social disabilities possible, focusing on quality rather than quantity (i.e., length) of life alone. This provides benefit to both the individual (by reducing suffering) and society (by reducing economic burden on the system).

Gerontology distinguishes among pathological (where there is accelerated physical, cognitive, and functional decline), usual (general breakdown in the body over time due to cumulative internal and external pressures over time), and successful aging (lack of physical disease and disability, high cognitive functioning, and active engagement in life). Multiple domains—including length of life, biological health, mental health, cognitive function, social competence, productivity, personal control, and life satisfaction—form the foundation of one’s health (Friedman & Kern, 2014). Successful aging involves selecting which elements will optimize life, allowing some domains to compensate for others (Baltes & Baltes, 1990).

One’s definition of thriving impacts how it is assessed, the extent to which the construct is continuous versus dichotomous, unidimensional versus multidimensional, subjective versus objective, and whether it can be captured at a single time point or necessitates seeing the person’s trajectory across life as a whole.

The common thread across these definitions is that thriving involves success across one or more domains. The traditional medical and psychological models tend to take a diagnostic approach, such that one is either healthy or unhealthy. Other perspectives more directly capture the continuous nature of biopsychosocial functioning, such that there is a broad range of functioning even among the healthy. Thriving refers to the higher end of this spectrum.

For our purposes here, we define *thriving* as subjective and objective success across multiple domains (e.g., physical, mental, cognitive, social, functional, economic), and we use the term interchangeably with *flourishing*. The domains that matter most may vary for different individuals and at different periods of time, depending on one's personality and social context. From this perspective, thriving is not a single number, but involves feeling and functioning well across multiple valued areas of life.

This definition is sufficient if we are only interested in identifying who or how many people are thriving at any given point in time. We suggest that *thriving in life* goes a step further and involves not only success at a single point in time but also a consistent trajectory of wellness over time. Thriving in life is a dynamic phenomenon that depends on multiple influences that interact and accumulate over the course of years and decades. Sustained states of thriving are rarely the outcome of a one-time fix or short-term behaviors that are not maintained; rather, thriving in life depends on the cumulative effects of a constellation of repeated behaviors combined with supportive environments. Just as plants need a regular supply of water and sunlight to flourish, human thriving depends on a sustained combination of salutary supports.

Predictors of Thriving

Numerous factors predict one's level of thriving, including one's personality, habitual behaviors, social relationships, socioeconomic status (SES), the environment, and culture.

Individual Factors

Some of the most consistent predictors of thriving are one's personality characteristics. Meta-analyses spanning thousands of participants find that conscientiousness (the tendency to be self-controlled, hardworking, dependable, organized, and socially responsible) and intelligence predict length of life on par with well-established risk factors (such as smoking, alcohol consumption, physical inactivity, and unhealthy diet; Calvin et al., 2011; Kern & Friedman, 2008). Personality accounts for over 40% of the variance in subjective well-being, with extraversion (the tendency to be sociable, talkative, assertive, enthusiastic, and active) and low neuroticism (the tendency to be irritable, moody, and temperamental) being the strongest predictors (Steel, Schmidt, & Shultz, 2008).

Behavioral Factors

Thriving is impacted not only by who we are but also by what we do. Habitual behaviors cumulatively impact one's health and well-being over time. Protective behaviors include moderate physical activity, healthy diet and weight control, restful sleep, immunizations, safe driving, wearing sunscreen, and regular medical checkups, whereas risky behaviors include smoking, drug use, alcohol abuse, thrill-seeking activities, and unsafe sex. For instance, regular physical activity can prevent and assist in the management of chronic illnesses and disease (Pedersen & Saltin, 2006), moderate sleep duration relates to lower mortality risk (Cappuccio, D'Elia, Strazzullo, & Miller, 2010), and the combination of not smoking, physical activity, health diet, and moderate drinking can predict up to a 14-year difference in length of life (Khaw et al., 2008). Such behaviors are physically healthy and relate to higher levels of psychological well-being, less mental distress, and better cognitive function.

Daily Activities

A related factor involves how time is spent, including employment, voluntary, home, and leisure activities. The impact of work is most clearly seen in the case of involuntary unemployment, which relates to a greater number of health problems, lower psychological well-being, and greater psychological distress (McKee-Ryan, Song, Wanberg, & Kinicki, 2005). Similarly, one of the greatest risk periods for early death is within the first few years after retirement. Beyond being necessary for meeting basic needs, work can provide a sense of identity, connection to like-minded others, and a source of personal accomplishment.

While work provides physical, psychological, social, and economic benefits, too much work can also be problematic. Technological developments have blurred the boundaries between work and home in many occupations. Working beyond contractual hours has been related to increased risk of one or more health problems, greater distress, and perceived work–life imbalance (Arlinghaus & Nachreiner, 2014).

Social Factors

The need to belong is one of the most pervasive and powerful fundamental human needs (Baumeister & Leary, 1995). Humans are extremely sensitive to even the slightest hint of social exclusion. Peer rejection and victimization in childhood predicts poor adjustment and psychopathology later in life. Loneliness is one of the strongest risk factors for failure to thrive—including higher risk of mortality, physical disease, and depressive symptoms (Hawkley & Cacioppo, 2010).

Social relationships range in quality; in general, positive relationships are protective against poor health outcomes, whereas hostile and negative relationships increase risk. Perceived social support and lower levels of interpersonal conflict may buffer the negative health-related consequences of stress and relate to lower risk of infection, morbidity, and mortality.

It is commonly believed that social relationships are one of the most important contributors to psychological well-being. However, this is complicated by how thriving is defined and measured. If thriving is defined in part as good social function, then social relationships are a marker of thriving, not a predictor. Associations among both objective and subjective relationship variables and subjective well-being may also be confounded by shared method variance and underlying variables such as personality traits. To distinguish predictors and outcomes, it may be useful to define factors such as connectedness (i.e., the ability to intimately connect with others) and fulfillment of one's sense of belonging as predictors and factors such as the quality of social relationships as outcomes.

Socioeconomic Factors

There is clear evidence for a social gradient, such that those who have a lower socioeconomic position have a shorter life expectancy, increased risk of mental and physical disease, and lower well-being. This appears to be a nonlinear relationship, with income making a greater difference at very low levels of income and less of an impact as income increases. Unfortunately, although narrowing income gaps may have the biggest impact on health and well-being around the world, inequality in most countries is increasing (Pickett & Wilkinson, 2015).

Although it is clear that people who have more money tend to be happier and healthier than people with less money, research suggests that how people spend their money can also influence their happiness. People report greater happiness after spending money on other people compared with spending money on themselves and derive more satisfaction from purchasing life experiences than purchasing material possessions (Dunn, Aknin, & Norton, 2014).

Environmental Factors

Individuals are not isolated, but are embedded within social and environmental contexts. Over the past century, some of the greatest improvements in physical and mental health have occurred through the availability of clean drinking water, proper sewage treatment, and the development of immunizations and antibiotics. Contact with nature relates to greater physical activity, social interactions with others, increased happiness, enhanced cognitive capacity, and less mental distress (Hartig, Mitchell, de Vries, & Frumkin, 2014). There is also emerging discussion about the potential impact of climate change, increased pollution, economic volatility, exposure to violence, and political displacement. The long-term impact of these external factors is unknown, but it is clear that proactive approaches that create healthy, safe environments are needed.

Cultural Factors

At a broader level, culture has a profound influence on individual characteristics, behavior, social relationships, and even the definition of thriving. For example, North Americans tend to associate happiness with personal achievement more closely than with social harmony, whereas the opposite pattern has been observed for Japanese (Uchida & Kitayama, 2009). Thus, pathways to thriving most likely vary across cultures. However, there are also likely to be some common predictors of thriving across cultures. For instance, people who inhabit regions of Italy, Japan, and the United States that have high proportions of centenarians tend to value family and other social relationships, smoke less, have a healthy diet, engage in moderate physical activity, and are generally engaged in life (Buettner, 2012). There is also evidence that there are universal needs (e.g., social support, respect, mastery, autonomy) that predict subjective well-being across the world, although some cultures might emphasize some needs more than others (Tay & Diener, 2011).

Cultivating Thriving

The different predictors of thriving offer a range of areas that can potentially be targeted to help more people thrive. Although intelligence and personality are often viewed as fixed traits that are not readily amenable to change, people can and do change, as part of the natural process of maturation, through intervention, and through goals to change. Such changes in personality longitudinally predict changes in life satisfaction and psychological well-being (Boyce, Wood, & Powdthavee, 2013).

As personality influences behavior, it may be possible for individuals to emulate the behaviors of those who are higher in conscientiousness, extraversion, and intelligence and lower on neuroticism. For example, leading a healthier lifestyle could produce some of the health-related benefits of being more conscientious.

Positive psychology has developed various interventions and activities to build psychological and social well-being, such as gratitude exercises, discovering and using one's strengths, random acts of kindness, mindfulness, and active constructive responding. Workplaces and schools have successfully incorporated some of these strategies, providing preliminary support for lower healthcare costs, happier employees, and greater profit.

The extent to which temporary changes in behavior and short-term well-being exercises impact consequential life outcomes, such as long-term social relationships and length of life, is unknown. Changing a behavior (e.g., overeating) will not reduce mortality risk if it is simply replaced by another unhealthy behavior (e.g., drinking). There are likely to be multiple mechanisms by which a trait exerts its influence on thriving, some pathways may be more malleable than others, and the causal impact of many mechanisms are yet to be determined (Friedman & Kern, 2014). Thus, it may be more effective to change the underlying characteristics than to target multiple mediators.

Public health and public policy are well suited to target the external context—creating conditions that support individual and community thriving. Environments can be designed to make healthy behaviors easier to do and more psychologically attractive. For instance, designing parks, communities, transportation systems, schools, and buildings that encourage physical activity may also produce a wide range of environmental, economic, and physical and mental health benefits. Countries where people must opt out of organ donation have higher consent rates (80–100%) than those with an opt-in policy (5–30%; Johnson & Goldstein, 2003).

Policies and legislation can also be used to create social norms and provide checks on behavior. For instance, many countries now levy high taxes on cigarette and tobacco, making it economically unsustainable to smoke. At the same time, policy makers need to tread carefully; not all factors that influence thriving are equally amenable to legislation. For example, screenings for prostate cancer successfully detect many cases, but many of those diagnosed will die of another disease long before the cancer develops. As treatment can cause substantial negative impacts on psychosocial functioning, blindly requiring screenings to target one indicator of thriving (physical health, indicated by lack of cancer) can needlessly undermine functioning in another domain. A systemic consideration of the potential impact that any action will have across multiple domains of thriving is needed.

As a whole, different strategies will likely be effective for different people. From a socioecological perspective, interventions that target multiple levels of influence should result in more powerful and sustained changes than interventions only targeting a single level.

Future Directions

Although optimal functioning has long been an area of scholarly interest, the rapid expansion and application of positive psychology has made it more visible and is bridging research and applications in the real world. However, many gaps remain. Research often looks for simple, singular, linear causes, whereas life is complex, interconnected, and dynamic. Future research will benefit from incorporating a systems perspective, interdisciplinary scholarship, and closer connections between research and practice.

Methodologically, thriving in life is challenging to study. Advances in computational social science provide opportunities for bringing together diverse data sources, which capture both patterns across large populations, and momentary behavioral expressions of thoughts, attitudes, and behaviors. The methodologies, tools, and data that are most useful to understanding thriving are yet to be determined, and as all methodologies have strengths and limitations, multimethod approaches are likely to produce more robust and comprehensive insights.

Much of the research and application to date has focused on individuals, but individual thriving is interconnected with the environment in which a person resides. Questions remain around how individual behaviors and choices influence the well-being of close and distant others and how to balance individual well-being with collective needs. Additional research around person and environment interactions could address how individuals relate to, are affected by, and impact upon the environment in which they live, as well as the broader biosphere.

Finally, although various interventions have been developed to cultivate thriving, the extent to which these are beneficial across individuals from different backgrounds, different periods of life, and under what circumstances is unclear. It is important to further develop a more nuanced understanding of individual fingerprints of thriving, which may depend on cultural differences, socioeconomic backgrounds, and individual values, needs, and motivations.

Conclusion

Thriving involves holistic success across multiple domains of life. Multiple factors impact a person or group's level of thriving at any given point in time. Although we have reviewed a range of factors that correlate with higher levels of well-being, the relative importance of different factors may vary between individuals. In this way, just as different plants thrive under different climates, there is no one-size-fits-all intervention or magic bullet for enhancing well-being; whereas different plants need different amounts of water, individuals may differ in the dose and types of social interaction they need to thrive. We also take the view that optimal well-being involves having a balanced life, with a mix of daily activities that enable individuals to fulfill a variety of needs. This implies that just as you can overwater a plant, it is also possible to have too much of one factor, at the cost of other domains, which undermines thriving as a whole.

Thriving in life not only involves functioning well at a single point in time but also involves one's trajectory over time. A focus on pathways emphasizes the importance of cultivating personal resources and supportive environments across the lifespan, as well as the need to understand how individual and social factors shift one's wellness trajectory over time. Harmful trajectories are not immutable, but early influences play a key role in setting a dominant trajectory. It may be relatively more effective to intervene at an early stage to establish healthier pathways in the first place than to try to correct unhealthy pathways in adulthood and old age. We need to know how different factors contribute to thriving across the lifespan, both naturally and through intervention.

Thriving in life is a complex, multiply-determined phenomenon. There are some universal and necessary ingredients, but the specific combination and importance of different factors will differ between individuals and even within a person at different periods of life. Research across a variety of disciplines is focusing on ways to enhance thriving, with potential benefit to both individuals and society as a whole.

Unrealistic Optimism and Health

James A. Shepperd[1] and Jennifer L. Howell[2]

[1]Psychology Department, University of Florida, Gainesville, FL, USA
[2]Psychology Department, Ohio University, Athens, OH, USA

When asked to predict their future, people are not evenhanded in their prognostications. Rather, they show a strong preference for optimism, believing that favorable outcomes are more likely on their horizon than is realistically possible. This unrealistic optimism occurs for a seemingly endless number of outcomes. For example, college women report that they are less likely than their peers to experience an unwanted pregnancy, smokers believe they are less likely than others smokers to suffer smoking-related illnesses, drivers report that they are less likely than other drivers to experience an automobile accident, and people generally believe they are less likely than are their peers to experience diseases including HIV, HPV and chlamydia, and cancer (for a review, see Shepperd, Klein, Waters, & Weinstein, 2013). The bias seems remarkably stable across time (Shepperd, Helweg-Larsen, & Ortega, 2003) and impervious to interventions designed to reduce it (Weinstein & Klein, 1995).

At first blush, unrealistic optimism seems problematic in that it could prompt people to take unnecessary risks, fail to take precautions, or otherwise make decisions that increase their odds experiencing harm. However, the relationship between unrealistic optimism and behavior is more complex. Understanding when unrealistic optimism is or is not problematic requires defining unrealistic optimism and understanding why it occurs. We distinguish between two types of unrealistic optimism, review the causes of unrealistic optimism, and discuss the consequences of unrealistic optimism for health.

Defining Unrealistic Optimism

Unrealistic optimism refers to the prediction that one's personal outcomes will be more favorable than can possibly be. On the surface, unrealistic optimism shares some overlap with *dispositional optimism*, which represents a trait tendency to hold positive expectation about the future. However, unrealistic optimism is empirically and conceptually distinct. Unrealistic

optimism is not just a positive expectation (like dispositional optimism); it is a positive expectation that cannot possibly be true.

But how do we determine that a person's predictions are unrealistically optimistic? Researchers have identified two types of unrealistic optimism that differ in the standard used to evaluate the predictions (Shepperd et al., 2013). The first type—unrealistic *absolute* optimism—occurs when people make overly favorable predictions about their futures relative to an objective, quantitative standard such as base rate data, prior experience, or what is realistically possible.

Several studies demonstrate unrealistic absolute optimism: researchers have shown that students overestimate the starting salaries they will receive after graduation from college, financial advisors overestimate future corporate earnings, and taxpayers overestimate how quickly they will file their income tax forms (see Carrol, Sweeny, & Shepperd, 2006 for a review). Other research demonstrates unrealistic optimism relative to base rate or epidemiological evidence. For example, relative to local baseline information, homeowners underestimate the chances that their house has radon gas (Weinstein & Lyon, 1999), and college students underestimate their personal risk for STDs including chlamydia and HPV (Rothman, Klein, & Weinstein, 1996). Other research demonstrates unrealistic optimism by comparing people's personal estimates with the experiences of a comparable control group. For example, female US Marines in one study estimated on average a 14.5% chance that they would get pregnant in the next 12 months, which was significantly lower than the 12-month pregnancy rate (22.0%) of a comparable group of female Marines (Gerrard, Gibbons, & Warner, 1991).

The second type of unrealistic optimism—unrealistic *comparative* optimism—occurs when people erroneously conclude that unfavorable outcomes are less likely to happen, and favorable outcomes more likely to happen, to them than to their peers. Researchers measure unrealistic comparative optimism in two ways. The first involves comparing an individual's comparative estimate with the comparative estimate indicated by an objective standard. To illustrate, a woman may predict that she is less likely than the average woman to get breast cancer. However, if her true risk, based on epidemiological predictors (e.g., family history, age at first menstruation, genetic predisposition), is average or above average, then she is displaying unrealistic comparative optimism. Evidence for this manifestation of unrealistic comparative optimism comes from studies of breast cancer, smoking-related diseases, and fatal heart attacks (see Shepperd et al., 2013).

The second manifestation of unrealistic comparative optimism occurs at the group level and does not identify whether any specific individual is unrealistically optimistic. It occurs when group members on average rate their risk of experiencing an unfavorable event as below average relative to other members of the group. The assumption is that the mean individual risk estimate of the group members for a particular event should be average, with estimates of people whose risk is below average balancing out the estimates of people whose risk is above average. If the group's mean estimate of experiencing an unfavorable event is below average, then the group is displaying unrealistic comparative optimism. For example, college students overwhelmingly report that they are less likely than other college students to become obese or to have their first marriage end in divorce (Rothman et al., 1996). Because personal estimates should balance out to be "average" rather than "below average," these students are displaying unrealistic comparative optimism.

Causes of Unrealistic Optimism

Researchers have identified three reasons why people are unrealistically optimistic (Shepperd, Waters, Weinstein, & Klein, 2015): (a) people are motivated to expect favorable future events,

(b) people overrely on personal information when making judgments, and (c) people process information in ways that lead them to be overly optimistic. First, people may be motivated to believe or have others believe that they are unlikely to experience unfavorable future events. The motivation may stem from several causes (Shepperd, Carroll, Grace, & Terry, 2002). For instance, it may arise because it feels good to imagine a positive future and feels bad to imagine a negative future. It also may arise from superstitious thinking, such as the belief that imagining favorable outcomes may somehow increase the likelihood that the favorable outcomes will transpire. Such thinking is not entirely superstitious in that an imagining a favorable outcome may facilitate actions designed to bring about the outcome. Finally, the motivation may reflect a perception of what other people believe they should think. Indeed, people believe that it is better to be unrealistically optimistic in most circumstances than to be accurate or pessimistic.

The second reason people may display unrealistic optimism arises from an overreliance on personal information when making judgments. People know their personal history, current actions, and future plans, and they use this information when predicting their personal likelihood of experiencing various outcomes. These future plans are typically plans to bring about desired outcomes and avoid undesired outcomes and may insufficiently weight, or fail to include altogether, possible setbacks, roadblocks, competing demands, and past failures. Consistently, people display greater unrealistic optimism for controllable events than uncontrollable events, presumably because they assume they will take more action to bring about desired outcomes than they actually do (see Shepperd et al., 2015).

Conversely, people often neglect or are unaware of other people's plans, intentions, and goal-directed behavior (i.e., that other people are employing, or intend to employ, actions to avoid undesired outcomes and achieve desired outcomes). Thus, they underweight other's experiences when making comparative estimates. In fact, supplying people with information about others' goal-directed behavior or intentions diminishes unrealistic optimism (see Shepperd et al., 2015). The reduction may occur because the information prompts people to recognize personal similarity with the comparison target and thus modify their estimates accordingly. Alternatively, the information may make the comparison target seem less abstract and more humanlike. Consistent with the latter possibility are findings that people display less unrealistic comparative optimism when the comparison target is a concrete, specific person as opposed to the amorphous *average person* (see Shepperd et al., 2015). Together, this evidence suggests that people often overrely on personal information and fail to use information about others when making comparative judgments.

The third reason people display unrealistic optimism arises from the way people process information. Three processes are particularly important (Shepperd et al., 2015). The first is that people making likelihood judgments gauge their chances of experiencing an outcome based on how well they match their stereotype of people who experience the outcome. Stereotypes, however, are often inaccurate or exaggerated. For example, the stereotype of the person who gets a sexually transmitted disease may be someone who has frequent unprotected sex with multiple sex partners. In comparison with this stereotype, many people naturally estimate that their risk is lower. The second process is that people making comparative judgments often omit the comparison part of the judgment. Instead, of comparing their chances relative to some standard or to the chances of the average person, people often merely consider their own chances, transforming the comparative judgment into a personal judgment with no clear reference group. Third, people making judgments often weight information more heavily to the extent it suggests that favorable outcomes lie ahead. Indeed, people seem to fail to encode information that optimism is unwarranted (Sharot, Korn, & Dolan, 2011).

The Consequences of Unrealistic Optimism

Examining the consequences of unrealistic optimism is difficult because the research is almost entirely correlational. Unrealistic optimism is challenging to manipulate, making it difficult to assess causal relationships between unrealistic optimism and health outcomes. Although unrealistic optimism may influence behavior, it is also possible that people display unrealistic optimism because of their current or intended behavior or some other third variable.

Three types of studies allow researchers to better examine the health consequences associated with unrealistic optimism: (a) longitudinal research, which can show that unrealistic optimism predates health decisions, (b) quasi-experimental studies that provide research participants the opportunity to engage (or not engage) in health-related behaviors, and (c) studies that equate participants on pertinent risk factors or past behavior and then examine whether participants high versus low in unrealistically optimism differ in health decisions, behaviors, or outcomes. All of the studies described in the sections that follow use at least one of these methodological approaches. To facilitate our discussion, we first discuss evidence suggesting that unrealistic optimism is beneficial for health followed by evidence that unrealistic optimism is problematic for health.

Health Benefits of Unrealistic Optimism

Numerous studies link dispositional optimism to hope, positive affect, and greater goal-directed persistence. Given the overlap (albeit a modest overlap) between dispositional optimism and unrealistic optimism, it is reasonable to assume that unrealistic optimism might have benefits. Consistent with this reasoning are the results of two studies. The first examined unrealistic absolute optimism among HIV-infected gay men, who reported that they were less likely than a comparison group of non-infected men to develop AIDS (Taylor et al., 1992). More importantly, greater unrealistic optimism among these HIV-infected men corresponded with reports of health-promoting behaviors such as a healthy diet, jogging, and getting adequate sleep.

The second study examined unrealistic comparative optimism among patients in a cardiac rehabilitation program. Although all study participants experienced some coronary event (myocardial infarction, bypass surgery angina, etc.), some patients displayed unrealistic comparative optimism about their risk of experiencing a future cardiac event, whereas others did not. The patients who reported the greatest unrealistic comparative optimism were less likely to experience a cardiac event (such as readmission to a hospital for chest pain/angina or experience of a heart attack) over the next 12 months, even when controlling for true risk (Hevey, McGee, & Horgan, 2014).

Health Costs of Unrealistic Optimism

The two studies just described are quite unique in demonstrating benefits of unrealistic optimism. Most published studies examining the consequences of unrealistic optimism suggest that unrealistic optimism can be problematic for health. Because unrealistic optimism represents an expectation that exceeds what is realistically possible, it can lead people to take unnecessary risks. To understand the health problems linked to unrealistic optimism, we examine the two forms of unrealistic optimism (absolute and comparative) separately.

Unrealistic Absolute Optimism

Unrealistic absolute optimism has a number of problematic consequences for health. For instance, it can lead to misplaced hope, as illustrated by a study of participants in a phase 1 clinical cancer trial. The researchers explained that the purpose of such trials is to establish the feasibility of a future randomized trial and that no participant was likely to experience benefits as a consequence of their participation. Nevertheless, 60% of the participants in the trial reported that they were more likely than the other trial participants to experience health benefits from the trial (Jansen et al., 2011). These estimates reflect unrealistic optimism because the trial participants believed they would experience health benefits when they were explicitly told that they would not. The findings also illustrate unrealistic comparative optimism in that patients believe that they were more likely than fellow clinical trial patients to experience benefits when they were not.

Other studies have demonstrated that unrealistic absolute optimism causes disappointment, regret, and other negative emotions when the future does not unfold as expected. For example, students in one study who awaited the results of a classroom examination felt worse about their exam performance if they were unrealistically optimistic about their performance than if they were accurate or unrealistically pessimistic, regardless of their actual exam performance (Sweeny & Shepperd, 2010).

Unrealistic absolute optimism can also have behavioral consequences. In a nationally representative sample of smokers, the more unrealistically optimistic smokers were about their lung cancer risk, the less likely they were to list quitting as a means to decrease lung cancer risk, and the more curable they viewed lung cancer to be (Dillard, McCaul, & Klein, 2006). Moreover, despite the fact that quitting smoking is more difficult the longer a person smokes, smokers typically overestimate their ability to quit, which may delay or undermine future attempts to quit. Indeed, greater unrealistic absolute optimism corresponded with lower intentions to quit smoking in the nationally representative sample of smokers just mentioned (Dillard et al., 2006).

Other negative consequences also arise from unrealistic absolute optimism. For example, one study examined attention to relevant health information among college students who engaged risky sexual activity. Compared with realists—who accurately perceived themselves to be at high risk for pregnancy and STDs—unrealistically optimistic students perceived an informational pamphlet about STDs and pregnancy as less relevant to them. As a result, their personal risk estimates were less responsive to the information provided in the pamphlet (Wiebe & Black, 1997). Perhaps most sobering is the finding that greater unrealistic optimism about risk for heart disease in a sample of older adults corresponded with the thickness of the carotid artery (Ferrer et al., 2012), a subclinical marker of atherosclerosis that is linked to increased heart attack risk.

Unrealistic Comparative Optimism

Research exploring the consequences of unrealistic comparative optimism for health is generally sparse, but several studies have demonstrated that it too can have negative health consequences. In one study, college drinkers who were unrealistically optimistic about their risk of experiencing alcohol-related problems in the next year reported consuming more alcohol than did realistic participants. More importantly, 6, 12, and 18 months after the initial survey, the drinkers who displayed unrealistic comparative optimism also reported more alcohol-related negative events (hangover, trouble with the police, missed classes, etc.) than did the realistic participants (Dillard, Midboe, & Klein, 2009). In a second study, older adults who reported unrealistic comparative optimism about their risk for heart attack reported less worry about their risk level than did participants who were accurate or unrealistically pessimistic. They also displayed less knowledge of risk factors and poorer recall of an essay they read earlier about heart attack risk factors (Radcliffe & Klein, 2002). Other research finds that people who displayed unrealistic comparative optimism about avoiding the H1N1 virus reported lower intentions to wash their hands and use hand sanitizers (Kim & Niederdeppe, 2013).

Other research suggests that the combination of high unrealistic comparative optimism and high dispositional optimism can be particularly problematic. People high in both types of optimism tend to be more defensive and more likely to display behaviors that infirm their health. For example, college students in one study imagined that a dental visit revealed that they needed a root canal. Students who were high in both dispositional and unrealistic comparative optimism were more dismissive of the hypothetical dental threat in the near future than were college students high in dispositional but low in comparative optimism. Moreover, when provided the opportunity to seek additional health information, these students were less likely to do so (Fowler & Geers, 2015).

Summary

Unrealistic optimism is remarkably pervasive, stable over time, and resistant to change. It appears in two forms: absolute and comparative unrealistic optimism. Specifically, people can be unrealistically optimistic relative to objective indicators of their risk (unrealistic absolute optimism) or in estimates of how their risk compares with the risk of their peers (unrealistic comparative optimism). Unrealistic optimism can arise from a motivation to believe (or have others believe) that one's future will be rosy, from disparity in information about oneself versus the objective standard or comparison target, or from cognitive processes that emerge when people are asked to evaluate their risk (e.g., reliance on stereotypes, insufficiently considering others, differential weight of favorable versus unfavorable information). Finally, although unrealistic optimism can have positive health consequences, a number of studies suggest that it can also produce negative health consequences. Perhaps the most challenging task facing researchers studying unrealistic optimism is clarifying when unrealistic optimism is linked to positive versus negative health outcomes.

Author Biographies

James A. Shepperd, PhD, is the R. David Thomas endowed professor of psychology at the University of Florida and the research director for the Southeast Center for Research to Disparities in Oral Health. Most of his research examines how people manage threatening information, which includes topics such as optimism, maintaining desired self-views, and information avoidance. Much of his work involves applying psychological theory to addressing health concerns such as screening for cancer.

Jennifer L. Howell, PhD, is an assistant professor at Ohio University. Her research focuses primarily on psychological threat management and health. She seeks to understand the proactive and reactive strategies people use to manage bad news, particularly about their health. This broad umbrella encompasses work on decision making, responses to feedback, defensiveness, physical health behaviors, risk, coping, individual differences, social cognition, attitudes, and communication.

Waiting for Health News

Angelica Falkenstein, Michael D. Dooley,
and Kate Sweeny

Department of Psychology, University of California, Riverside, CA, USA

Uncertain waiting periods are a regular part of the healthcare experience. Patients await uncertain news when they undergo diagnostic medical tests, engage in periods of "watchful waiting," or anticipate learning the efficacy of an administered treatment. Medical waiting periods can range from minutes to months, with patients left in limbo until they are contacted with results. Although research documenting the psychological effects of such waiting periods is relatively sparse, empirical evidence underscores the exceptional distress that patients experience while awaiting news related to their health. For example, waiting for medical results can provoke the same levels of stress as receiving the bad news of a cancer diagnosis (Lang, Berbaum, & Lutgendorf, 2009). One study even found that people awaiting medical news experience anxiety equivalent to patients admitted to psychiatric facilities for generalized anxiety disorder (Scott, 1983), underscoring the significant distress health uncertainty can cause.

In this entry, we discuss the nature of uncertain and highly important medical waiting periods as well as how waiting experiences change over time. We then discuss how waiting experiences predict responses to both desirable and undesirable news, ending with suggestions for ways to make medical waiting periods easier for patients to endure.

The Central Role of Anxiety

A small but growing body of research documents the distressing nature of both medical and nonmedical waiting periods. Although the experience of waiting for inevitable events (e.g., waiting rooms, queuing) may be frustrating and uncomfortable, people experience particular distress when they await uncertain news. Uncertainty is characterized by heightened anxiety (Sweeny & Falkenstein, 2015), which is often accompanied by rumination (Sweeny & Andrews, 2014). Generally speaking, people experiencing self-relevant uncertainty feel motivated to seek out information to alleviate uncertainty and associated anxiety. During medical

waiting periods, however, additional reliable information is largely unavailable until the test results are in.

Because medical waiting periods are characterized by irresolvable uncertainty, anxiety persists as the predominant emotional experience (Sweeny & Cavanaugh, 2012; Sweeny & Falkenstein, 2015). Indeed, patients report anxiety as the most prevalent emotion during diagnostic waiting periods, exceeding levels of anger, confusion, tension, and intrusive thoughts (Montgomery & McCrone, 2010). Research with patients undergoing biopsy procedures similarly documents high levels of anxiety (Northouse, Jeffs, Cracchiolo-Caraway, Lampman, & Dorris, 1995), surpassing levels among college students, high-risk controls (Maxwell et al., 2000), and, in some cases, clinical thresholds (Poole et al., 1999). High anxiety during medical waiting periods not only exerts deleterious effects during the waiting period itself, such as an inability to concentrate and plan (Thorne, Harris, Hislop, & Vestrup, 1999), but may also influence patients' cognitive processing abilities down the line (Scott, 1983).

Anxiety experienced during waiting periods surpasses even levels of anxiety in response to bad news, suggesting that in some respects, waiting can be more difficult than receiving bad news (Sweeny & Falkenstein, 2015). To illustrate, a study of women undergoing fertility treatment found that these women experienced high levels of anxiety while awaiting results of in vitro fertilization, contrasted by high levels of disappointment but relatively low levels of anxiety in the face of negative pregnancy test results (Boivin & Lancastle, 2010), indicating that both waiting and receiving bad news are difficult but qualitatively different experiences.

Change Across the Waiting Period

Although waiting periods provoke high levels of anxiety and rumination, the intensity of these experiences fluctuates over time. Trends of anxiety and rumination tend to follow a U-shaped curve, with the highest levels occurring at the beginning of a wait (e.g., directly after a medical test), followed by a respite, only to ramp up again as news becomes imminent (Sweeny & Andrews, 2014). The shape of this pattern likely mirrors patterns of attentional focus and outcome salience and highlights people's tendency to shirk optimism and embrace pessimism in an attempt to brace for the worst when news is imminent (Shepperd, Ouellette, & Fernandez, 1996; Sweeny & Krizan, 2013). Pessimistic expectations are often accompanied by anxiety (Sweeny & Andrews, 2014; Sweeny, Reynolds, Falkenstein, Andrews, & Dooley, 2016), and people lower their expectations to the greatest extent right before news arrives (Sweeny & Krizan, 2013).

The pattern of anxiety during nonmedical waiting periods translates to medical waiting periods. For instance, the majority of patients awaiting an elective cardiac catheterization reported increases in anxiety over time as the procedure approached (Harkness, Morrow, Smith, Kiczula, & Arthur, 2003). Similarly, women awaiting a breast biopsy procedure increasingly sought social support as the biopsy neared, with open-ended responses revealing that many women experienced increases in anxiety during this period (Lebel et al., 2003). Women who reported relatively low anxiety immediately after a breast biopsy also experienced increases in anxiety while waiting for the biopsy results (no change for women already high in anxiety; Poole et al., 1999). Despite the stress of waiting in the healthcare context, past research has often ignored the diagnostic phase, instead focusing on understanding patients' experiences after a diagnosis. However, a growing literature illustrates that diagnostic phases are emotionally dynamic and difficult for patients to endure (Montgomery & McCrone, 2010).

Variability Across Different Types of Waiting Periods

Waiting for medical news often has the potential to cause high levels of anxiety, but not all outcomes provoke the same levels of distress. Intuitively, waiting experiences depend on the importance of the news at hand; surely waiting for news of a tumor biopsy is more nerve-wracking than awaiting news of a cholesterol test. Situational factors, such as the importance of an outcome or the risk associated with a negative outcome, are indeed one source of variability in people's waiting experiences. For instance, couples recalled greater distress while trying to conceive their youngest to the extent that they had placed greater importance on parenthood during that time (Sweeny, Andrews, Nelson, & Robbins, 2015). Couples who had a higher risk of complications also recalled experiencing more anxiety and intrusive thoughts as they tried to conceive.

Furthermore, the length of the wait influences how people respond to news. When waiting for a potentially desirable outcome, people prefer shorter waiting periods. However, when the news is likely to be undesirable or has potentially detrimental ramifications, people prefer longer waiting periods that ostensibly give them time to prepare for the devastating blow (Montgomery & McCrone, 2010).

It is important to note that not all medical waiting periods elicit anxiety and rumination. In a study investigating the wait for genetic risk information, patients did not seem to be particularly distressed (Phelps, Bennett, Iredale, Anstey, & Gray, 2006), an observation that differs dramatically from studies of women awaiting breast biopsy results (e.g., Poole et al., 1999). Additionally, pregnancy may be an inherently unique medical waiting period. Even women who have previously miscarried see the wait for baby as a generally positive experience, although women with recurrent miscarriages experience more stress (Nelson, Robbins, Andrews, & Sweeny, 2015).

Individual Differences Affecting the Waiting Experience

In addition to situational factors, research has linked dispositional factors and a broad range of personal resources to experiences of uncertainty. Higher dispositional optimism is often associated with less distress while waiting (Stanton & Snider, 1993; Sweeny et al., 2015). However, dispositional optimists are just as likely as their pessimistic peers to brace for the worst as the moment of truth approaches (Sweeny & Falkenstein, 2017). Chronic anxiety (Novy, Price, Huynh, & Schuetz, 2001), intolerance of uncertainty (Sweeny et al., 2015), and negative appraisal patterns (Stanton & Snider, 1993) exacerbate waiting distress, making people high in these characteristics especially ill-suited to wait for health news.

Conversely, people with more social, emotional, and cognitive resources demonstrate greater ability to cope with uncertainty-related distress. For example, people with more personal resources recall less distress during the time when they were trying to conceive (Sweeny et al., 2015), and people high in self-esteem are buffered against some indicators of waiting distress (Shepperd et al., 1996; Sweeny & Andrews, 2014). Ample research highlights strong support networks as pivotal to positive health-related outcomes, which may stem from supportive others helping people reduce or cope with uncertainty (Uchino, 2009). Together, these findings suggest that ensuring the availability of social, emotional, and cognitive resources may be instrumental in improving patients' ability to navigate medical waiting periods.

Although some individual differences consistently predict waiting distress or the lack thereof, studies investigating demographic characteristics have yielded inconsistent associations with waiting experiences. For example, some studies have found that age predicts distress during the wait for a potential breast cancer diagnosis (e.g., Novy et al., 2001), but others have failed to find such a link (Montgomery & McCrone, 2010). Some studies also show that family health history (Novy et al., 2001) and previous experience with the issues at hand (e.g., screenings, miscarriages; Maxwell et al., 2000; Schnur et al., 2008) predict heightened distress while waiting, although a quantitative review found that the greatest declines in expectations (i.e., more pessimism) precede news about unfamiliar outcomes (Sweeny & Krizan, 2013). Further research is needed to determine the role that characteristics such as age, previous experience, socioeconomic status, and gender play into how patients wait for medical news.

Effects of Waiting Experiences on Responses to Health News

Beyond predictors of waiting experiences, researchers have also examined how waiting experiences shape reactions to news once it arrives. For instance, even pessimists overwhelmingly prescribe optimism to others faced with uncertain, self-relevant outcomes, revealing a normative belief that there is some inherent benefit in expecting good outcomes (Armor, Massey, & Sackett, 2008). Research exploring expectations during waiting periods supports this idea, linking optimistic expectations with reduced distress (Sweeny & Andrews, 2014; Sweeny et al., 2016). Optimism, however, seems to backfire when confronted with bad news. Disconfirmed optimistic expectations are met with greater disappointment and shock compared with confirmed pessimistic expectations (Krizan, Miller, & Johar, 2010; Sweeny et al., 2016). Optimism also provides no benefit when the news is good: people with optimistic expectations are less elated by good news than are people who lower their expectations and brace for the worst (Sweeny et al., 2016).

In contrast, pessimistic expectations may provide motivational benefits to prepare for bad news. People who expect a bad outcome might take steps to mitigate some of the difficulties that could accompany bad news (Sweeny, Carroll, & Shepperd, 2006). For example, a woman anticipating a breast cancer diagnosis could inquire about her employer's extended leave policy or arrange for childcare. The literature on defensive pessimism convincingly shows that at least for some people, pessimistic expectations and associated anxiety can serve as a motivating force to take action (Norem & Cantor, 1986). However, pervasive distress can impede daily functioning and sound decision making. Thus, delaying the descent toward pessimism until the end of a wait may allow patients to capitalize on the benefits of both optimism and pessimism, suggesting that well-timed optimism and well-timed shifts from optimism may be key to an optimal overall medical waiting experience (Sweeny et al., 2006).

Key Future Directions for Research on Waiting for Health News

Because poorly timed pessimism and prevalent distress may reduce patients' ability to function and thus cope with uncertainty surrounding their health, interventions are needed to target patients' distress and promote positive strategies to cope with uncertainty. For example, patients may also better cope with a wait if they are able to take their mind off of the news at hand. Although some research points toward distraction as a harmful method of coping (Lebel et al., 2003; Sweeny et al., 2016), other studies support the efficacy of the strategy (e.g., Boivin & Lancastle, 2010).

One possibility is that distraction is only helpful to the extent that people are actually cognitively diverted from their worries and fears, with unsuccessful attempts further compounding the problem. If this is the case, research aimed at understanding activities that effectively distract from anxiety and intrusive thoughts could highlight promising interventions for those experiencing highly stressful medical waiting periods. For instance, research on flow demonstrates that autonomous activities that match one's skill level can create cognitive immersion in the task as well as an energized focus, such that one loses reflective self-consciousness and awareness of time. Flow has been associated with motivation to perform and decreased anxiety (Csikszentmihalyi & Rathunde, 1993), indicating it may foster an action orientation in patients and help decrease emotional distress. Other methods of distraction, such as fostering cognitive busyness, may also prove fruitful in helping people cope while waiting for uncertain medical results.

Healthcare providers may also be able to meaningfully shape patients' waiting experiences for the better by communicating effectively with patients. For example, women with abnormal mammogram results experience less anxiety when waiting for follow-up testing if they are satisfied with the initial information they received from their healthcare provider (Pineault, 2007). Doctors and nurses with the responsibility of communicating such information may be in a unique position to ease patients' future distress by ensuring that patients not only comprehend the information communicated to them but also are satisfied with the amount of information they receive. Patients may also have an easier time waiting to the extent that they know what to expect. If medical staff and healthcare facilities provide information to patients about typical waiting experiences in the form of counseling or informational pamphlets, patients may be better able to endure the wait for health news.

Additionally, word use during medical visits, much like the quality of rapport between physician and patient, is associated with important patient outcomes such as patients' feelings toward their physician and adherence to treatment recommendations (Falkenstein et al., 2016). For example, patients liked physicians more when physicians used fewer negative emotion words and reported greater adherence intentions when physicians used less "I" language. Further investigation of word use may illuminate similar relationships with patients' waiting experiences after a medical consultation, pointing to a relatively simple way to decrease distress while patients wait.

Medical waiting periods are unavoidable and generally stressful experiences for patients. As research on extended periods of health-related uncertainty burgeons, we hope to find ways for patients and healthcare providers to ease the burden of waiting for health news.

Author Biographies

Angelica Falkenstein is a doctoral candidate in Social/Personality Psychology program at the University of California, Riverside. Her research focuses on expectation management processes as people anticipate important news in their lives and how expectations for news relate to other key waiting experiences such as emotion regulation and cognition. Angelica is also interested in waiting experiences in the context of healthcare and how such experiences and healthcare interactions predict patient outcomes.

Michael D. Dooley is a doctoral candidate in the Social/Personality Psychology program at the University of California, Riverside. Mike's interest focuses on the provision of social support in close relationships, particularly when support needs are uncertain or unclear. How do supportive others recognize when support is desired? How do they decide what support to provide? His research covers supportive behaviors and decision making in a variety of contexts, including waiting for uncertain health news.

Kate Sweeny is an associate professor of psychology at the University of California, Riverside. Her work seeks to understand the experience of awaiting uncertain news. What makes waiting so stressful? Do some people have an easier time waiting than others? Are there ways to "wait well?" She addresses these questions in contexts ranging from the wait for an exam grade to the wait for biopsy results, news of pregnancy, and the outcome of medical tests.
